The ability of atmospheric aerosols to act as cloud condensation nuclei (CCN) is influenced by both the particles’ size and chemistry. For particles formed in the atmosphere via nucleation of vapors, this means that they must undergo significant growth before they can become active as CCN. Direct atmospheric observations at high altitudes of the life cycle and chemistry of aerosol particles from nucleation to cloud droplets are still scarce. We present first results from a comprehensive 6-month field campaign (December 2017 - May 2018) conducted at the GAW station Chacaltaya in the Bolivian Andes. The station is at an altitude of 5240 m a. s. l., in the Cordillera Real, which separates the Amazon basin from the Altiplano. Regular regional new particle formation events, the influence of the emissions from the nearby city of La Paz on an almost daily basis, and of air masses from the Amazon during the rainy season make this a highly interesting site to study atmospheric particle formation and growth processes. To this purpose we deploy several state-of-the-art mass spectrometers. This abstract focuses on results from a chemical ionization mass spectrometer with filter inlet for gases (FIGAERO-CIMS), which is used to investigate the nature and relative importance of anthropogenic and biogenic organic components contributing to the growth of newly formed particles to sizes where they can become active as CCN.
The Fate of Arctic Black Carbon Aerosol from Clouds to Snow

Marco Zanatta1 (marco.zanatta@awi.de), Hannes Schulz1, Stephan Mertes2, Simonas Kecorius2, Johannes Schneider3, Heiko Bozem4, Emma Järvinen5, Olivier Jourdan6, Regis Dupuy6, André Ehrlich7, Andreas Herber1

Black carbon (BC) aerosol is considered to play a strong role in Arctic warming. However, the lack of measurements represents a large source of uncertainty in assessing the total radiative forcing of BC. In order to quantify the presence and properties of BC we performed simultaneous airborne and shipborne field experiments between Svalbard and the Fram Strait in May/June 2017. The BC particles were thereby measured in the cloud-free atmosphere, in particle residuals of mixed-phase clouds and in snow, by means of a single particle soot photometer. Within the ACloud (Arctic Cloud Observations Using airborne measurements during polar Day) experiment, vertical distribution of BC and its presence in cloud particles were investigated. Simultaneously, during the PASCAL (Physical feedbacks of Arctic PBL, Seaice, Cloud And Aerosol) campaign, BC atmospheric concentration was monitored at sea level from the RV Polarstern and more than 200 snow samples were collected over the sea ice for BC quantification. Shipborne and airborne observations showed extremely clean Arctic conditions above 65°N, with BC mass concentration below 10 ng m⁻³ at sea level and strong vertical variability (from 5 to 70 ng m⁻³). BC cloud residuals, sampled with a counter-flow virtual impactor, were larger in diameter (300 nm) as compared to outside-cloud conditions (150 nm). The analysis of snow samples will allow understanding the time evolution of BC concentration and its metamorphism during the melting season.
Insoluble Brown Carbon Emitted by Marine Engines: Relevance to a Warming Arctic

Joel C. Corbin1,2 (joel.corbin@nrc-cnrc.gc.ca), Hendryk Czech3, Dario Massabo4, Fengshan Liu1, Simone Pieber2, Juergen Orasche5, Benjamin Stengel3, Francesco Buatier de Mongeot4, Claudio Mennucci4, Amewu Mensah6, Marco Zanatta7, Gert Jakobi5, Prem Lobo1, Ralf Zimmermann1,5, Andre Prevot2, Imad El Haddad2, Martin Gysel2

The majority of ships travelling through the Arctic operate on heavy fuel oil (HFO). The exhaust associated with HFO combustion contains light-absorbing black carbon (BC) particles but also substantial amounts of brown carbon (brC). This brC absorbs more strongly at shorter (blue) wavelengths than at longer (red) ones, and can dominate the total light aerosol light absorption by HFO-combustion aerosols. Here, we show that it is fundamentally different to brC produced by sources such as biomass-burning. We show that this brC is insoluble, thermally refractory, and absorbs in the near infrared. These properties resemble those of the tar balls which have been previously observed from biomass combustion, rather than to the light-absorbing organic molecules that have been the focus of recent brC research. These properties also mean that common techniques for measuring BC may result in strongly biased estimates of aerosol light absorption. The insolubility of this brC means that it may accumulate on snow and ice, perhaps explaining recent observations that 32% of albedo reduction in Arctic snow is due to non-BC particles. Further field measurements are needed to quantify these light-absorbing brC particles in order to understand anthropogenic impacts on the Arctic environment.
Measurements of light absorbing particles in the boundary layer of the high southern latitudes are scarce, particularly in the McMurdo Dry Valleys (MDV), Antarctica. During the 2013 - 2014 austral summer near-surface boundary layer refractory black carbon (rBC) aerosols were measured in air by a single particle soot photometer (SP2) at multiple locations in the MDV. Near-continuous rBC atmospheric measurements were collected at Lake Hoare Camp (LH) over two months and for shorter periods at more remote locations. Snow samples were also collected in a 1m pit on a glacier near the camp. The range of concentrations rBC in snow were 0.3 - 1.2 ± 0.3 ng-rBC/g-H2O, and total organic carbon were 0.3 - 1.4 ± 0.3 mg/L. At LH, the average background rBC mass aerosol concentrations was 1.3 ng/m3. rBC aerosol mass concentrations were slightly lower, 0.09 - 1.3 ng/m3, at the most remote sites in the MDV. Concentration spikes as high as 200 ng/m3 were observed at LH, associated with local activities. During a foehn wind event, the average rBC mass concentration increased to 30-50 ng m⁻³. Here we show the rBC increase could be due to resuspension of locally produced BC, which may remain on the soil surface until redistributed during high wind events. Quantification of local production and long-range atmospheric transport of rBC to the MDV is necessary for understanding the impacts of this species on regional climate.
Early Winter Sea Ice Dynamics and Ice Production in the Ross Sea during PIPERS

Ted Maksym1 (tmaksym@whoi.edu), Steve Ackley2, Sharon Stammerjohn3, Jean-Louis Tison4, Kathrin Hoeppner5
1Woods Hole Oceanographic Institution, Woods Hole, United States, 2University of Texas at San Antonio, San Antonio, United States, 3University of Colorado Boulder, Boulder, United States, 4Universite Libre de Bruxelles, Bruxelles, Belgium, 5German Aerospace Center (DLR), Wessling, Germany

The Ross Sea sea ice cover is one of the few regions of the cryosphere that have been expanding in recent decades. However, 2017 saw a significantly delayed autumn ice advance and record low early winter sea ice extent. To better understand the causes and impacts of this variability on sea ice production, we present a suite of in situ and satellite observations made during the PIPERS (Polynyas, Ice Production and its seasonal Evolution in the Ross Sea) cruise in April-June 2017. To assess the relative role of sea ice dynamics and thermodynamics in sea ice production, four arrays of GPS and ice mass balance buoys were deployed in the outflows of the Ross Ice Shelf and Terra Nova Bay Polynyas. High-resolution synthetic aperture radar imagery are used to provide regional context. Despite high rates of ice production in the polynyas, the ice remained thin due to rapid export and northward drift. Compared to the only prior winter observations made in 1995 and 1998, the ice was thinner, with less ridging and snow cover, reflecting a younger ice cover. Surprisingly, granular ice was less prevalent in 2017, particularly in the outer pack, due to less snow ice formation and less pancake ice formation at the advancing ice edge. We discuss the relative roles of ice dynamics and thermodynamics in both the polynyas and the main ice pack, and the dynamic interactions between these regions in governing total sea ice production.
Air-sea-Ice Interaction Associated with the 2016 and 2017 Weddell Polynyas

Kent Moore\textsuperscript{1,2} (gwk.moore@utoronto.ca), Ethan Campbell\textsuperscript{3}, Earl Wilson\textsuperscript{3}, Casey Brayton\textsuperscript{4}, Stephen Riser\textsuperscript{3}, Matthew Mazloff\textsuperscript{5}, Lynne Talley\textsuperscript{5}

\textsuperscript{1}University of Toronto, Physics, Toronto, Canada, \textsuperscript{2}University of Washington, Jackson School for International Studies, Seattle, United States, \textsuperscript{3}University of Washington, Physical Oceanography, Seattle, United States, \textsuperscript{4}University of South Carolina, Physical Oceanography, Columbia, United States, \textsuperscript{5}Scripps Institution of Oceanography, UC San Diego, Physical Oceanography, San Diego, United States

Maud Rise, a seamount in the Weddell Sea, is a location where polynyas occasionally form. The most dramatic of these events was the \textasciitilde 300,000km\textsuperscript{2} polynya that occurred over the 3-year period from 1974-1976. Another smaller polynya developed in 1994 and there is evidence of a persistent halo of reduced ice cover in the region that may be a signature of a Taylor Cap. The presence of a polynya can lead to vigorous air-sea interaction resulting in a densification of the surface waters and a convective overturning of the water column. There is still much that is unknown regarding how they form as well as the characterization of the atmospheric forcing that occurs within them and the oceanic response. In 2016, a polynya developed in late July and persisted for approximately 3 weeks. In September 2017, the polynya returned and has remained open through November. Here we use new high resolution atmospheric, oceanic and cryospheric datasets to examine the air-sea interaction that occurred within the recent polynyas. Observations from SOCCOM under-ice profiling floats show prominent cold, fresh, high-oxygen anomalies to a depth of 1700m after the 2016 event. In addition, there was an intermittency to the area of open water within the polynya in both 2016 and 2017 that was associated with variability in the wind field suggesting that a coupling exists between the atmosphere and ocean in the region.
Quantification of Sea-ice Production in Weddell Sea Polynyas (Antarctica)

Günther Heinemann¹ (heinemann@uni-trier.de), Rolf Zentek¹, Lukrecia Stulic², Ralph Timmermann², Stephan Paul², Andreas Preußer¹

¹University of Trier, Environmental Meteorology, Trier, Germany, ²Alfred Wegener Institute, Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

A multi-method approach is used to quantify sea ice production polynyas in the southern Weddell Sea for the period 2002-2015. We use
1) a regional climate model (CCLM) with 5km and 15 km resolution (C05/15),
2) retrievals from MODIS data at a high resolution of 1-2km and
3) simulations of a sea ice-ocean Model (FESOM) with a resolution down to 3 km.

Methods 2) and 3) need atmospheric forcing, which is taken from different reanalyses (ERA-I, CSFR, JRA55, NCEP2) as well as from CCLM data. Estimates of sea ice production and comparisons of the different methods are presented for polynya areas of the Weddell Sea. We study the following polynyas: Antarctic Peninsula (AP), Ronne Ice Shelf (RO), Iceberg A23a (IB), Filchner Ice Shelf (FI), Coats Land (CL) and Brunt Ice Shelf (BR). In all methods, the largest ice production (IP) is found for RO and for BR. However, significant differences between different methods and forcing data sets are found for polynya area (POLA) and IP. In particular, relatively too low temperatures in JRA and C05 lead to higher IP compared to ERA in the MODIS retrievals. Estimations based on CCLM simulations agree generally well with MODIS/ERA-I, but tend to be smaller due to the coarser resolution of the microwave sea ice data used in CCLM. In contrast, FESOM yields a generally larger ice production and shows also a pronounced sensitivity to the atmospheric forcing, but the effect on POLA and IP depends on the region.
Coastal polynyas on PIPERS: enhanced ice growth in strong katabatic wind events

Stephen Ackley¹ (stephen.ackley@utsa.edu), Ted Maksym², Sharon Stammerjohn³
¹Univ of Texas San Antonio, Snow and ice Geophysics Laboratory, San Antonio, United States, ²Woods Hole Oceanographic Institution (WHOI), Woods Hole, United States, ³Univ of Colorado, Boulder, United States

The PIPERS cruise to the Terra Nova Bay (TNB) polynya during April-June 2017 focused on joint measurements of air-ice-ocean wave interaction. Measurements were taken during intense katabatic wind events (over 35 m s⁻¹) and temperatures of -15°C. Wave amplitudes of over 2m and 7-9 sec periods built and large amounts of frazil ice crystals grew. The frazil ice gathered initially into short plumes that were added together laterally to create longer and wider streaks, an apparently “self-herding” characteristic of ice in small pieces, found in other granular materials. The wave field within the wider streaks was dampened and enhanced the development of pancake ice. Eventually, the open water areas sealed off and developed a uniform pancake ice cover. As the waves died off, sustained katabatic wind velocities resulted in a wide area of concentrated, rafted, pancake ice of 30 to 40cm thickness that was rapidly advected downstream until the end of the katabatic event. High resolution TerraSar-X radar satellite imagery showed the length of the ice area produced in one single event extended over 300km or ten times the length of the open water/frazil ice area during the polynya event. The TNB polynya is therefore an “ice factory” where frazil ice is manufactured into pancake ice floes that are then pushed out of the assembly line, rafted into “dragon skin” ice and advected, until the katabatic wind dies off at the coastal source.
Salinity Response to Atmospheric Forcing of the Terra Nova Bay Polynya

Deborah A Le Bel¹, Christopher J Zappa¹ (zappa@ldeo.columbia.edu), Giorgio Budillon², Arnold L Gordon¹
¹Lamont-Doherty Earth Observatory of Columbia University, Ocean and Climate Physics, Palisades, United States, ²Parthenope University of Naples, Naples, Italy

The density and salinity of High Salinity Shelf Water (HSSW), a key component of Antarctic Bottom Water emanating from the Ross Sea, are intensified by brine rejection induced by ice formation within the Terra Nova Bay (TNB) polynya. Meteorological observations from Automatic Weather Stations in conjunction with ocean mooring data from 2007 and a satellite-derived opening of TNB polynya delineate higher-frequency water column salinity variability linked to atmospheric forcing. Lagged correlation analysis indicates that on average salinity response lags the polynya opening by two days and the wind forcing by four days. Closer examination reveals stronger lag correlations of salinity with the wind in the fall and with polynya extent in the winter/spring. A one-dimensional mixed layer model incorporating thermodynamic ice formation captures the order ten day oscillations in salinity linked to polynya expansion and contraction. The model illustrates two stages of the seasonal scale salinity response to forcing. The depth-integrated heat content governs the time required for the water column to reach the freezing point as wind mixing and heat loss redistribute the salinity and density profiles. Once the excess heat is removed from the water column, heat loss is primarily through the latent heat released during ice formation and the time to reach complete homogenization of the water column depends only on the integrated salinity deficit.
Sea Ice Deformation and Heat Fluxes through Leads in Arctic

Pierre Rampal$^{1,2}$ (pierre.rampal@nersc.no), Einar Ólason$^{1,2}$, Timothy Williams$^{1,2}$, Abdoulaye Samaké$^{1,3}$, Véronique Dansereau$^4$

$^1$Nansen Environmental and Remote Sensing Center, Bergen, Norway, $^2$Bjerknes Centre for Climate Research, Bergen, Norway, $^3$Université de Bamako, Bamako, Mali, $^4$CNRS, Univ. Grenoble-Alpes, Institut des Sciences de la Terre (ISTerre), Grenoble, France

Sea ice deformation is extremely localised in both space and time, and associated with intense fracturing, the opening of leads and the formation of ridges. In particular, the spatial and temporal properties of lead patterns control the surface heat fluxes between the ocean and the atmosphere, with a potentially strong impact on the dynamics of the ocean mixed layer and the stability of the atmosphere boundary layer. In this talk, we will present how a new generation sea ice model, called neXtSIM, is able to reproduce the statistics of Arctic sea ice deformation, as retrieved from buoys and satellite (SAR) observations. The simulated lead fraction is also compared to the estimates calculated from the AMSR-E satellite observations. The statistics of simulated heat fluxes through leads are finally presented and their scaling properties investigated.
Arctic Global Change Impacts Little Auk Foraging and Fitness in East Greenland

Françoise Amélineau1,2 (francoise.amelineau@gmail.com), David Grémillet2, Ann Harding3, Wojciech Walkusz4,5, Rémi Choquet2, Jérôme Fort1

Ongoing global changes apply drastic environmental forcing onto Arctic marine ecosystems: sea surface temperatures are increasing, sea-ice is declining and anthropogenic pollution is reaching this area despite its remoteness. To test the effects of these changes on marine ecological functioning in the Arctic, we used a 12-year integrative study of little auks (Alle alle), which are the most abundant seabirds in the North Atlantic and feed on zooplankton. In East Greenland, we monitored their foraging behavior, diet, fitness proxies (adult survival and body condition), hatching date and chick growth rate. We tested linkages between these biological variables and a set of environmental parameters from the breeding and wintering sites, as well as their mercury contamination. Little auks showed substantial foraging plasticity, notably via an increase in foraging effort in the absence of sea-ice. Yet, in contrast to former studies conducted over shorter time periods, their fitness proxies were also impacted by environmental changes: adult body condition decreased across years, and with increasing wind speed, and adult diet changed across the study period. Hatching date was gradually delayed, and chick growth rate tended to decrease with time. However, no trend was found for adult survival despite a high variability. Overall, our study shows how global changes affect a key Arctic species, and stresses the importance of monitoring arctic ecological processes in the longer term.
Divergent Trends and Unsynchronized Dynamics across a Seabird Community

Casey Youngflesh\textsuperscript{1} (casey.youngflesh@stonybrook.edu), Stephanie Jenouvrier\textsuperscript{2,3}, Heather J. Lynch\textsuperscript{1}

\textsuperscript{1}Stony Brook University, Ecology and Evolution Department, Stony Brook, United States, \textsuperscript{2}Woods Hole Oceanographic Institution (WHOI), Biology Department, Woods Hole, United States, \textsuperscript{3}Centre d’Études Biologiques de Chizé (CEBC), Centre National de la Recherche Scientifique/Univ La Rochelle, Villiers en Bois, France

Global change is evident around the globe. Understanding how ecological communities are structured and how they might respond to these changes is of critical importance. However, in many cases, studies focus on a single species. Taking a community perspective, we looked at both long-term and year-to-year responses for a community of Antarctic seabirds and explored how environmental forcing might be driving demographic- and population-level processes. Data on breeding success and abundance for six sympatrically breeding seabird species located in East Antarctica were available from 1981-2013. Hierarchical Bayesian models were used to assess trends in these metrics, the degree of community-level synchrony in breeding productivity, as well as the contributions of environmental factors to this synchrony. We find a surprising discordance between trends in abundance and breeding success, with several species showing increasing abundance even as breeding success declines. In addition, we found little evidence for synchrony in breeding productivity, which was only weakly correlated with environmental factors thought to contribute to breeding success. In contrast to this overall pattern of asynchronous dynamics, exceptionally poor years were seen to drive similar negative responses among species and accordingly, measures of population dynamics aggregated over the community appear to provide more specific feedback on extreme environmental conditions than any individual species.
Predicting Population Response of Emperor Penguin to Future Climate Change

Sara Labrousse1 (sara.labrousse@gmail.com), Stephanie Jenouvrier1, Marika Holland2, Jimmy Garnier3, Julienne Stroeve4, Christophe Barbraud5, Henri Weimerskirch5, Hal Caswell1
1Woods Hole Oceanographic Institution, Woods Hole, United States, 2National Center for Atmospheric Research (NCAR), Boulder, United States, 3University of Savoy, Chambéry, France, 4National Snow and Ice Data Center, Boulder, United States, 5CNRS, Chize, France

The Emperor Penguin (EP) is an Antarctic seabird threatened by future sea ice change. I present novel approaches to predict population and species responses to future climate change using climate models developed in the assessment report of the IPCC. The MUP (Measuring, Understanding, and Predicting) approach, provides a general framework where an enhanced understanding of climate-population processes, along with improved long-term data, are merged into coherent projections of future population responses to climate change. Population forecasting studies have often been analyzed in terms of climate conditions at a particular location. We projected that the Terre Adélie EP population will decline dramatically by 2100. However, climate change will also produce changes in the spatial distribution of habitat quality (e.g. sea ice change in Antarctica). We developed a species-level threat assessment using a spatially explicit model. At least two-thirds of the EP colonies are projected to become endangered by future sea ice decline. We also recently included complex dispersal processes in a novel meta-population model because individuals may respond to climate change by moving permanently to other locations. For EP, relative to a scenario without dispersion, dispersal can either offset or accelerate climate driven population declines. Finally, new population modeling methods and remote-sensing products hold promise for reducing uncertainties to improve ecological predictability.
Influence of Antarctic Sea Ice Dynamic and Coastal Polynyas on Emperor Penguins

Sara Labrousse¹ (sara.labrousse@gmail.com), Stéphanie Jenouvrier¹, Christophe Barbraud², Charles A. Bost², Florian Orgeret²
¹Woods Hole Oceanographic Institution (WHOI), Woods Hole, United States, ²Centre d’Études Biologiques de Chizé (CEBC), Villiers en Bois, France

Emperor penguins breed on fast ice during the Antarctic winter when the constraint to acquire resources is high, thus, seasonal and interannual variability in fast ice and coastal polynyas are likely to effect adult and juvenile foraging performance at-sea, and ultimately their survival and population dynamics. Breeding emperor penguins use polynyas as a predictable open water access for feeding by reducing the commuting time and energy expenditure between colony and food supply. Antarctic coastal polynyas are key bio-physical features, however, our understanding of their use by emperor penguins is largely theoretical. To tackle these issues, we use both (i) tracking data of juvenile emperor penguin movement and behaviour at-sea over 2 years and (ii) the longest time series available on demographic parameters of emperor penguins at the breeding colony of Dumont d’Urville from 1952-2016. We first describe if juvenile emperor penguins use polynyas as a foraging habitat and whether diving and foraging behaviour is affected by sea ice and its spatio-temporal variability. In a second time, we investigate the combined roles of surface wind, polynya properties and fast ice spatio-temporal variability on the demography of emperor penguins. The novelty of combining juvenile tracking data with demographic data allows suggesting mechanisms by which sea ice and polynyas effect emperor penguin demography through both their breeding success and the following juvenile performance at-sea.
Mechanisms of *Pygoscelis* Penguin Population Response to Environmental Change

Kristen Gorman¹,²,³ (kgorman@pwssc.org), Tony Williams⁴, William Fraser³

¹Prince William Sound Science Center, Cordova, Alaska, United States, ²Simon Fraser University, Biological Sciences, Burnaby, British Columbia, Canada, ³Polar Oceans Research Group, Sheridan, Montana, United States

Breeding colonies of Adélie (*Pygoscelis adeliae*), chinstrap (*P. antarcticus*), and gentoo (*P. papua*) penguins occurring west of the Antarctic Peninsula (wAP) are demonstrating pole-ward range shifts that correlate with long-term warming trends of the region. We examined mechanistic relationships that link marine ecosystem variability with demographic parameters that drive population change. At Anvers Island, where reductions in sea ice have been notable, *Pygoscelis* penguins became more similar isotopically throughout the breeding season, due to depletion in d13C and d15N of blood tissue. Crèched chicks of all species occupied similar trophic levels and the proportions of prey provisioned were similar across species within years. Crèched Adélie penguin chicks were isotopically enriched at Avian and Charcot Islands, southern breeding colonies where sea ice is more prominent. At the regional scale, a provisioning diet enriched in d15N resulted in heavier five-week-old Adélie penguin chicks. Corticosterone hormone did not mediate variation in breeding performance. We found no overall genetic structure among Adélie penguins. However, pairwise comparisons including Charcot Island were significant. Variability in sea ice-associated food webs of the wAP is an important determinant of *Pygoscelis* penguin reproductive performance, but not at the physiological level. A lack of genetic structure suggests dispersal may importantly structure population responses to future ecosystem change.

Changes in penguin populations on the Antarctic Peninsula (AP) have been linked to several environmental factors, but the potentially devastating impact of volcanic activity has not been considered. Genetic, biogeochemical and modern count studies all show gentoo populations increasing during ‘warmer’ periods. Using detailed biogeochemical analysis, we tracked penguin colony change over c. 8,500 years on Ardley Island, currently home to one of the AP’s largest populations of gentoo penguins. By comparing our data with sub-fossil evidence of penguin occupation and records of past climate, sea-ice extent and volcanic activity from across the AP, we found that the first sustained penguin colony was established on Ardley Island c. 6,700 years ago. The colony experienced five population peaks during the Holocene, reaching its maximum, c. 4,000-3,000 years ago during a phase of regional warming, but there are no consistent relationships with local-regional atmospheric and ocean temperatures or sea-ice conditions. Instead, three of the five phases of colony expansion were ended abruptly by the deposition of volcanic ash from large eruptions of the nearby Deception Island. Sustained post-eruption colony recovery took, on average, 400-800 years, and was slowest following the most disruptive event, c. 5,500 years ago. We are currently undertaking biomarker and DNA analysis of lake sediments and sub-fossils from the AP to better understand drivers of long-term penguin population change.
A New Antarctic Blowing Snow Particle Characterization Data Set

The rate of mass transport of blowing snow in numerical models depends quite strongly on the size distribution of the particles being transported. Field observations of blowing snow using instruments are equally susceptible to the anticipated particle parameters used to calibrate those instruments. The blowing snow size distributions presented by Budd et al (1966), measured at Byrd Station, West Antarctica, can be found as the basis of most such models.

We present a new data set, collected during blowing snow events over Antarctic sea ice. Like Budd et al, we used formvar-coated microscope slides to collect 3d replicates of snow particles inside aerodynamic traps during three discrete storms during the SIPEX-2 and AWECS expeditions. We then acquired high-resolution digital scans of these formvar replicates, to allow detailed computational analysis of the particle characteristics (size, sphericity, etc.). Our method allows not only a significant advance over the 2-dimensional “equivalent rectangle” size evaluation of Budd et al., but through the acquisition of scans at multiple focal depths (microns separation) we can also determine the 3rd dimension for many of the measured particles. The minimum particle size category identified using the methods employed by Budd et al was >35 microns. We find a substantially greater number of small particles than are included in the 1966 blowing snow particle size distributions.
New Insights into the Atmospheric Oxidising Capacity above the Antarctic Plateau

Markus Frey¹ (maey@bas.ac.uk), Holly Winton¹, Joel Savarino², Rolf Weller³, Jan-Marcus Nasse⁴
¹Natural Environment Research Council / British Antarctic Survey, Cambridge, United Kingdom, ²University of Grenoble Alpes, CNRS, IRD, Institut des Géosciences de l’Environnement, Grenoble, France, ³Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, ⁴Universität Heidelberg, Inst. für Umweltphysik, Heidelberg, Germany

Field studies in the high and mid latitudes have demonstrated that snowpack emissions of reactive trace gases driven by photolysis alter regional atmospheric composition, the fate of pollutants and the polar ice core archive of past environmental change. Of particular interest are reactive nitrogen and halogen species released by surface snow, which in turn influence atmospheric levels of ozone and hydroxyl radicals. Previous field campaigns at South Pole and Dome C showed that surface-near air on the high East Antarctic Plateau in summer is highly oxidising due to the interplay of photolytic snow emissions, a shallow boundary layer and cold temperatures. However, open questions remain regarding the atmospheric oxidant budget. Here we present new observations carried out at Kohnen Station (75ºS 0ºW) in summer 2017, located at a similar latitude as Dome C. Measurements included nitrogen oxides (NO and NO₂), atmospheric nitrate collected on filters, ozone, slant-column BrO, actinic flux and atmospheric turbulence. In contrast to Dome C a distinct and strong diurnal cycle of ozone with an amplitude of more than 10ppbv is observed. We discuss these new data with respect to potential sinks and sources, and compare to the other sites on the Antarctic Plateau.
The Great Antarctic Climate Hack, Sponsored by the SCAR AntClim21 RSP

Joellen Russell¹ (jrussell@email.arizona.edu), Nancy Bertler², Thomas Bracegirdle³, Alia Khan⁴, Marilyn Raphael⁵
¹University of Arizona, Phoenix, United States, ²Victoria University of Wellington, Wellington, New Zealand, ³British Antarctic Survey, Cambridge, United Kingdom, ⁴University of Colorado Boulder, National Snow and Ice Data Center, Boulder, United States, ⁵University of California Los Angeles, Los Angeles, United States

In October 2017, the first, #GreatAntarcticClimateHack was held in La Jolla, CA at the Scripps Institution of Oceanography. The aim was to bring together climate modelers, climate data users, and observational field scientists to decide on metrics to evaluate current earth system model output. With the upcoming release of CMIP6 and subsequent preparation for IPCC reports it is imperative that the broad Antarctic and Southern Ocean science community is well prepared to make the next step in advancing both regional and global climate science. A key unique goal of the workshop was to involve both specialists and non-specialists in the development of climate model evaluation metrics that address cross-disciplinary scientific priorities. Discussion and participation across broad Antarctic science communities was therefore a key aspect of the #GACH[BTJ1] . Results of the workshop are metrics that will be incorporated into the Earth System Model Validation Tool (ESMValTool), as well as a forthcoming publication.
A Long-term Hindcast Simulation with COSMO-CLM² over Antarctica

Alexandra Gossart¹ (alexandra.gossart@kuleuven.be), Niels Souverijns¹, Irina V. Gorodetskaya², Matthias Demuzere³, Jan T.M. Lenaerts⁴, Nicole van Lipzig¹

¹KU Leuven, Department of Earth and Environmental Sciences, Leuven, Belgium, ²University of Aveiro, Centre for Environmental and Marine Studies, Aveiro, Portugal, ³Ghent University, Laboratory of Hydrology and Water Management, Gent, Belgium, ⁴University of Colorado Boulder, Department of Atmospheric and Oceanic Sciences, Boulder, United States

The surface mass balance (SMB) of the Antarctic ice sheet (AIS) is crucial to understand Antarctica’s contribution to 21st century sea level rise. Therefore, it is essential to understand the large scale atmospheric processes that affect accumulation as it is the only source term of the ice sheet.

Given the scarcity and low spatial coverage of observations over the AIS, the regional climate modeling approach, which is not very common over Antarctica, is the adequate tool to gain insights in AIS SMB. In this respect, COSMO-CLM 5.0 was coupled to the Community Land Model (CLM4.5) and adapted for Antarctic conditions. ERA-Interim is used as initial and lateral boundaries for a time period of 30 year (1986-2016; excluding 3 years of spin-up time) at a resolution of 0.22° by 0.22° over the whole Antarctic continent. Lackings in the model representation of basic climatic variables such as temperature and wind speed were tackled by adapting the turbulence scheme, implementing a two-moment cloud microphysics parametrization, as well as several modifications to the Community Land Model (e.g. snow metamorphosis, wind dependent compaction,...).

Here, we present the results of this long-term COSMO-CLM² simulation adapted for Antarctica. Results are compared to observations from automatic weather stations, field campaigns and radiosondes. In the next steps a blowing snow module and refined cloud-aerosol-precipitation interactions will be implemented into the model.
Modeling the Dynamics of the Stable Boundary-Layers over the Antarctic Plateau

Etienne Vignon1,2 (etienne.vignon@univ-grenoble-alpes.fr), Christophe Genthon3, Frédéric Hourdin3, Bas J. H. van de Wiel4, Hubert Gallée5, Jean-Baptiste Madeleine5, Eric Bazile6, Peter Baas4
1EPFL, LTE, Lausanne, Switzerland, 2IGE, Grenoble, France, 3LMD, Paris, France, 4Technical University, Geoscience and Remote Sensing, Delft, Netherlands, 5UPMC/LMD, Paris, France, 6CNRM-GAME, Toulouse, France

The 5th IPCC report states that the Antarctic Plateau is one of the regions where the near-surface temperature is the less well constrained in climate models and re-analyses. The misrepresentation of the stable boundary layer (SBL) may be suspected. Investigation of meteorological measurements at Dome C evidenced the extreme nature of the SBL at this location. The summertime diurnal cycle, the very strong stratifications in winter and the two-regime behavior of the SBL dynamics challenge our understanding of the SBL and its parametrization by climate models. After characterizing the Dome C SBL from measurements, we present an innovative conceptual model that provides insights into the SBL dynamics, explaining the reversed ‘S-shaped’ dependency of the near-surface inversion with the wind speed. The LMDZ General Circulation Model, involved in the next CMIP/IPCC exercise, is then evaluated in 1D and 3D configurations. Extensive sensitivity tests to the turbulence parametrization, resolution and surface parameters are presented. They lead to a satisfactory configuration of the model’s physics, in which the turbulent mixing sharply decreases with increasing stability. The analysis of simulations further sheds light on the critical roles of radiation and subsidence in the heat budget of the SBL. Radiative and humidity issues associated to strong biases in the SBL representation are discussed, paving the way for both observational and modeling studies in the future.
Extreme wind gust conditions are frequently observed in the coastal regions of Antarctica. At some locations they can even reach hurricane force. The strong winds are typically of katabatic origin occasionally intensified by passing cyclones. Even though the extreme wind conditions have been recognized, the wind gusts have received only a little attention from the scientific community. To better understand the climatology and dynamic origins of the gusts, the data from eddy covariance stations installed near the Finnish Antarctic station ABOA during the austral summers of 2010/2011 and 2014/2015 was analyzed. The region is located about 130 km from the coast and is primarily covered by a gently sloping glacier and has the Basen nunatak as a defining feature. Energetic gravity waves generated by the nunatak have been previously studied as well as the katabatic winds which are often present. The local, small scale dynamics is predominantly influenced by the position in relation to the Basen nunatak. A comparison of an upwind site and a site near the Basen nunatak demonstrates the spatial variability of the wind gust climatology in the Antarctic ABL. Further analysis of the high resolution time series isolates the dynamic structure of the wind gusts and results are supplemented by SODAR data.
Causes of Accelerated Warming of the Arctic in Winter

John Fyfe¹ (john.fyfe@canada.ca)
¹Environment and Climate Change Canada, Victoria, Canada

Over recent decades, the rate of winter warming increased dramatically over the Arctic while plummeting to near zero over northern midlatitudes. Climate models predicted neither. The reasons for the warming slowdown over northern midlatitudes are well understood; the reasons for the warming acceleration over the Arctic are not. Here we show, using a novel combination of atmospheric reanalyses and climate model simulations, that these phenomena are linked through a large amplitude signal of internal trend variability with opposing sign over the Arctic and northern midlatitudes. For the Arctic, we estimate that internal trend variability accounted for 50-90% of the increased rate of Arctic warming since the early 1980s. Uncertainties in trend estimates depend on atmospheric reanalysis, climate model, and trend period and length considered. These results challenge the perception of a dominant influence from human activities on recent warming rates over the Arctic, suggesting instead that multi-decadal internal variations had an impact nearly as large as, or larger than, the human influence.
Arctic Temperature Trends: A Role of Internal Variability and External Forcing

Vladimir Semenov¹ ² (vasemenov@mail.ru), Pavel Demchenko¹
¹A.M.Obukhov Institute of Atmospheric Physics, Russian Academy of Sciences, Moscow, Russian Federation,
²Institute of Geography RAS, Moscow, Russian Federation

Relative contributions of internal atmospheric variability, lower boundary conditions and external radiative forcing to the recent warming trends in high northern latitudes are investigated based on large (30 members) ensemble of numerical simulations with an atmospheric general circulation model (AGCM). The model is forced with the same historical boundary conditions (sea surface temperatures and sea ice concentrations) for 1979-2012 period and different initial conditions with and without time varying radiative forcing. It is found that simulated ensemble mean Arctic temperature changes considerably underestimate the observed temperature increase. The difference between model results and observations may not be explained by internal atmospheric variability that is reasonably well simulated by the model. Analytical model describing climate zonal trend uncertainty as a function of internal fluctuations of zonal temperature anomalies is suggested and found to successfully describe AGCM results. Introducing direct radiative forcing considerably improves the model’s results in simulating Arctic temperature trends. The strongest contribution of direct radiative forcing is found in the European part of Russia and in the Western Arctic. Comparison of the simulated trends with observations suggests possible problems with sea ice concentration data used to force atmospheric models.
Non-linear Impacts of Future Anthropogenic Aerosol Emissions on Arctic Warming

Srdan Dobricic1, Luca Pozzoli2 (luca.pozzoli@ec.europa.eu), Elisabetta Vignati1, Rita van Dingenen1, Julian Wilson1, Simone Russo1, Zbigniew Klimont2
1European Commission, Joint Research Centre, Ispra, Italy, 2International Institute for Applied Systems Analysis, Laxenburg, Austria

Past reductions of anthropogenic aerosol concentrations in Europe and North America could have amplified Arctic warming. In the future the impact of air pollution policies may differ, because the major anthropogenic sources of atmospheric aerosols are increasingly in Asia. In this study numerical experiments indicate that, while reduced carbon dioxide (CO2) emissions weaken Arctic warming, future reductions of anthropogenic aerosol concentrations can either amplify or diminish it. Interactions between regional atmospheric aerosol concentrations in Asia and internal climate variability may differently initiate and sustain atmospheric planetary waves propagating into the Arctic. In a non-linear manner they may redistribute atmospheric and oceanic meridional heat fluxes at the high latitudes. In experiments until 2050 lower anthropogenic aerosol concentrations combined with current CO2 emissions amplified Arctic warming by increasing atmospheric meridional heat fluxes, but when combined with lower CO2 emissions they further diminished Arctic warming by decreasing oceanic meridional heat fluxes.
Does the Atlantic Windstorms Have Significant Influences on the Arctic Warming?

Baek-Min Kim¹ (bmkim@kopri.re.kr)

¹Korea Polar Research Institute (KOPRI), Unit of Sea-ice Prediction, Inchon, Korea, Republic of

During the northern winter, strong Atlantic windstorms often intrude into the Arctic and play important roles as a moisture supplier into the Arctic. Recent unprecedented Arctic warming event happened in early January of 2016 is the best example: In this episode, the Atlantic sector of Arctic experienced tremendous warming more than 25 DegC than its daily climatology due to the entry of strong Atlantic windstorm of 950 hPa as its central pressure. However, quantitative assessments on the role of Atlantic windstorms on the Arctic warming episodes are rare in the current literatures. Here we provide robust statistical evidences that strong Atlantic windstorms tend to move northeastward to the Arctic and induce significant Arctic warming. Positive North Atlantic Oscillation (NAO) condition and, thus, intensified upper-level winds and tropospheric instability contribute favorable conditions for the intensification of the stronger storms. Enhanced poleward energy transport by moisture intrusion is observed during the lifecycle of the Atlantic windstorms of strongest 10-20% category. The increase of Arctic temperature critically depends on the strength of storm. This linkage between strong Atlantic windstorms and Arctic warming events are well simulated by the two independent climate model simulations.
The winter Arctic atmosphere is under the influence of two very different circulation systems. The eastern Arctic is impacted by extra-tropical cyclones that travel from Iceland towards the Barents Sea along the primary North Atlantic storm. In contrast, the circulation in the western Arctic is characterized by a quasi-stationary region of high pressure known as the Beaufort High. Both of these circulation systems play important roles in the Arctic climate system. Here we show that the winter of 2017 featured a reversal of the normally anticyclonic surface winds and sea ice motion in the western Arctic. We argue that this reversal can be traced to a collapse of the Beaufort High as the result of the intrusion of low-pressure systems from the North Atlantic, along the East Siberian Coast, far into the Arctic Basin. Thin sea ice as the result of an extremely warm autumn of 2016 contributed to the formation of an anomalous thermal low over the Barents Sea that, along with a northwards shift of the tropospheric polar vortex, permitted the intrusion of low-pressure systems deep into the Arctic Basin. This collapse was associated with 2-sigma sea-level pressure, surface wind and sea ice circulation anomalies in the western Arctic. As the Arctic sea ice continues to thin, such reversals may become more common and impact ocean circulation, sea ice, and biology.
Towards a Rain-dominated Arctic

Richard Bintanja¹ (bintanja@gmail.com)
¹KNMI, De Bilt, Netherlands

Climate models project a strong increase in Arctic precipitation over the coming century, which has been attributed primarily to enhanced surface evaporation associated with sea-ice retreat. Increases in Arctic precipitation are thus firmly linked to Arctic warming and sea-ice decline. Since the Arctic is still quite cold, especially in winter, it is often (implicitly) assumed that the additional precipitation will fall mostly as snow. However, little is known about future changes in the distributions of rainfall and snowfall in the Arctic. In this study we use 37 state-of-the-art climate models in standardised twenty-first-century (2006-2100) simulations to show a decrease in average annual Arctic snowfall, despite the strong precipitation increase. Rain is projected to become the dominant form of precipitation in the Arctic region (2091-2100), as atmospheric warming causes a greater fraction of snowfall to melt before it reaches the surface, in particular over the North Atlantic and the Barents Sea. The reduction in Arctic snowfall is most pronounced during summer and autumn when temperatures are close to the melting point, but also winter rainfall is found to intensify considerably. Projected (seasonal) trends in rainfall and snowfall will heavily impact Arctic hydrology (e.g. river discharge, permafrost melt), climatology (e.g. snow, sea-ice albedo and melt) and ecology (e.g. water and food availability).
At first sight, the two poles differ in some fundamental ways. Whilst the Arctic consists of ocean surrounded by continents, the Antarctic is a continent surrounded by ocean; where the Antarctic has no permanent human habitation, the Arctic is inhabited by indigenous peoples and other local communities. Those differences find a clear expression in the distinct legal arrangements and governance mechanisms for the Arctic and the Antarctic. At the same time, two polar regions share certain important similarities that, we argue, render their comparison valuable. Among others, what they have in common is the paramount importance of scientific research and informing relevant decision-making with best available scientific knowledge on changes in socio-ecological systems and biophysical environments of the Arctic and Antarctic. How is the science-policy interface organized in the two regions? What are the differences and similarities between them? What are the pros and cons of present arrangements centered in case of the Antarctic around the Scientific Committee on Antarctic Research (SCAR) and around the Arctic Council (AC), albeit in a much looser manner, in case of the Arctic? Are there lessons that two poles could learn and benefit from each other? This paper examines the above issues. As such presented work spans not only boundary between science and policy-making, but also between the Arctic and the Antarctic, providing fertile ground for further research and collaboration.
Engaging, Involving and Empowering Stakeholders for Arctic Climate Prediction

Halldor Johannsson¹ (halldor@arcticportal.org), Dragana Bojovic², Marta Terrado², Luisa Cristini³, Isadora Christel², Gerlis Fugmann⁴, Francisco Doblas-Reyes⁵
¹Arctic Portal, Akureyri, Iceland, ²Barcelona Supercomputing Centre, Barcelona, Spain, ³Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, ⁴Association of Polar Early Career Scientists, Alfred-Wegener Institute, Helmholtz Center for Polar and Marine Research, Germany, Potsdam, Germany, ⁵Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain

The Arctic environment is changing rapidly with new opportunities and threats, calling for enhanced collaboration between academia and stakeholders. The EU H2020 project APPLICATE aims to improve climate prediction, applying user engagement to share knowledge by a three-level approach:

Engaging. Using optimum communication tools, APPLICATE targets the broader stakeholder community: (i) scientific and intergovernmental organisations, as advanced data users that can highlight knowledge gaps; (ii) Public and private sector, who benefit from enhanced operational predictive capacity; (iii) Society at large, general public and local communities; (iv) relevant international projects.

Involving. Interacting with stakeholders in meetings and via the Polar Prediction Matters Blog, APPLICATE extends discussion and knowledge exchange. A User Group composed of representatives from various stakeholder groups, closely follows and collaborates with the project.

Empowering. Relationships with stakeholders are achieved through their participation in project meetings and activities. Co-development of user-relevant metrics improves our understanding of impacts and opportunities of potential changes in the Arctic and their effects. Active collaboration helps produce sound project results and relevant products and services, supporting stakeholders decision making, training and education.

User engagement supports informative decision making and capacity to adapt to new conditions in the Arctic.
Crossing Boundaries in Science - INTERACT Science Diplomacy

Margareta Johansson1, Terry Callaghan2,3 (terry_callaghan@btinternet.com)
1Lund University, Lund, Sweden, 2Sheffield University, Sheffield, United Kingdom, 3Tomsk State University, Tomsk, Russian Federation

At a time of increasing geopolitical tensions, it is important to adopt all diplomatic activities including those in science. INTERACT is a network of 83 research stations in 18 countries (including all Arctic nations). The Stations share activities, data and experiences independent of nationality. Funding through the EU, USA and Canada allowed INTERACT to offer Transnational Access (TA) funding at a pan-Arctic scale for the first time. TA has so far funded about 600 researchers to work in infrastructures outside their own national facilities. A community of grant holders has cemented a multinational and multidisciplinary team of researchers working throughout the North. In addition, the INTERACT experience has been used as a model within various Arctic nations and has contributed to the establishment of national networks linked internationally. The science diplomacy operated by INTERACT has received attention and support from various Embassies and has explicitly improved relationships between Russian and western researchers and infrastructures. INTERACT seeks to improve the wellness of Indigenous Peoples and other Arctic residents. For the first time, it provides a one-stop-shop (a Red Phone) for alerting infrastructures throughout the Arctic to identify, observe and respond to potentially hazardous environmental events. It has also worked with Russian and other local governments and universities to improve the relevance and awareness of science to local peoples.
Antarctic Cities: Rethinking the Gateways

Juan Francisco Salazar¹ (j.salazar@westernsydney.edu.au), Elizabeth Leane², Daniela Liggett³, Hanne Nielsen⁴, Gabriela Roldan⁵, Claudia Estrada⁶, Elias Barticevic⁶, Liam Magee¹, Paul James¹

¹Western Sydney University, Institute for Culture and Society, Sydney, Australia, ²University of Tasmania / Institute for Marine and Antarctic Studies, Hobart, Australia, ³University of Canterbury, Christchurch, New Zealand, ⁴University of Tasmania, Hobart, Australia, ⁵Universidad de Magallanes, Punta Arenas, Chile, ⁶Chilean Antarctic Institute INACH, Punta Arenas, Chile

The five recognized Antarctic gateways cities of Cape Town, Christchurch, Hobart, Punta Arenas and Ushuaia all stand on the Southern Ocean Rim. As all significant engagement with the South Polar Region is co-ordinated through these cities, they have a unique opportunity to act as custodian cities of this ecologically and geopolitically fragile region. Each city is formed by long and complex histories of engagement with the Antarctic going back to the nineteenth century. However, until now these cities have been thought of primarily as exit/entry points for tourists and base-personnel traveling to Antarctica. This presentation provides an overview of the international collaborative research project Antarctic Cities and the Global Commons: Rethinking the Gateways which is the first study to offer a systematic rethinking of both the engagement and outlook of these cities — not as five far-flung ports competing for the same commercial opportunities but as members of an interlinked network. This rethinking is crucial in offering ways of reorienting these cities not just as thoroughfares, but as urban centers that can embody the cosmopolitan values associated with Antarctic custodianship: international co-operation, scientific innovation, and ecological conservation. As the cities envision their urban futures this project explores a possible shift in urban practices and imaginaries from ‘gateway cities’ to ‘custodian cities’.
We investigate generic algorithms to improve variability in modeled carbon export by emphasizing the influence of plankton community structure. We conducted tests on a 1D lower trophic level model set at various time-series stations in the North Atlantic, and each community was allowed to modify the settling and remineralization rates of detritus-based on their traits (i.e. diatoms produce fast sinking particles with higher remineralization rates, while particles from prokaryotes are slower with lower remineralization rates). Additional tests were conducted on aggregation, mineral ballasting, and DVM. Results indicate that a community-based scheme is superior in representing temporal and spatial changes in export and transfer efficiencies without any region-specific parameterization. As communities adapt to different hydrography, so does the regional export efficiency. Cross-latitude comparisons show that high latitudes, which sustain larger plankton, receive higher export efficiencies compared to both low latitudes and experiments using constant global rates. Such an export mechanism has important implications for regional and global models since hydrography is thus tightly coupled to export through community structure, which may improve predictive skills for future ocean communities and carbon export. We present experiments in 1D from subtropics to Arctic, as well as initial tests in the Arctic in a 3D operational model.
Spring blooms provide insight into the importance of physical versus ecological controls of ocean productivity and export, and potential responses to climate change. We present high temporal resolution records from the Southern Ocean Time Series south of Australia, for physical drivers (temperature, salinity, surface mixed layer depth, currents, wind speeds, insolation, and air-sea heat fluxes) and biological responses for four (NPZD) trophic levels commonly used in biogeochemical models (Nutrient depletions and Phytoplankton community structure from automated sample collections; Zooplankton from four-frequency acoustics; POC and ballast mineral Detrital fluxes from sediment traps, as well as net community production (NCP) from O₂/N₂).

Chlorophyll increased slightly ahead of the spring mixed layer shoaling, when zooplankton populations were lowest. The summer zooplankton increase was accompanied by shallower daytime migrations, especially for the high frequency (small) sound scatterers. Diatoms dominated biomass in spring, when NCP was highest, and continued to be important in summer even after silica was depleted. Nonetheless, seasonal N/Si drawdown shows non-diatoms were important to export and the major biogenic mineral reaching the ocean interior was carbonate, along with global median levels of POC export, despite low dissolved iron levels. These results suggest the current maximal state of the Si pump may not limit future Southern Ocean carbon export.
Effects of Sea Ice on the Biogenic Carbon Export in High-Arctic Svalbard Fjords

Gérald Darnis (gerald.darnis@qo.ulaval.ca), Catherine Lalande, Steffen Swoboda, Janne Søreide, Finlo Cottier, Philipp Assmy, Jørgen Berge

1Université Laval, Quebec City, Canada, 2UNIS The University Centre in Svalbard, Longyearbyen, Norway, 3The Scottish Association for Marine Science, Oban, United Kingdom, 4Norwegian Polar Institute, Tromsø, Norway, 5UiT The Arctic University of Norway, Tromsø, Norway

Variation in the strength, timing and composition of the biological carbon pump determines energy transfer to higher trophic levels and the capacity of the ocean to sequester atmospheric CO2. The lack of knowledge on sinking fluxes in Svalbard fjord ecosystems limits our understanding of the drivers of this critical process for carbon cycling. By comparing two Svalbard fjords with different environmental settings, our aim is to assess the nature of annual sinking fluxes in these systems and identify forcing factors and implications for food web processes. We analyzed samples from autonomous ocean observatories with sediment traps at 100 m depth in ice-free Kongsfjorden and in the seasonally ice-covered Rijpfjorden. The total mass and protist flux was an order of magnitude higher in Kongsfjorden than in Rijpfjorden. However, timing of the sharp protist peak flux was similar in the two fjords. Over three annual cycles in Rijpfjorden, the peak flux of the obligate ice-algal diatom Nitzschia frigida preceded the peak flux of the pelagic diatom spring bloom by only one to two weeks. Sinking flux linked to ice-algal and phytoplankton blooms appeared to be intense but brief events followed by low post-bloom export, except in 2014 in Rijpfjorden. Drivers of the observed flux patterns are interpreted based on oceanographic and sea-ice cover information, and surface fluorescence data as a proxy for pelagic primary production.
The Gypsum Gravity Chute to the Arctic Abyss

In the ice-covered central Arctic Ocean vertical carbon flux has been considered especially low with some notable exceptions that highlight the importance of fast-sinking aggregates for the biological carbon pump. Incorporation of ballast minerals into sinking aggregates can significantly increase the carbon export efficiency from the surface ocean to depths below the pycnocline. However, little is known about the importance of ballasting in the ice-covered Arctic Ocean, and in particular the composition of ballast minerals. Lacking a mineral shell the haptophyte algae *Phaeocystis* is usually remineralised above the pycnocline. Here we show that, during the TRANSSIZ expedition in spring 2015, gypsum crystals released from melting sea ice were trapped by an under-ice *Phaeocystis* bloom. A geochemical model indicates that the gypsum crystals formed at temperatures below -6.5°C and were subsequently released during the melting of sea ice and coincident to the formation of the under-ice *Phaeocystis* bloom. This led to an accelerated and enhanced vertical export of gypsum-ballasted *Phaeocystis* aggregates to the sea floor at 2147 m water depth. Our findings suggest an important and previously unknown role of cryogenic gypsum in ballasting under-ice *Phaeocystis* blooms. Current environmental changes in the Arctic likely favour this gypsum gravity chute with consequences for carbon export and energy partitioning between pelagic and benthic Arctic ecosystems.
Importance of Zooplankton Grazing for Arctic Pelagic-benthic Coupling

Ingrid Wiedmann¹ (ingrid.wiedmann@uit.no), Elena Ceballos Romero², Feliciano de Soto³, María Villa-Alfageme², Morten Hvitfeld Iversen⁴

¹UiT The Arctic University of Norway, Department of Arctic and Marine Biology, Tromsø, Norway, ²Universidad de Sevilla, Departamento de Física Aplicada II, Sevilla, Spain, ³Universidad Pablo de Olavide, Departamento de Sistemas Físicos, Químicos y Naturales, Sevilla, Spain, ⁴University of Bremen, Faculty of Geosciences and MARUM, Bremen, Germany

Field observations are always point measurements and it can be demanding to elucidate driving processes for pelagic-benthic coupling based on only these data. We complemented therefore our field observations (hydrography, suspended biomass, particle export estimated with short-term sediment traps modified with a gel containing glass jar) at three contrasting Arctic sites around Svalbard with a novel microscopic simulation for particle dynamics to reproduce the particle production, sinking and degradation and estimate the vertical export.

Our observations showed that particle size and abundance changed with depth, suggesting that strong zooplankton grazing on settling aggregates at the base of the mixed layer (ML) caused a change in the attenuation mechanisms with depth. This conclusion is supported by the results of the simulations, because the observed vertical fluxes could be reproduced if a significant depth decrease in the particle degradation rate (e.g. three fold) below the ML was applied in the simulation.

In this work, we show the potential of the combination of field observations and process modelling, allowing to improve the information obtained from a few points of field observation in relation to processes in the water column and to identify potential drivers for organic carbon export from the surface ocean to the sea floor.
To understand how warming in the West Antarctic Peninsula (WAP) has affected the polar ecosystem and the global carbon cycle, a multi-decade sediment trap time-series is analyzed in relation to environmental (temperature, sea ice duration) and biological (primary and bacterial production, zooplankton abundance) factors. The continental shelf region of the WAP has experienced over 6°C increase in winter temperatures since 1950. The recent warming and declines in sea ice have been associated with changes at all levels of the WAP ecosystem, including reduction in phytoplankton biomass, shift in phytoplankton community composition, reduction in krill abundance, as well as decline in top predators such as Adelie penguins. These changes to the phytoplankton and krill have resulted in notable changes in particulate organic carbon (POC) flux, as these components represent two major drivers to the biological carbon pump. The Palmer Long Term Ecological Research program has been conducting extensive studies along the WAP for the past 25 years, including deployment of a moored sediment trap which intercepts sinking particles at 170 m in the water column. Data from this sediment trap time-series is unique in its longevity, allowing us to understand how POC flux has changed seasonally and annually over two decades. Evidence of environmental changes at the ocean surface are reflected at depth in the sediment trap data as a decrease and shift in timing of POC flux over the past two decades.
Using Microseismicity to Study the Role of Subglacial Fluids in Basal Slip

Thomas S. Hudson¹,² (tsh37@cam.ac.uk), Alex Brisbourne¹, Robert S. White²
¹British Antarctic Survey, Cambridge, United Kingdom, ²University of Cambridge, Dept. Earth Sciences, Cambridge, United Kingdom

Icequakes are triggered by glacier or ice sheet movement. Here, we are particularly interested in basal icequakes, primarily induced by basal slip of ice over bedrock or sediment. The specific icequakes investigated in this study are associated with Skeiðarárjökull, an outlet glacier of the Vatnajökull ice cap, Iceland. To detect and locate these icequakes, we use a network of 13 seismometers deployed on the glacier surface. The seismic energy that travels from the icequake source to the seismometers can be used to understand the processes that generate the icequake. We use moment tensor analysis combined with modelling to investigate whether subglacial fluids exert influence during a basal icequake event, and to what extent they govern slip occurring. Although these results are associated with a relatively small outlet glacier in Iceland, the glacier is sufficiently thick and fast moving that these results are likely also relevant for ice sheet behavior. The role of subglacial fluids in promoting basal slip observed here could therefore aid our understanding of ice sheet dynamics, both in Greenland and Antarctica.
Recent changes of cryosphere and glacier dynamics in north-western Spitsbergen were based on infrastructure of the Nicolaus Copernicus University Polar Station, located in Kaffiøyra. It was mainly related to mass balance, ablation and snow accumulation on three glaciers: Waldemarbreen, Irenebreen and Elisebreen. Changes in the surface area and recession of the land and sea-terminating glaciers were analysed. Changes in the outflow from Waldemarbreen were analysed in detail. The active layer of permafrost was also covered by measurements, especially its thermals and thickness changes.

Systematically field studies of glaciers mass balance components were carried out from 1996 to 2017, and remain some of the longest measurement series run on Svalbard. The measurements of the glaciers’ recession and the magnitude of thawing of the active layer of permafrost on Kaffiøyra are similarly unique in terms of their length. All the studies aimed at understanding the intensity and size of changes in the cryosphere of north-western Spitsbergen, the Kaffiøyra region, as well as processes ruling them nowadays, as a result of changes taking place in this part of the globe. Like other contemporarily glaciated areas, the Kaffiøyra region is a place of wide variety of cryosphere components, which in recent years have been rapidly responding to climate change.
On Various Approaches to Map Glaciers and their Changes

Liss Marie Andreassen (lma@nve.no), Hallgeir Elvehøy, Bjarne Kjøllmoen, Joaquin M. C. Belart, Jessica De Marco

1Norwegian Water Resources and Energy Directorate (NVE), Oslo, Norway, 2University of Iceland, Institute of Earth Sciences, Reykjavik, Iceland, 3University Of Toulouse, Laboratoire d’Etudes en Geophysique et Oceanographie Spatiales, Toulouse, France

Accurate glacier surveys are essential in glacier monitoring. Surface elevations are needed for glaciological calculations, and repeated surveys are used to detect glacier changes of glaciers and to reanalyse glaciological mass-balance series. Whereas traditionally ground surveys and aerial photogrammetry were used for glacier surveys, today a wealth of approaches to map glaciers exists. Possibilities include laserscanning (LIDAR), aerial photos and high resolution satellite imagery. What is suitable depends on scale, for smaller glaciers and ice patches unmanned aerial vehicles (UAV) and ground surveys may be appropriate, for larger glaciers other approaches are needed.

Here we report on experiences of mapping glaciers and glacier changes in mainland Norway using various mapping techniques. Over recent years 1/3 of the glacier area has been mapped using airborne laser scanning. We compare this data with previous laserscannings and aerial photogrammetry where available. We also demonstrate how scanned historical aerial photos can be used to reconstruct glacier surface elevations. We show that new satellite sensors such as Pleiades can be used for glacier change detection and reanalysis. We also discuss the possibilities and shortcomings of using UAVs for glacier survey for our reference glaciers. Finally, we present a geodetic mass balance estimate of all glaciers in Norway from the 1960s to the 2010s. Results reveal an overall mass loss and area shrinkage in this period.
IACS Working Group on Ice Thickness Estimation - What Have we Achieved?

Daniel Farinotti¹² (daniel.farinotti@ethz.ch), Liss M. Andreassen¹, Huilin Li⁴
¹Laboratory of Hydraulics, Hydrology and Glaciology (VAW), ETH Zurich, Zurich, Switzerland, ²Swiss Federal Institute for Forest Snow and Landscape Research WSL, Birmensdorf, Switzerland, ³Norwegian Water Resources and Energy Directorate (NVE), Oslo, Norway, ⁴State Key Laboratory of Cryospheric Sciences, Tian Shan Glaciological Station, CAREERI, CAS, Lanzhou, China

The Working Group (WG) on Ice Thickness Estimation, hosted by the International Association for Cryospheric Sciences, was established in 2015 with the goal of (a) performing a model intercomparison experiment for models that estimate glacier ice thickness from surface characteristics, (b) associating a distributed ice thickness estimate to all glaciers included in the Randolph Glacier Inventory, and (c) supporting the World Glacier Monitoring Service in the effort of creating a database centralizing ice thickness measurements across the Globe.

In this contribution we report from the WG’s activities during its three years of existence. We highlight our successes - particularly including the results obtained within the Ice Thickness Models Intercomparison eXperiment (ITMIX) and the release of new versions of the Glacier Thickness Database (GlaThiDa) -, report on the challenges faced during our work, and provide an outlook for the activities that will follow from our endeavours.

We hope our experiences to be insightful, inspiring, and motivating for WG’s yet to come.

On behalf of http://www.cryosphericsciences.org/wg_glacierIceThickEst.html
Glacier sliding velocity is difficult to measure because the subglacial environment is typically inaccessible. We propose an approach to infer sliding velocity based on glacier surface velocities measured by remote sensing, as well as the physics of ice rheology.

Until recently, measuring the spatial distribution of glacier surface velocity was challenging because it required expensive high-resolution satellite acquisitions. Moreover, these acquisitions are often subject to cloud obstructions, which make it challenging to acquire images at a sufficient frequency to estimate high ice velocities. In the last years, the development of UAVs has offered the possibility to acquire images at an unprecedented resolution and frequency, and at a fraction of the cost of satellite images. Here we use such acquisitions to derive a high resolution surface velocity field of the Gorner glacier (Swiss Alps) and its evolution through the 2017 summer season.

The same glacier was then modeled using a finite element ice flow model (Elmer/ice), using as inputs the drone-derived surface DEM, a glacier bed topography available from geophysical surveys, appropriate boundary conditions, and assuming a zero sliding velocity. The modeled surface velocities thus corresponds to the pure deformation velocity component. Assuming that the sliding velocity corresponds to the difference between the deformation velocity and the UAV-derived surface velocity one can finally derive the sliding velocity.
Simulating the Evolution of Rhonegletscher Since 1600 with Úa and GERM

Simon Förster¹ (foerster@vaw.baug.ethz.ch), Matthias Huss¹, Hilmar Guðmundsson²
¹Laboratory of Hydraulics, Hydrology and Glaciology (VAW), ETH Zürich, Zürich, Switzerland, ²British Antarctic Survey, Cambridge, United Kingdom

At the end of the Little Ice Age (around 1850), glaciers in the Alps reached their last maximum extent. However, it is still uncertain what caused the preceding advance and the following retreat. Several studies have concluded that temperature alone cannot explain this behaviour. A precipitation increase of about 25% could explain the anomaly, but this is not supported by observations. Further processes have been proposed, including changes in solar radiation (due to either solar activity variations or aerosols in the atmosphere), surface impurities on ice and snow, and dynamical effects in both the atmosphere and the glaciers. We will test some of these processes in a model study and determine their relative importance by coupling the ice flow model Úa to the mass balance part of the Glacier Evolution Runoff Model (GERM).

We simulate the evolution of Rhonegletscher between 1600 and today using the coupled model based on different temperature and precipitation reconstructions, e.g. Casty et al. (2005), the PAGES2k database, and Pauling et al. (2006). We compare these simulations to a simpler approach prescribing the mass balance as a function of temperature and precipitation. Furthermore, we validate the simulations with observations of glacier length change, flow velocity, and geometry change.
Protection Strategies in a More Accessible Maritime Arctic

Lawson Brigham\textsuperscript{1} (lwb48@aol.com)
\textsuperscript{2}University of Alaska Fairbanks, International Arctic Research Center, Fairbanks, United States

Profound Arctic sea ice retreat is creating greater marine access and potentially longer seasons of navigation throughout the region. Arctic natural resource developments onshore and offshore are linking the Arctic to global markets using advanced marine transportation systems. These key drivers of change require a holistic approach to enhancing marine safety and environmental protection in the Arctic marine environment. The Arctic Council’s Arctic Marine Shipping Assessment (AMSA) identified 17 recommendations that covered three critical themes: I. Enhancing Arctic Marine Safety (through International Maritime Organization measures and international instruments/binding agreements such as for search and rescue); II. Protecting Arctic People and the Environment (through identifying indigenous marine use, designating Arctic marine protected areas, and addressing measures for oil spills, air emissions, invasive species, and more); and, III. Building the Arctic Marine Infrastructure (such as establishing Arctic traffic systems, investing in hydrography and charting, and developing enhanced response capacity). This will be a review of current and future strategies, including ecosystems-based management, being used to address the impacts of greater marine operations and shipping throughout the Arctic Ocean. All of the multi-faceted approaches for protection must address the serious maritime infrastructure gap throughout the Arctic.
Conserving Abundance, or How to Avoid What Has Happened Everywhere Else

Henry Huntington (hhuntington@oceanconservancy.org)
1Ocean Conservancy, Eagle River, United States

Many conservation approaches focus on scarcity and vulnerability. Fear of extinctions rightly drives endangered species laws. The recognition of biological hot spots understandably leads to the designation of protected areas. Concern about overharvesting produces fish quotas and hunting limits. These are necessary and appropriate measures. They fall short, however, of protecting the abundance that still characterizes many aspects of Arctic ecosystems. In a global context, Arctic fisheries are well managed, and the Arctic has vast expanses of relatively undisturbed, connected habitats. The risk is that we take such bounty for granted, encroaching bit by bit into more and more areas, willing to take a little more here and there, over and over. The end result is an Arctic that looks much like the rest of the world: relic populations of large animals living in small fragments of habitat. One alternative is to recognize and protect what remains abundant, rather than reacting only to scarcity. Cautionary approaches to fisheries management in Arctic Canada and Alaska provide one example, which may soon be extended to the international waters of the central Arctic Ocean. Widespread habitat protections offer another mechanism, allowing some types of human use but extending over far larger areas than just the most spectacular aggregations of wildlife. This presentation will suggest a new vision for Arctic conservation, recognizing what makes the Arctic distinct in today's world.
A Step-wise Plan for Integrated Ecosystem Science in the Central Arctic Ocean

Jacqueline Grebmeier¹ (jgrebmei@umces.edu), Henry Huntington²
¹University of Maryland Center for Environmental Science, Chesapeake Biological Laboratory, Solomons, United States, ²Ocean Conservancy, Eagle River, United States

The international waters of the central Arctic Ocean are experiencing rapid sea ice reduction and transition to a seasonally open system that can lead to increased human usage. With these changes there is a need for better understanding of the Central Arctic Ocean (CAO) ecosystem and its connectivity to the surrounding seas. Multiple efforts are underway to develop an integrated ecosystem assessment for the CAO. Coincidently, the five Arctic coastal states (Canada, Denmark/Greenland, Norway, Russian Federation, United States of America) and five distant-water fishing jurisdictions (the European Union, Iceland, Japan, People’s Republic of China, Republic of Korea) are negotiating a closure to commercial fishing in these waters until sufficient scientific information is available to support management decisions related to commercial fisheries within an ecosystem approach. Recently, a series of three international “dialogue” meetings have occurred to encourage international arctic science community discussions for an ecosystem approach to minimize unregulated fisheries in the CAO. We propose a step-wise approach in which basic monitoring is undertaken to detect ecosystem component status and any significant changes. This approach will facilitate determining if and when more intensive efforts are needed to gather data on specific ecosystem components, fish population dynamics, and potential outcomes to track ecosystem response and fish populations in the changing Arctic region.
Towards a Representative System of Marine Protected Areas in the Southern Ocean

Cassandra Brooks¹ (cassandra.brooks@colorado.edu)
¹University of Colorado Boulder, Environmental Studies, Boulder, United States

Global threats to ocean biodiversity have generated a worldwide movement to take action towards better conservation and management. A number of international targets have recommended the adoption of marine protected areas (MPAs) in national and international waters. While establishing MPAs in international waters has proved to be incredibly challenging in most of the world, national governments and the Commission for the Conservation of Marine Living Resources (CCAMLR) have succeeded in adopting multiple MPAs in the Southern Ocean. But are these MPAs representative of Southern Ocean biodiversity and ecosystems? This talk will present on the current status of Antarctic MPAs and future trends using existing benthic and pelagic bioregionalizations as well as other ecological data sets as a proxy for biodiversity. Results show that currently about 8% of the Southern Ocean is protected in MPAs. While this is a relatively large proportion of protected areas when compared to other international waters, it falls short of existing international MPA targets. Further, current Antarctic MPAs are not fully representative of all bioregions. Yet CCAMLR is currently negotiating a variety of additional MPA proposals and if these are adopted in the coming years, CCAMLR may be the first international ocean management organization that meets global ocean biodiversity targets.
Joining Forces in Implementing the CEP’s Climate Change Response Work Program

Birgit Njaastad¹ (njaastad@npolar.no), Ewan McIvor²
¹Norwegian Polar Institute, Tromsø, Norway, ²Australian Antarctic Division, Hobart, Australia

In 2015 the Antarctic Treaty’s Committee for Environmental Protection (CEP) adopted a Climate Change Response Work Program (CCRWP: www.ats.aq/documents/ATCM39/att/atcm39_att072_e.doc), to be implemented as a matter of priority and kept under regular review. In 2017 the CEP established a subsidiary group with the responsibility to oversee the implementation of the CCRWP, through facilitating coordination and communication between stakeholders, by updating and by reporting on progress of implementation to the CEP.

In this presentation, the aim is to highlight and discuss opportunities and challenges regarding the science-management interaction in implementing the CCRWP. A large portion of the CCRWP points to knowledge gaps, as well as research and monitoring needs that would support future conservation efforts in a changing Antarctic environment. Knowledge about ongoing research programs/projects (from Parties, SCAR, WMO, etc.) that seek to or will provide insight into CCRWP issues will be important in this context, and even more so ensuring an appropriate flow of new knowledge from this work, thus facilitating the further implementation of CCRWP actions and tasks. SCAR and the science community will play an important and active role in this context. Furthermore, the science community will be important in supporting the SGCCCR’s work in developing management advice on basis of new knowledge within the framework of the CCRWP.
Anthropogenic Transfer of Species between Antarctic Biogeographic Regions

Kevin A. Hughes1 (kehu@bas.ac.uk), Peter Convey2, Luis Pertierra3, Greta Vega4, Pedro Aragón3, Miguel Á. Olalla-Tárraga4

1British Antarctic Survey, Environment Office, Cambridge, United Kingdom, 2British Antarctic Survey, Cambridge, United Kingdom, 3Museo Nacional de Ciencias Naturales, Centro Superior de Investigaciones Científicas, Madrid, Spain, 4Rey Juan Carlos University, Department of Biology and Geology, Physics and Inorganic Chemistry, Madrid, Spain

The distribution of terrestrial biodiversity within Antarctica is complex, with 16 distinct biogeographic regions currently recognised within the Antarctic Treaty area. Much of this diversity is endemic not only to Antarctica as a whole, but to specific regions within it. Further complexity is added by inclusion of the associated sub-Antarctic ecosystems found on islands in the Southern Ocean. Within Antarctica, scientific, logistic and tourism activities may inadvertently move organisms over potentially long distances. Species translocation can disrupt natural species distribution patterns and biogeography through:

(1) movement of spatially restricted indigenous species to other areas of Antarctica;
(2) movement of distinct populations of a more generally distributed species from one area of Antarctica to another, leading to genetic homogenisation and loss of assumed local patterns of adaptation; and
(3) further dispersal of introduced non-native species from one area of Antarctic to another.

Species can be moved between regions in association with people and their cargo by ship, aircraft and overland travel. Movement of cargo by ship between stations located in different biogeographic regions is likely to present one of the greatest risks, particularly as coastal stations may experience similar climatic conditions, making establishment more likely. We make practical recommendations aimed at reducing the risk of species transfer between Antarctic regions.
The future of Earth's large ice sheets in Antarctica and Greenland represents the greatest uncertainty in projections of future sea level, and the behaviour of the West Antarctic Ice Sheet, in particular, is difficult to predict. The UK-NERC iSTAR Programme (www.iSTAR.ac.uk) is a 7-year effort (2010-17) to improve understanding of West Antarctica's combined Pine Island Glacier-Amundsen Sea system. Of all glaciers worldwide, Pine Island Glacier is the one now making the biggest single contribution to sea level rise. This imbalance has been driven by changes in the Amundsen Sea, which have brought warm ocean waters into contact with floating ice.

iSTAR's objectives were: understanding the transport of ocean heat towards the ice sheet, understanding the sub-ice processes affecting ice melt; and understanding the response of the inland glacier to the ocean-induced changes. Data acquisition campaigns focussed on the ocean, the ice shelf, the inland glacier and the ice sheet. Data analysis, remote sensing and modelling are still on-going. We present an overall summary of the iSTAR Programme and some of the main results and conclusions so far.
On the Bathymetry of Getz Ice Shelf Cavity from Airborne Gravity Data Inversion

Wei Wei1 (wwei@utexas.edu), Jamin S. Greenbaum1, Donald D. Blankenship1, Tom G. Richter1, Duncan A. Young1, Sanghoon Lee2, Wongsang Lee2, Anna Wåhlin3, Karen Assmann3
1University of Texas, Institute for Geophysics, Austin, United States, 2Korean Polar Research Institute, Incheon, Korea, Republic of, 3University of Gothenburg, Gothenburg, Sweden

The Getz Ice Shelf, stretches along ~500 km of coastline in the Amundsen Sea Sector of West Antarctica, is the largest meltwater source in Antarctica. Getz Ice Shelf itself has nearly constant melt rate of 4.3 ± 0.4 meters of water per year, which is possibly affected by intrusions of modified Circumpolar Deep Water (mCDW). The warm, salty mCDW crosses the continental shelf break through the Dotson-Getz Trough and melts the floating ice shelf from below. Bathymetry has significant implication for possible CDW pathways and is required as one crucial boundary condition for cavity circulation modeling. However, no direct observation of bathymetry under Getz Ice Shelf is available yet. Here, we perform airborne gravity data inversion with multiple geophysical data constraints to obtain an inferred bathymetry. Our results indicate a sill between Siple Island and Carney Island complicates flow of mCDW through the Getz Ice Shelf from east to west and may impact ice shelf basal melt rates. To explore this further, we put the bathymetry in the context of MITgcm (MIT General Circulation Model). A similar approach can be applied to small ice shelves from East Antarctica in the future.
Floating ice shelves that fringe the majority (74%) of Antarctica’s coastline provide a direct link between the ice sheet and the surrounding oceans, and changes in their constitution have been shown to influence the flow of inland ice due to their buttressing effect. This process has become increasingly important over recent decades as Antarctic ice shelves have thinned, retreated, and collapsed - events that have been recorded largely by European satellites. At the Antarctic Peninsula, ice shelf retreat has been observed throughout the satellite era (18% over 50 years), and large sections of the Larsen-A, Larsen-B, and the Wilkins Ice Shelf collapsed, catastrophically in 1995, 2002, and 2008, respectively. In the Amundsen Sea, ice shelves at the terminus of the Pine Island and Thwaites glaciers have thinned at rates in excess of 5 meters per year for more than two decades. Both signals are indicative of long-term changes in the regional climate, and have impacted on the ice inland. We use CryoSat-2 to map ice thickness change on Antarctic ice shelves by exploiting the dense spatial sampling and repeat coverage provided by the SARIn mode data acquired by CryoSat-2 from 2010 to the present day. We find that ice shelf thinning rates exhibit large fluctuations over short time periods, and the improved spatial resolution of CryoSat-2 enables us to resolve the spatial pattern of thinning with ever greater detail in Antarctica.
Channelized Melting Drives Thinning under a Rapidly Melting Antarctic Ice Shelf

Noel Gourmelen¹ (noel.gourmelen@ed.ac.uk), Dan Goldberg²
¹School of GeoSciences, University of Edinburgh, Edinburgh, United Kingdom

Ice shelves play a vital role in regulating loss of grounded ice and in supplying freshwater to coastal seas. However, melt variability within ice shelves is poorly constrained and may be instrumental in driving ice-shelf imbalance and collapse. High-resolution altimetry measurements from 2010 to 2016 show that Dotson Ice Shelf (DIS), West Antarctica, thins in response to basal melting focussed along a single 5 km-wide and 60 km-long channel extending from the ice shelf’s grounding zone to its calving front. If focused thinning continues at present rates, the channel will melt through within 40-50 years, almost two centuries before melt through is projected from the average thinning rate. Our findings provide evidence of basal melt-driven sub-ice shelf channel formation and its potential for accelerating the weakening of ice shelves.
Ice--ocean Wave Interaction on Ice Shelves

Bradley Lipovsky1 (brad_lipovsky@fas.harvard.edu)
1Harvard University, Cambridge, United States

Distant storms, tsunamis, and earthquakes generate waves in floating ice shelves. In several instances, seismic observations have clearly demonstrated a mechanistic link between periods of elevated wave activity and iceberg calving. The detailed mechanical interpretation of observed seismograms is complicated, however, by the existence of numerous types of waves that propagate in the coupled ice--ocean--earth system. Here, I describe wave propagation in an elastic, finite-thickness, buoyantly floating ice layer above a uniform and inviscid water layer. I place particular focus on waves with wavelength greater than the ice thickness, as have recently been observed on the Ross, Pine Island, and Amery Ice Shelves. I show that mode uncoupling occurs at long period such that waves occur as either symmetric or flexural modes. I calculate the stresses associated with the seismically observed wave field on the Ross Ice Shelf. In the context of linear elastic fracture mechanics, this stress field provides a mechanistic explanation for the occurrence of ice shelf rifting during periods of elevated ocean swell. This theory paves the way for more realistic depictions of iceberg calving in large scale ice sheet models.
Early Weakening of the Larsen B Ice Shelf Prior to Break-up

Theodore Scambos¹ (teds@nsidc.org), Marin Klinger¹
¹University of Colorado at Boulder, National Snow and Ice Data Center/CIRES, Boulder, United States

Precursor changes in the Larsen B Ice shelf beginning more than a decade before its disintegration have been identified, and coincide with a trend towards reduced sea ice cover and increased foehn winds. Ice flow speeds in the major tributary glaciers of the Larsen B increased, even in the period prior to the loss of critical areas of the ice shelf (which began in 1998 for the Larsen B), and elevation of the ice shelf surface decreased. Ice shelf surface lowering is interpreted as resulting from actual ice shelf thinning for this area, since field studies on both the Larsen A and B noted the upper firm of the shelf was almost completely converted to ice. Examination of satellite images spanning 1963 - 1997 shows that Larsen B shear margins and some suture zones evolved significantly prior to significant ice shelf retreat. Overall, these changes suggest either increased ocean-driven basal melt or effects of increased surface meltwater on grounded glacier outflow are a cause of early shelf weakening that leads eventually to disintegration. Available ocean temperature data show that modified Weddell Deep Water, having a temperature 0.1-0.4°C above the surface freezing point, is present near the former ice fronts in some 1995-2012 profiles, but to date has not been detected within the embayments near the glacier grounding lines or beneath the ice shelves.
While the change and variability of Antarctic sea ice extent, area and seasonality are well documented, very little information is available on broad-scale change and variability of sea ice-free coastal regions. This is an important topic since there is mounting evidence of potentially strong relationships between coastal sea ice distribution and the characteristics and stability of glacier tongues and ice shelves, such that a lack of the protective “buffer” of sea ice could potentially enhance flexure and fatigue of exposed outer ice-shelf margins by storm-generated ocean swells.

In this study we introduce and examine two methods that focus on sea-ice free regions: a simple, large-scale index called the “Antarctic Coastal Exposure Index”; and a second method which determines the Coastal Exposure Length. For this study we use satellite imagery from 1979 through to 2016 and examine temporal and spatial occurrence and trends. Results show that the West Antarctic coastal regions are dominated by an increase in coastal exposure, particularly in the West Antarctic Peninsular region, but also in the Amundsen Sea. In East Antarctica, trends, when viewed as a longitude-time plot, show that a decrease in coastal exposure around the eastern Antarctic has a distinct westward progression over the summer months. Not all increases in coastal exposure are found within West Antarctica, with some smaller pockets of East Antarctica also showing a positive trend.
Melting at the base of an ice shelf or a glacier tongue freshens and cools the fluid in the ice-ocean boundary layer, producing Ice Shelf Water (ISW), a water mass colder than the sea water surface freezing point. If ISW becomes \textit{in situ} supercooled by pressure release, ice crystals can persist. These crystals add to the mass of the coastal sea ice cover, forming a porous, friable layer, called the sub-ice platelet layer, which can be several metres thick beneath the two-metres of sea ice. Consequently platelet ice formation not only causes sea ice to be thicker, but it also alters the hydrostatic relationship between sea ice elevation and thickness, influencing satellite altimeter determination of sea ice thickness. Here we report on the sea ice thickness distribution in the SW Ross Sea in spring, and describe how this distribution is influenced by interaction with the ice from the continent. The SW Ross Sea is fringed by a number of ice shelves (e.g. McMurdo, Hells Gate, Ross) and glacier tongues (e.g. Drygalski, Erebus), features that have the potential to form ISW. We have conducted airborne sea ice thickness surveys using electromagnetic (EM) induction sounding. These regional surveys have been supported over smaller geographic areas by detailed on-ice sea ice and snow thickness measurements, by on-ice EM induction transects of sea ice thickness, and by under-ice oceanographic observations that track the heat deficit and mixing in the upper ocean at selected sites.
Wave Propagation in Frazil/Pancake Ice: The Beaufort Sea MIZ during Fall 2015

Peter Wadhams¹ (pw11@cam.ac.uk), Giuseppe Aulicino¹, Flavio Parmiggiani²
¹Università Politecnica delle Marche, Ancona, Italy, ²CNR-ISAC, Bologna, Italy

The wave frequency and the physical properties of the ice cover determine the way in which waves propagate in ice. Large floes interact with waves via a scattering process which results in an exponential decay of incoming wave energy with distance. Very small floes, like pancake ice where the individual cakes may be less than 3 m in diameter, interact in a different manner; they behave like a continuum and can be considered as a very viscous fluid which not only causes decay of the waves but also causes them to propagate with a different dispersion relation. A careful analysis of in situ measurements, collected in the Beaufort Sea during fall 2015 through the use of directional wave buoys, has allowed us to examine attenuation rates, spectral spread rates and anomalous dispersion for different ice conditions met in the MIZ during several in situ experiments. The buoys deployments lasted 1-3 days temporally and spanned up to 100 km spatially. After inter-calibrating the buoys, the vertical displacement (heave) time series for the buoys was hence analyzed for calculation of the scalar wave energy spectra and bulk wave parameters (i.e., significant wave height, dominant wave period). As expected, our measurements show that waves play an important role in inhibiting the fall freeze-up of the Beaufort Sea, especially near the ice edge facing the prevailing easterly winds. Results on the attenuation of waves in different MIZ conditions are presented and discussed.

PIPERS: Overview of the 2017 Winter Cruise in the Ross Sea Pack Ice

Stephen Ackley¹ (stephen.ackley@utsa.edu), Sharon Stammerjohn², Ted Maksym³, Peter Guest⁴, John Cassano⁵
¹Univ of Texas San Antonio, Snow and Ice Geophysics Laboratory, San Antonio, United States, ²Univ of Colorado, Boulder, United States, ³Woods Hole Oceanographic Institution (WHOI), Woods Hole, United States, ⁴Naval Postgraduate School, Monterey, United States

The PIPERS cruise on N. B. Palmer into the early winter Ross Sea took place between April 11 and June 14 2017. The keystone project was to investigate the Atmosphere-Ice-Ocean interaction in the Terra Nova Bay and Ross Ice Shelf coastal polynyas. The cruise however involved multidisciplinary and complementary activities that were conducted in several different phases of the cruise. These activities were: ARGO and SOCCOM Float deployments north of the sea ice; marginal ice zone(MIZ) wave buoy deployments and sampling activities; along track sampling for physical oceanography, trace metals, and trace and noble gasses; ice thickness, roughness and physical property sampling at ice stations; gas fluxes (CO2, DMS, Methane) and sea ice biogeochemistry sampling at ice stations and in polynyas; boundary layer profiling using drone aircraft and met towers at ice stations; and atmosphere, ice and ocean investigations in the coastal polynyas. An overview of some of the newer technologies used on the cruise and how measurements were coordinated will be described here for these multiple phases of the cruise. Other presentations will be identified for specific details and results.
The PIPERS (Polynyas, Ice Production and seasonal Evolution in the Ross Sea) project conducted a research expedition to the southwestern Ross Sea aboard the RVIB Palmer during April-June 2017. Its main objective was to assess the local/large-scale controls on sea ice production, water mass transformation, and carbon/trace metal inventories during an autumn-winter transition. Between 1979 and 2015 the Ross Sea was notable for showing strong positive sea ice trends in all seasons (strongest in autumn and spring). The PIPERS expedition however took place prior to the lowest austral summer sea ice extent ever observed in the Ross Sea since 1979. This anomalous 2017 summer season followed record-breaking anomalies that first emerged the preceding winter-spring of 2016. Subsequently, during the autumn of 2017, the ice edge was slow to recover during March-April, but by late May, the ice edge east of ~165W finally reached its climatological location, while the ice edge between 165E to 165W remained anomalously south (by ~240km). This ice edge anomaly then shifted eastward during winter-spring 2017. To help explain these anomalous sea ice conditions, air-sea-ice and ice-climate interactions leading up to and during the PIPERS cruise will be described and discussed. These regional analyses will then be compared to the ship-based observations acquired during PIPERS to help validate and distinguish local/large-scale controls on sea ice production and thickness evolution.
Variability of Sea Ice Production in Ross Ice Shelf Polynya

Xi Zhao¹ (xi.zhao@whu.edu.cn), Xiaoping Pang¹, Zian Cheng¹
¹Wuhan University, Chinese Antarctic Center of Surveying and Mapping, Wuhan, China

The Ross Ice Shelf Polynya (RISP) has the highest sea ice production in the Southern Ocean. We calculated sea ice production of RISP from 2003 to 2015 by a thermodynamical model based on sea ice concentration derived from AMSRE, SSMIS and AMSR2, and ERA-Interim meteorological data. The result of ice production model is sensitive to parameter variation. The value of the parameters such as the latent heat of sea ice fusion and the bulk transfer coefficients have a great impact on the results of the model. When different parameter value are chosen, the ice production results vary as much as 46%. The wintertime total ice productions of RISP for 2003-2015 range 164-313 km³ with an average of 219 km³, showing no obvious temporal trend. The ocean surface produces ice at a high rate within the distance of 20-30 km from the ice shelf front. In most high production areas, the ice production significantly increases. Some local regions show a contrarily significant decreasing trend as a result of ice shelf expansion and iceberg events. The monthly total RISP ice production ranges from 14 to 76 km³, showing substantial fluctuations in each month during 2003-2015. The seasonal variation of each year also shows substantial fluctuations. Finally, the ice production by RISP is related to sea ice extent in Ross sea section and its contributions to the increasing trend are discussed.
Observing the Stratosphere at South Pole with High-energy Muons in IceCube

Serap Tilav\textsuperscript{1} (tilav@udel.edu)
\textsuperscript{1}University of Delaware, Physics and Astronomy, Newark, DE, United States

The IceCube Neutrino Observatory, located at the geographical South Pole, records high-energy muons at depths of 1450-2450m in the Antarctic ice. While the sensors look for rare astrophysical neutrinos as signal, downgoing muons with energies above 400 GeV are able to penetrate and trigger the detector at a rate of 2.15 kHz. The bulk of the downgoing muons are created by cosmic ray interactions in the lower stratosphere and their rate best correlates with the temperature variations around 50-150 hPa (12-20 km) layers. Here we report on the observation of both seasonal modulation of the rates and the short term correlations with the stratospheric temperatures.

\(^1\)NASA Langley Research Center, Science Directorate, Atmospheric Composition Branch, Hampton, United States, \(^2\)Science Systems and Applications, Inc., Hampton, United States, \(^3\)Forschungszentrum Jülich, Jülich, Germany, \(^4\)ETH Zurich, Zurich, Switzerland, \(^5\)Karlsruhe Institute of Technology, IMK, Karlsruhe, Germany, \(^6\)Jet Propulsion Laboratory, California Institute of Technology, Pasadena, United States, \(^7\)Australian Antarctic Division, Kingston, Australia, \(^8\)CNR-ISAC, Rome, Italy, \(^9\)University of Wyoming, Laramie, United States, \(^10\)Max-Planck-Institute for Chemistry, Mainz, Germany

After more than three decades of research, the role of polar stratospheric clouds (PSCs) in stratospheric ozone depletion is well established. However, important questions remain unanswered that have limited our understanding of PSC processes and how to accurately represent them in global models, calling into question our prognostic capabilities for future ozone loss in a changing climate. A more complete picture of PSC processes on vortex-wide scales is emerging from a suite of contemporary satellite missions: the Michelson Interferometer for Passive Atmospheric Sounding (MIPAS) on Envisat (2002-2012), the Microwave Limb Sounder (MLS) on Aura (2004-present), and the Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) on CALIPSO (2006-present). These datasets have motivated numerous research activities that both extend and challenge our present knowledge of PSC processes and modeling capabilities. The SPARC PSC initiative was organized in January 2015 to address key questions related to PSCs and their representation in global models with the following main objectives: identify key PSC parameters required by global models; identify strengths and limitations of the PSC datasets; define a methodology to obtain the key PSC properties required by models from the observational datasets; develop a state of the art PSC climatology; and identify remaining open science questions. In this presentation, we describe the PSCI activities, key findings, and remaining open questions.
The MIPAS instrument onboard ESA’s Envisat satellite operated from July 2002 until April 2012. The infrared limb emission measurements represent a unique dataset of day- and nighttime observations of polar stratospheric clouds (PSC) up to both poles. The cloud detection sensitivity is comparable to spaceborne lidars like the CALIOP instrument on the CALIPSO satellite (operating since June 2006). Both instruments allow the differentiation of PSC types, like solid particles of ice and nitric acid trihydrate (NAT), as well as liquid droplets of super-cooled ternary solution (STS). From the MIPAS and CALIOP measurements an unprecedented database PSC type observations is now available for validation and improvement of PSC schemes in chemistry transport and chemistry-climate models for a better predictability of future polar ozone loss in a changing climate.

The spatial, intra-seasonal, and inter-annual variation in the PSC type occurrence have been analysed for MIPAS and compared to CALIOP as well as model results. Key parameters such as Volume and Area PSC, frequently used as a proxy for ozone depletion, have been investigated in comparison with model results of the Chemical Lagrangian Model for the Stratosphere (CLaMS). Finally, an analysis of mountain wave (MW) induced formation of NAT and ice clouds based on measurements of the nadir looking AIRS instrument and the MIPAS climatology - focusing on both hemispheres - will be presented.
To understand better the effects of changing emissions, possibly changing transport pathways and chemistry in a rapidly changing Arctic atmospheric environment, consistent observations of key species for a duration preceding and spanning our current time period are invaluable. Since the late 1990's observations have been taken in the Arctic at several NDACC sites (Network for the Detection of Atmospheric Composition Change). These FTIR (Fourier Transform Infra-Red) instruments that pass through a process of intercomparison to maximize consistency of spectral data and retrievals, routinely acquire spectra for many species. The remotely sensed vertical distributions provide trends and a measure of variability of species in both the tropospheric and stratospheric and aid in evaluating transport and chemistry processes. In this presentation, we will discuss trends in trace species and focus on carbonyl sulphide a key precursor to the stratospheric sulphate aerosol layer with highly variable sources in a changing Arctic.
Analysis of Middle Atmospheric H2O and O3 Measurements at Ny-Ålesund, Svalbard

Franziska Schranz¹ (franziska.schranz@iap.unibe.ch), Brigitte Tschanz¹, Niklaus Kämpfer¹
¹University of Bern / Institute of Applied Physics, Bern, Switzerland

The ground based ozone and water vapour radiometers GROMOS-C and MIAWARA-C have been located at the Arctic research station AWIPEV at Ny-Ålesund, Svalbard (79°N/12°E) since September 2015. Both radiometers were built at the University of Bern, Switzerland and are specially designed for campaigns. The instruments measure the vertical distribution of ozone and water vapour in the middle atmosphere with a high time resolution and under most weather conditions. GROMOS-C provides hourly ozone profiles whereas for MIAWARA-C a resolution of 2-4 hours is realistic, depending on the atmospheric opacity. The unique datasets from these instruments are used to study dynamical events and the chemistry of ozone and water vapour in the middle atmosphere. We present an overview of the data from two years with characteristic events in summer and winter such as effects of sudden stratospheric warmings or the tertiary ozone layer. Special emphasis is given to the investigation of the link between ozone and water vapour concentrations in the upper stratosphere and lower mesosphere. The specified dynamics version of the Whole Atmosphere Community Climate Model (SD-WACCM) is used to support this investigation.
Ground-based measurements provide critical data for the validation of satellite retrievals of atmospheric trace gases and for the assessment of long-term stability of these measurements. As of February 2018, the Canadian-led Atmospheric Chemistry Experiment (ACE) satellite mission has been making measurements of the Earth’s atmosphere for nearly fourteen years and Canada’s Optical Spectrograph and InfraRed Imager System (OSIRIS) instrument on the Odin satellite has been operating for sixteen years. As ACE and OSIRIS operations have extended beyond their planned two-year missions, there is an ongoing need to validate the trace gas profiles for the satellite instruments.

To this end, fifteen Canadian Arctic ACE/OSIRIS Validation Campaigns have been conducted during the spring period (February - April in 2004 - 2018) at the Polar Environment Atmospheric Research Laboratory (PEARL) in Eureka, Nunavut (80N, 86W). The spring period coincides with the most chemically active time of year in the Arctic, as well as a significant number of satellite overpasses. A suite of as many as 12 ground-based instruments, as well as frequent balloon-borne ozonesonde and radiosonde launches, have been used in each campaign. This presentation will focus on an overview of the measurements made by the ground-based, balloon-borne and satellite-borne instruments during the recent ACE/OSIRIS Arctic Validation campaigns and highlight how these have been used for satellite validation.
Wave-ice-Ocean Interactions during Storm-induced Sea Ice Breakup

Lucia Hosekova\(^1\) (l.hosekova@reading.ac.uk), Yevgeny Aksenov\(^2\), Stefanie Rynders\(^2\), Andrew Coward\(^2\)

\(^1\)University of Reading, Department of Meteorology, Reading, United Kingdom, \(^2\)National Oceanography Centre, Southampton, United Kingdom

The Marginal Ice Zone (MIZ), an area of transition between open ocean and sea ice is characterized by highly fragmented ice cover and strong temporal and spacial variability. Over the last three decades, it has been undergoing dramatic expansion in the Arctic due to sea ice retreat and increased wave activity. We present a model development which implements surface ocean wave effects into global ocean model NEMO and sea ice model CICE to account for a number of physical processes specific to the MIZ, in particular sea ice breakup due to waves and the effect of floe size distribution on lateral melting of sea ice. We perform high resolution model studies of recently documented large storm events in polar areas and investigate the impact of waves on both sea ice and upper ocean, identifying potential mechanisms for momentum and heat exchange between waves, ocean, sea ice and atmosphere following periods of enhanced wave activity.
Bridging the Scales in Sea Ice Deformation for Sea Ice Damaged by Winter Storms

Polona Itkin¹ (polona.itkin@npolar.no), Annu Oikkonen², Gunnar Spreen³, Jari Haapala²
¹Norwegian Polar Institute, Fram Centre, Tromsø, Norway, ²Finnish Meteorological Institute, Helsinki, Finland, ³University of Bremen, Bremen, Germany

In the changing Arctic where the sea ice is getting thinner and at the same time moving faster, also ice deformation processes are increasing. The magnitude of deformation rates are however hard to compare as they depend on spatial and temporal scales of the measurements. Here we present results from the N-ICE2015, an expedition to the ice covered region north of Svalbard in the first half of 2015. The deformation rates we measured on N-ICE2015 by buoy arrays were one of the highest ever recorded in the Arctic at similar scales (10-100 km at 1-3 hour interval). We also measured the deformation at shorter scales (100 m-5 km at 10 min interval) from the ship radar images. To bridge between the spatial scales we will supplement these two deformation estimates by deformation rates from satellite remote sensing (SAR) images based on sea ice drift (1-500 km at 1 day interval). These three datasets will allow us to quantify the scaling law relationships over a large range of spatial and temporal scales, and help us to estimate the extent and consequences of the major deformation events observed. During N-ICE2015 the sea ice in the Atlantic sector of the Arctic was impacted by several powerful storms. These storms penetrated deep into the pack ice and permanently damaged the ice. We will use the deformation rates obtained from SAR sea ice drift to estimate the importance of the ice age and distance to the ice edge for deformation and healing processes of sea ice.
Impact of Severe Storm Conditions on the Marginal Ice Zone in the Southern Ocean

Marcello Vichi1 (marcello.vichi@uct.ac.za), Sebastian Skatulla2, Keith Machutchon2, Ehike de Jong3, Clare Eayrs4, Jhon Mojica Moncada4, David Holland5, Alessandro Toffoli6, Alberto Alberello6, Miguel Onorato7, Clinton Saunders8, Anriette Bekker8, Warren Joubert9

The winter marginal ice zone (MIZ) in the Southern Ocean is one of the least explored regions of the world ocean, where synoptic weather, sea-ice and oceanic processes are more tightly interlinked. Remote sensing observations have revealed the large variability of the Southern Ocean sea ice over the past 20 years, and the increased spatial resolution of sensors now allow to capture synoptic patterns in the ice edge. The actual reliability of these data is however not known because of the very few in situ observations particularly during the winter period. This contribution reports on a process study conducted in July 2017 in the Indian Ocean sector, aimed at studying the winter MIZ, the relation with met-ocean conditions and how they impact navigation performances. The response of the MIZ to a large-scale storm was documented by means of sea-ice observations, ice-drift buoys, wave cameras and the ship-response to vibrations. The sea ice was composed of pancakes of varying dimensions that did not show compaction for more than 150 km into the MIZ. The preliminary results hint at a coherent large-scale response of the pancake ice field to wind and swell, with drifts of up to 0.8 m/s, more typical to brash ice conditions rather than the observed semi-consolidated surface. The results are analysed in conjunction with atmospheric reanalyses data and ocean forecasting models to provide insights on the process dynamics and improve future polar predictions in the southern hemisphere.
Wave-induced Floe-floe Collisions and Ocean-sea Ice Momentum Transfer

Agnieszka Herman1 (oceagah@ug.edu.pl)

1University of Gdansk, Institute of Oceanography, Gdynia, Poland

In the marginal ice zone (MIZ), waves entering from the open ocean often induce collisions between neighboring ice floes. Due to limited observational data, it is not known to what degree wave-induced collisions contribute to the stress within the ice and to the dissipation of wave energy in MIZ. In this paper, wave-induced collisions between ice floes are analyzed with a numerical, discrete-element model. The model simulates surge motion of an ensemble of ice floes on a prescribed wave field. It is shown that the collision pattern depends on ice concentration, wave steepness, floe size relative to wavelength, floe-size distribution, as well as the restitution coefficient and drag between the ocean and the ice. For relatively large ice floes, the results are very sensitive to the formulation of wave forcing and ice-water drag. If the forcing correctly takes into account floe size relative to the wavelength, the model accurately reproduces surge RAOs of single floes, as well as accelerations and forces of floes impacting a structure. The modelling results are used to estimate the granular temperature, as well as covariance between ice floes’ velocities and forces acting on them for a wide range of conditions. This is crucial for developing parameterizations of source terms related to wave-induced collisions in the granular-temperature evolution equation used in large-scale sea ice models.
Waves, Turbulence, and Thin Sea Ice at the Autumn Air-Ice-Ocean Interface

Madison Smith¹ (mmsmith@uw.edu), Jim Thomson¹, Lettie Roach²
¹University of Washington, Applied Physics Lab, Seattle, United States, ²National Institute of Water and Atmospheric Research (NIWA), Wellington, New Zealand

Winds, waves, and turbulent mixing at the air-ice-ocean interface set the exchange of momentum, heat, and gases between the ocean and atmosphere. Surface waves and associated near-surface turbulence are particularly tightly coupled in thin, new ice. We present observations made from drifting buoys in autumn pancake sea ice in the Arctic and Antarctic during Sea State and PIPERS programs, respectively. Coincident measurements of sea ice, wind, waves, and turbulence from the buoys allow quantification of feedbacks between ice growth, attenuation of waves, and suppression of turbulence. Thin ice attenuates waves from open water conditions, preferentially attenuating high frequency waves. Thus, the net effect of ice is to increase the dominant wave period and length. We find that floe diameter throughout the growth process is proportional to the ratio of wavelength squared to wave height (known as the tensile failure mode), indicative of a feedback between ice growth and wave attenuation. Near-surface wave-breaking turbulence is simultaneously reduced, due to decreased wind input transfer velocity. Thin ice also has the potential to increase turbulence below the surface due to shear between the ice and ocean. As air-ocean production of turbulence weakens, the ice-ocean interface becomes the dominant source for shallow turbulence. Our results suggest parameters for estimating near-surface turbulence in thin pancake and frazil ice, which are ubiquitous in autumn marginal ice zones.
Wave-ice Interactions during the Antarctic Circumnavigation Expedition

Alberto Alberello¹, Luke Bennetts², Susanne Lehner³, Egbert Schwarz³, Keith MacHutchon⁴, Konny Reichert¹, Alessandro Toffoli¹ (alessandro.toffoli@unimelb.edu.au)
¹The University of Melbourne, Parkville, Australia, ²University of Adelaide, Adelaide, Australia, ³German Aerospace Center (DLR), Hamburg, Germany, ⁴University of Cape Town, Cape Town, South Africa

Southern Ocean waves play a crucial role in global climate system. Besides regulating energy exchanges in the upper ocean via turbulent mixing, waves influence sea ice formation and its break up. However, the underlying physics involved in wave-ice interactions poorly understood. The rate of wave energy dissipation and the intensity of the wave induced drift are still uncertain. During the Antarctic Circumnavigation Expedition waves and their interaction with sea ice was investigated, with the wave climate monitored via an onboard wave radar WaMoS II that provided the full two-dimensional wave spectrum and the surface current. Concurrently, satellite images overlapped with some of the cruise track allowing a cross-comparison of onboard and remote wave measurements. Global altimeter and SAR wave mode data as well as Sentinel-1 and TerraSAR-X scenes were used. Compared to onboard measurements, remote sensing provides information on the metocean conditions at a much larger areal scale. Here, we examine data collected during the crossing of an ice band between Balleny Islands and the Mertz Glacier when a swell was coming from an easterly direction. The wave energy dissipation is found to be frequency dependent, i.e. the ice cover acts as band pass filter where the maximum dissipation occurs at frequency comparable with the ice floe length, corroborating previous laboratory experiments. Moreover, the wave-induced ice drift is found to exceed predictions based on the Stokes' drift.
Deep Scattering Layers, the Feeding Ground of Antarctic Deep-diving Predators

Camille Le Guen1 (cmmalg@st-andrews.ac.uk), Roland Proud1, Matteo Bernasconi2, Lars Boehme3, Inigo Everson3, Paul Fernandes4, Joshua Lawrence5, Richard Sherley5, Andrew Brierley1

1University of St. Andrews, School of Biology, St. Andrews, United Kingdom, 2Institute of Marine Research, Bergen, Norway, 3University of East Anglia, Norwich, United Kingdom, 4University of Aberdeen, Aberdeen, United Kingdom, 5University of Exeter, Exeter, United Kingdom

During the day, myctophids (lanternfish), krill, squid and jellyfish form layer-like aggregations in the mesopelagic zone (200-1000m deep) to reduce exposure to visual predators. These layers can be detected by echosounders and are known as deep scattering layers (DSLs). Myctophids are very abundant in DSLs and offer great potential as a protein source for human consumption, but play a key trophic role as food for predators. In the framework of the Commission for the Conservation of Antarctic Marine Living Resources, pressing management issues arise because myctophids make up to 90% of the diet of deep-diving air-breathing predators such as King Penguins (Aptenodytes patagonicus, dive depth >350m) and Southern Elephant Seals (Mirounga leonina, dive depth >1500m). More data on DSLs are needed to develop a biogeographic zonation and understand likely future responses to climate change before any large-scale exploitation begins. A unique data set of DSL geographic variability in depth and echo-intensity (proxy for biomass) throughout the Southern Ocean was collected during the Antarctic Circumnavigation Expedition (ACE), along with CTD data and satellite remote sensing. We also collected position, depth and accelerometry data from predators off the coasts of South Georgia and Kerguelen as the ACE vessel approached each island. The tracking data are co-located with the DSL landscape to better understand predator-prey interactions and inform fisheries and conservation management.
Climate Change and Polar Range Expansions: Could Cuttlefish Cross the Arctic?

Jose Xavier\textsuperscript{1,2} (jccx@cantab.net), Lloyd Peck\textsuperscript{2}, Peter Fretwell\textsuperscript{2}, John Turner\textsuperscript{2}

\textsuperscript{1}MARE, University of Coimbra, Life Sciences, Coimbra, Portugal; \textsuperscript{2}British Antarctic Survey, Cambridge, United Kingdom

Climate change can have major effects on the distribution of species. In marine ecosystems, the cold waters of the Arctic have restricted warmer water species from crossing between Eurasia and North America. However, with Arctic waters becoming warmer, various marine species have expanded their distribution. Cuttlefish are fast-growing, voracious predators and are absent in American waters. The European cuttlefish \textit{Sepia officinalis} is the most northerly distributed cuttlefish, with potential to expand its range and cross to the American continent. Our climate model predictions suggest that the \textit{S. officinalis} could potentially reach American shores, by 2300 via the north Atlantic with medium mitigation of greenhouse gas concentrations; we predict that adult dispersal of cuttlefish across the Atlantic sector would require a migration distance of over 1400 km at depths below 200 m and temperatures above 7 °C (temperature below which cuttlefish cannot maintain routine metabolic processes physiologically). If they reach American shores they could have large impacts on coastal marine ecosystems, due to their wide diet (e.g. diet covers many shallow-water crustacean and fish species) and its potential as prey, and due to their short life-history strategy of “live fast, die young”. Discussions to how cuttlefish may also be present in the Antarctic in the future, and their possible impacts in Antarctic marine coastal ecosystems is discussed.
Feed like a Toothfish: Foraging Behavior from In Situ and Ex Situ Analysis

Laura Ghigliotti1 (laura.ghigliotti@ge.ismar.cnr.it), Simonepietro Canese2, Erica Carlig1, Davide Di Blasi1, Sara Ferrando3, Lorenzo Gallus3, Steve Parker4, Eva Pisano1, Marino Vacchi1
1National Research Council of Italy, Institute of Marine Sciences (ISMAR), Genoa, Italy, 2Istituto Superiore per la Ricerca e la Protezione Ambientale (ISPRA), Rome, Italy, 3University of Genova, Genoa, Italy, 4National Institute of Water and Atmospheric Research (NIWA), Nelson, New Zealand

In the Ross Sea, the world’s largest Marine Protected Area has recently been created. In this area, the commercially harvested Antarctic toothfish Dissostichus mawsoni, plays a key ecological role as the piscine apex predator. Although trophic interactions have been well documented on the continental slope and northern seamounts in the region, observations from sea-ice covered coastal margin areas are much more limited.

Our aim is to better describe Antarctic toothfish natural history by studying the feeding ecology of this species in sea-ice covered areas.

During field activities, conducted in November from the fast ice at McMurdo Sound (2015) and Terra Nova Bay (2016), sampling methods, based on vertical longline fishing, were combined with low impact visual sampling techniques, relying on the use of Baited Underwater Video cameras (BUVs).

The diet and age structure of the Antarctic toothfish sampled in sea ice covered areas, as well as hypotheses on the feeding strategies emerging from the combination of sensory system information, feeding structure morphology data and behavioral records, are presented.
Can Isoscapes of Mesopelagic Fish Predict Top Predator Hotspots?

Andrea Walters1 (andrea.walters@utas.edu.au), Rowan Trebilco2, Sophie Bestley1, Ben Raymond3, Andy Revill4, Mark A. Hindell1, Mary-Anne Lea1, Jess Melbourne-Thomas2,3, Andrew Constable2,3

1University of Tasmania, Institute for Marine and Antarctic Studies, Hobart, Australia, 2Antarctic Climate and Ecosystems Cooperative Research Centre, University of Tasmania, Hobart, Australia, 3Australian Antarctic Division, Hobart, Australia, 4Commonwealth Scientific and Industrial Research Organisation (CSIRO), Hobart, Australia

Assessment of marine predator habitat use can reveal geographic hotspots of foraging activity, and when linked with diet information can provide an improved understanding of biological processes and predator dependence on trophic resources. Mesopelagic myctophid fish, as a key trophic link between the mesozooplankton and higher trophic levels (seabirds, penguins and marine mammals), are expected to be a good indicator of biological hotspots in oceanic waters. To explore this idea we developed spatially-resolved isoscapes using Southern Ocean mesopelagic fish populations. Fish were sampled along survey transects from the Antarctic shelf to BANZARE Bank and waters to the west and east during January to February 2016. The wide spatial range aimed to account for variability in the nutrient sources and oceanographic conditions in the southern Kerguelen Plateau region. The mesopelagic distributions were analysed in relation to the spatial distribution of flying seabirds and subsurface feeders (e.g. seals, penguins) based on telemetry data. We investigated multi-species spatial overlap areas and examined the extent to which isotope mapping of prey distributions can be used to identify important oceanic areas for marine predators in the southern Indian Ocean. This integrative approach can provide important insights into the structure and function of Southern Ocean ecosystems, and aid large-scale efforts to identify areas of ecological significance for marine seabirds and mammals.
Range Shifts in Arctic and Antarctic Zooplankton: The Role of Themisto Amphipods

Charlotte Havermans1,2 (charlotte.havermans@awi.de), Wilhelm Hagen1, Christoph Held2, Holger Auel1
1University of Bremen/BreMarE, Marine Zoology, Bremen, Germany, 2Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany

Both the Arctic and Southern Ocean, in particular the southwest Atlantic sector, are experiencing rapid environmental changes. In the southwest Atlantic sector of the Southern Ocean, a long-term trend of density changes of key pelagic species has been noted over the last decades. A decline in Antarctic krill is hypothesized, whilst salps are on the rise and shifting their distribution poleward. A similar poleward expansion is anticipated for a third key player, the amphipod crustacean Themisto gaudichaudii, leading to an increasing overlap of the distributions of these three species. In Arctic waters, two congeneric amphipod species co-exist: T. libellula, a genuine Arctic species and T. abyssorum, considered sub-Arctic boreal. Despite their overlapping distributions, the two species seem to occupy distinct ecological niches and are preyed upon by different predators. Due to the ongoing Atlantification of the Arctic, a range expansion of T. abyssorum concomitant with a retraction of T. libellula’s range are very likely to occur. Due to major knowledge gaps in the ecology, biology and genetic connectivity of Themisto species, the consequences of these shifts for food web structures and biogeochemical cycles remain largely unexplored. In this context, we carried out a comparative study of Themisto populations at both poles. Their distribution, genetic and trophic connectivity were investigated with population genetics, molecular diet analyses and feeding experiments.
Drivers of Jellyfish Diversity, Demography and Distribution in European Arctic

Maciej Mańko¹ (mmanko@ug.edu.pl), Marta Głuchowska², Agata Weydmann¹

¹Institut of Oceanography, Department of Marine Plankton Research, Gdynia, Poland, ²Institute of Oceanology of the Polish Academy of Sciences, Sopot, Poland

Jellyfish, here as pelagic ctenophores and cnidarians, are increasingly important for the functioning of marine ecosystems worldwide. They feed on preys ranging from unicellular protists to large fish, simultaneously, in spite of their relatively low energy density, they also constitute a prey of choice for numerous predators even as large as cods or seabirds. Although jellyfish are undoubtedly relevant at the global scale, still little is known about them in polar areas, especially with regard to factors affecting their spatially and vertically structured biodiversity and population structure.

To elucidate the role of jellyfish in the European Arctic, we have characterized their diversity, size structure and demography in stratified vertical samples (1000 m to the surface) collected in 2012 from the two latitudinal sections in the Fram Strait, a crucial pathway for warm and biologically rich Atlantic waters to the Arctic. Overall, we have identified 13 taxa, with Aglantha digitale and Dimophyes arctica being the most numerous.

We have then contrasted our data on jellyfish with both environmental (salinity, temperature, depth) and biotic (descriptors of whole plankton community, chlorophyll a) ecosystem characteristics using numerical ecology tools to elucidate how these factors shape jellyfish diversity and distribution in the European Arctic.
Atmosphere-surface Energy Budget Process Relationships over Central Greenland

Matthew Shupe\textsuperscript{1,2} (matthew.shupe@noaa.gov), Nathaniel Miller\textsuperscript{1,2}, Christopher Cox\textsuperscript{1,2}, Ola Persson\textsuperscript{1,2}
\textsuperscript{1}University of Colorado Boulder, CIRES, Boulder, United States, \textsuperscript{2}NOAA Earth System Research Laboratory, Boulder, United States

The Greenland Ice Sheet (GIS) plays important roles in global climate, impacting sea-level rise, circulation patterns, and potentially the ocean thermohaline circulation. Variability in the GIS mass budget results from numerous processes including surface melt, runoff and precipitation. In the context of a warming Arctic, surface melt is increasing dramatically, making it essential to understand key processes that control variability in surface temperature and melt. The surface energy budget, comprised of radiative, turbulent, and conductive heat fluxes, controls surface temperature variability. To represent surface temperature and melt in current and future climates, numerical models must accurately represent the surface energy budget, including the partitioning of energy into individual terms and the key atmospheric drivers. This presentation draws on a comprehensive set of surface and atmosphere measurements made at Summit, Greenland to examine the surface energy budget. Changes in surface radiation, largely driven by the solar cycle and clouds, elicit responses in the surface temperature, turbulent sensible and latent heat fluxes, and conductive heat flux. Relationships are developed that relate radiative forcing terms and responding terms as they manifest over a full annual cycle. These relationships are then used to evaluate how surface energy budget processes are represented in model and reanalysis products, including ERA-Interim, CFSv2, and CESM.
On the Clear-sky Cooling during Polar Night over the Sea Ice in the Arctic

Dmitry Chechin¹ (dmitry.chechin@awi.de), Christof Lüpkes¹, Irina Makhotina²
¹Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, ²Arctic and Antarctic Research Institute, St. Petersburg, Russian Federation

We present a simple analytical model of the atmospheric boundary layer (ABL) over the sea ice during polar night in clear-sky conditions. The model represents coupling between the ABL and sea ice in the presence of leads. Both steady-state and time-dependent analytical solutions are obtained. The solutions describe air and surface temperatures as functions of many parameters among which are wind speed and sea ice concentration. In particular, analytical solutions describe the transition from coupled to decoupled ABL state when wind speed is decreasing. The model demonstrates the warming effect of leads and shows that leads might contribute to decoupling over the ice. Analytical solutions are compared to those of a more complex numerical single-column atmospheric model coupled to the thermodynamic model of the sea ice. Also, observations from several recent Russian „North Pole“ drifting stations are used to demonstrate the sensitivity of the thermal regime over the sea ice to wind speed. The observations show that stronger wind speeds are associated with warmer temperatures, while for weak winds decoupling often occurs. Analytical solutions provide several possible explanations of the observed dependency of temperature on wind speed.
We present a polar-oriented evaluation of CNRM-CM6-1, the updated version of the atmosphere-ocean coupled model developed at CNRM (Meteo France/CNRS) and CERFACS to contribute to CMIP6 and YOPP. The nominal horizontal resolution is 150km in the atmosphere and 1° in the ocean. Main evolutions since CMIP5 include a fully new physics in the ARPEGE Climat atmosphere model, the version 3.6 of NEMO ocean model, enhanced vertical resolutions in the atmosphere and the ocean, a revised atmosphere-ocean coupling strategy in the presence of sea ice and revised sea ice parameters in the GELATO sea ice model. The focus is on the representation of the air-ice-ocean interface, including the boundary layers, sea ice and the upper ocean. The evaluation is done in atmosphere-only mode (with a one-dimensional version of the GELATO sea ice model embedded into the SURFEX surface scheme), in coupled mode following the CMIP6 DECK protocol and in seasonal prediction mode using the coupled model initialized with ocean-sea ice reanalyses produced with Mercator Océan. Improvements include reduction of a bias in geopotential heights in both polar regions, a more realistic representation of temperature inversions over ice-covered seas, and overall better simulations of Arctic and Antarctic sea ice in all seasons. Seasonal predictions are used to assess predictive skill, as well as analysing how persisting biases at the air-ice-ocean interface develop from close-to-observed initial conditions.
The Atmospheric Boundary Layer Response to Sea Ice Fragmentation

Marta Wenta¹ (marta.wenta@phdstud.ug.edu.pl), Agnieszka Herman¹
¹University of Gdansk, Institute of Oceanography, Gdynia, Poland

The response of oceanic and atmospheric boundary layer (ABL) to subgrid-scale variations of sea ice properties and fracturing has only recently attracted attention and mostly focused on the mixing occurring in the ocean. Additionally, processes taking place on the level of individual ice floes are not fully understood and therefore not taken into account in mesoscale Numerical Weather Prediction (NWP) models parameterizations. In response to growing need of improving the models performance, a series of high-resolution simulations with Weather Research and Forecasting (WRF) model is performed for different spatial sea ice distributions, ice concentrations and ambient wind speed profiles. The model parameters are set to represent Arctic winter conditions. The results indicate that the structure of ABL is highly sensitive to the spatial distribution of sea ice and open water. With identical ice concentration, considerable variability of several domain-averaged quantities like surface turbulent heat flux or ABL water vapor content for different arrangements of leads and ice floes is found. Furthermore the formation of convective cells is determined. The structure and size of the cells is significantly dependent on the sea ice distribution and wind speed applied to the model. We suggest that NWP models need improvement and new parameterizations of the ABL are necessary. Our study may provide a basis for such development and guidance for the planning of field measurements.
Observations of Strong Gap Flows in the Nares Strait Region (Greenland)

Günther Heinemann¹ (heinemann@uni-trier.de), Clemens Drüe²
¹University of Trier, Environmental Meteorology, Trier, Germany, ²University of Trier, Trier, Germany

The boundary layer structures of gap flows were studied in northwest Greenland during the aircraft-based experiment IKAP PS (Investigation of Katabatic winds and Polish during Summit) in June 2010. The measurements were performed using the research aircraft POLAR 5 of the Alfred Wegener Institute (AWI, Bremerhaven). The aircraft was equipped with a suite of meteorological sensors, including a turbulence measurement system on a nose boom with a sampling rate of 100 Hz.

In the area of the Nares Strait a stable, but fully turbulent boundary layer with strong winds of up to 22 m/s was found during conditions of relatively warm synoptically induced northerly winds through the Nares Strait. Strong surface inversions were present in the lowest 100 m to 200 m. As a consequence of channeling effects a well-pronounced low-level jet (LLJ) system was documented. The channeling process is consistent with gap flow theory and can be shown to occur at the topographic gap between Greenland and Canada represented by the Smith Sound. While the flow through the gap and over the surrounding mountains leads to the lowering of isotropic surfaces and the acceleration of the flow, the strong turbulence associated with the LLJ leads to the development of an internal thermal boundary layer past the gap.
The Iceland Greenland Seas Project: Meteorological Highlights

¹University of East Anglia, School of Environmental Sciences, Norwich, United Kingdom, ²Woods Hole Oceanographic Institution (WHOI), Woods Hole, United States, ³University of Bergen, Bergen, Norway, ⁴University of Toronto, Toronto, Canada, ⁵British Antarctic Survey, Cambridge, United Kingdom, ⁶University of East Anglia, Norwich, United Kingdom, ⁷Icelandic Met Office, Reykjavik, Iceland, ⁸University of Leeds, Leeds, United Kingdom, ⁹Uni Research, Bergen, Norway

A coordinated meteorological and oceanographic field campaign over the Iceland and southern Greenland Seas is scheduled for February and March 2018. The aim being to characterise the atmospheric forcing and the ocean response of coupled atmosphere-ocean processes; in particular cold-air outbreaks in the vicinity of the marginal-ice-zone and their triggering of oceanic heat loss and the generation of dense water masses. We will observe the spatial structure and variability of surface flux fields in the region and the weather systems that dictate these fluxes, through the first meteorological field campaign in the Iceland Sea. This will be done as part of a coupled atmosphere-ocean field campaign in winter 2018 involving a rare wintertime research cruise, airborne observations and a host of ocean and atmosphere observing systems. We will make in situ observations of air-sea interaction processes from several platforms. Here we will present some highlights from the meteorological component of the field campaign - illustrated by observations from some of the research aircraft cases.
Future Emergence of Deep Convection in the Arctic and Impact on the AMOC

Camille Lique\textsuperscript{1} (camille.lique@ifremer.fr), Matthew Thomas\textsuperscript{2}, Helen Johnson\textsuperscript{3}, Yves Plancherel\textsuperscript{3}
\textsuperscript{1}Laboratoire d’Océanographie Physique et Spatiale, IFREMER, Plouzane, France, \textsuperscript{2}Yale, New Haven, United States, \textsuperscript{3}University of Oxford, Oxford, United Kingdom

We investigate the potential for deep Mixed Layer Depths (MLDs) to appear close to the Arctic sea ice edge under a warming climate, using results from present day simulations of two climate models, and also from simulations with a 4 times increase in atmospheric CO\(_2\) levels, representing a future, warmer climate. Under a warming climate, we expect
(i) a reduction of the AMOC,
(ii) a MLD shoaling in the North Atlantic and
(iii) a northward retreat of the sea ice edge.

We document the changes affecting the MLD in the Arctic and the North Atlantic. There is a strong shoaling in the present-day areas of deep convection in the North Atlantic, but also a deepening in the Eurasian Basin, where MLD can episodically reach up to \(\sim1000\) m. The temporal and spatial structures of the changes in ocean surface properties reveal a strong surface warming (linked with the sea ice edge retreat) and a strong salinization (due to Arctic gyre intensification driven by stronger surface stress as the sea ice pack is shrinking). Together, these changes decrease stratification, triggering convective events. A quantitative Lagrangian diagnostic of climate model output allows us to determine where the ML subduction contributes to the AMOC.

For present-day conditions, AMOC main contributors are subduction in the Labrador, Irminger and Greenland Seas. In contrast, in the 4xCO\(_2\) simulations, the AMOC is greatly reduced and subduction in the Arctic and the subtropical gyre contribute significantly to the AMOC.
Ocean Heat Transport Changes Connecting the Midlatitudes to the Arctic

Aleksi Nummelin¹, Camille Li²,³ (camille@uib.no), Paul Hezel²,³
¹Johns Hopkins University, Baltimore, United States, ²University of Bergen, Bergen, Norway, ³Bjerknes Centre for Climate Research, Bergen, Norway

Arctic amplification of global warming has many drivers, including important feedbacks related to changes in sea ice and the vertical structure of the atmosphere. In the ocean, climate models simulate a weakening of the Atlantic Meridional Overturning Circulation and its associated ocean heat transport at midlatitudes, but an increase in the ocean heat transport to the Arctic Ocean. These opposing trends indicate what could appear to be a discrepancy in the reported ocean contribution to Arctic amplification. Here, we clarify how ocean heat transport affects Arctic climate under strong greenhouse warming using a set of the 21st century simulations performed within the Coupled Model Intercomparison Project. The results suggest that subpolar atmosphere-ocean interactions are key to linking midlatitude and Arctic ocean changes: future reductions in subpolar ocean heat loss enhance ocean heat transport to the Arctic Ocean, driving an increase in Arctic Ocean heat content and contributing to the intermodel spread in Arctic amplification. Implications for understanding the rapidly changing Barents Sea ice cover, which has been linked to midlatitude weather extremes, are discussed. Finally, the results caution against extrapolating the forced oceanic signal from the midlatitudes to the Arctic.
Changes in Arctic Hydrological Cycle in a Rapidly Warming Arctic

Hotaek Park¹ (park@jamstec.go.jp), Daqing Yanag², Xiangdong Zhang³
¹JAMSTEC, Yokosuka, Japan, ²Environment Canada, Victoria, Canada, ³University of Alaska Fairbanks, Fairbanks, United States

The decreasing areal extent and thickness of the Arctic sea ice have apparently increased heat and moisture fluxes from the ocean to the atmosphere in particular in autumn and early winter. These changes may locally affect air temperature, moisture, and cloud cover, and in turn remotely cause anomalous weather, such as cold and snowy winters, in the subarctic and mid-latitude regions. As a consequence, changes in the hydrological regime and its thermal conditions may occur. To investigate these changes, statistical analyses have been conducted on various observational records and modeling output. It has been identified that permafrost has warmed due to changes in snow cover in addition to global warming effects. The warmed permafrost was also implicated for the alternation of seasonality, variability, and magnitude of Arctic river discharge, such as an earlier occurrence of spring peak and an increase in the annual discharge. At the same time, the warming climate has also increased river water temperature, resulting in a larger heat flux into the Arctic Ocean when combined with the increased discharge. The increase in heat flux from the northern rivers may have contributed to the recently observed sea ice melt. This presentation will review sea ice-retreat-induced processes driving intensification of Arctic water cycle in a warming climate and evaluate robustness of the previous findings using the latest field observations and modeling experiments.
The influence of Arctic sea ice cover decline on mid-latitude climate has been studied extensively in the light of the drastic sea ice decline of the last decades. However, most previous studies focused on the atmosphere. Here we present results of coupled climate model sensitivity simulations with the Alfred Wegener Institute Climate Model (AWI-CM). We artificially reduced Arctic sea ice in the coupled system with various different methods and investigated the response of the coupled system. Atmospheric responses include an AO minus type large-scale circulation response along with a southward shift of the mid-latitude storm track. In the ocean, the thinner and therefore weaker Arctic sea ice cover leads to an intensified Beaufort Gyre, and with a time lag of 50-80 years to increased outflow through the Fram Strait. Ultimately, the entire Arctic and North Atlantic ocean circulation is intensified leading to an Atlantification of the Barents Sea / Kara Sea. Surprisingly, at least in the investigated time scale of 150 years the influence on the Atlantic Meridional Overturning Circulation (AMOC) is limited.
Continuous measurements of summer Arctic sea ice over the past four decades have revealed a large year-to-year variability superimposed on the negative trend (Stroeve et al. 2014). Excursions from the forced trend, if big enough, could impact mid-latitude weather and climate but the mechanisms behind such linkages remain uncertain. In this study we investigate the winter atmospheric response to summer sea ice anomalies using coupled model experiments based on the CNRM-CM6 high-top model recently developed for CMIP6. 40-member ensemble simulations in which sea ice albedo is reduced from realistic values to the ocean value are run for 15 months, yielding an ice-free state during the first summer after initialization. The atmospheric response to sea ice loss shows a classical polar warming as well as weakened westerlies that promote a negative NAO-like sea level pressure pattern during winter. We present how sea ice loss affects wintertime synoptic variability by looking at the position and strength of the jet stream, the frequency of blocking events and the sinuosity of the flow. The importance of stratospheric pathways in setting the winter atmospheric response is also discussed. Following Screen et al. (2017), we examine the respective contribution of the dynamical and thermodynamical part of the response to sea ice loss and link it with the occurrence of cold extremes over Northern Europe. We assess the robustness of the response by comparing our results to previous studies.
Impacts of Arctic warming on mid-latitude climate and weather have recently been studied extensively. Simulated winter atmospheric circulation response to the Arctic sea ice loss varies among model studies. This makes difficult to understand an observed relationship of northern midlatitudes weather and climate with the Arctic sea ice loss. Recognizing the differences among sea ice concentration (SIC) data due to various sources and algorithm, it became an issue whether or not SIC uncertainties contribute to varying model results. Here we conducted a large ensemble simulation of climate impacts of the Arctic sea ice loss using 18 sea-ice configurations derived from 6 different datasets. Based on large resembles (n=3600) we found that a mean response to the Arctic sea ice loss, while SST being fixed across all runs, is a negative AO-like signal. However, sea ice anomalies in the GIN Seas appear to have a control on amplitude and details of the AO-minus response. We propose a mechanism in which sea ice anomalies in the GIN Seas modulate otherwise a mean negative AO-like response of the BK Seas ice loss by the formation of a blocking high with upscale energy flux from transient eddies. The results imply that
(1) both sea ice coverage in the GIN Seas and North Atlantic SST must be critically evaluated in AGCM and/or coupled experiments, and that
(2) possible structure embedded in variability of air-sea-ice interaction over the GIN Seas must be further quantified.
Svalbard Science Forum: Added Value through Cooperation

Cecilia A. M Sandström1,2 (casa@rcn.no), Helén J. Andersen1,2, Margrete N. S. Keyser1,2, Carina Leander1,2
1Research Council of Norway, Oslo, Norway, 2Svalbard Science Forum, Longyearbyen, Norway

The Svalbard Science Forum (SSF) promotes coordination and collaborative efforts in research activities in Svalbard. Our objective is to contribute to the development of Svalbard as a platform for international research cooperation in the Arctic and enforce Svalbard’s position as a key location in high Arctic research. SSF’s tasks include managing the database “Research in Svalbard” (RiS) which contains information relating to more than 3300 Svalbard related projects. RiS is established in cooperation with the Norwegian Polar Institute and is a valuable source for information on previous, current and future research activities in the region. SSF is always working towards helping both researchers and management and strives to simplify registration of research projects, bookings of logistics and applications to the Governor of Svalbard by offering all services via one portal: the RiS database.

The SSF organises workshops and administers two funding schemes targeted towards the Svalbard research community: Svalbard Strategic Grant and Arctic Field Grant. Svalbard Strategic Grant supports seed money for workshops and collaborative activities where the goal is to enhance international and inter-disciplinary cooperation and/or initiate pilot studies for planning of larger projects with relevance to Svalbard. Arctic Field Grant support costs for fieldwork by students and/or researchers conducting fieldwork in the area of Svalbard and Jan Mayen.
The Forum of Arctic Research Operators (FARO): The First 20 Years

James Drummond¹ (james.drummond@dal.ca), Piotr Glowacki², Jennifer Mercer³, Sergey Priamikov⁴, Hyoung Chul Shin⁵
¹Dalhousie University, Physics and Atmospheric Science, Halifax, Canada, ²Polish Academy of Sciences, Polar and Maritime Research Department, Warsaw, Poland, ³National Science Foundation Foundation, Office of Polar Programs, Alexandria, United States, ⁴Arctic and Antarctic Research Institute of Roshydromet (AARI), Sankt-Peterburg, Russian Federation, ⁵Korea Polar Research Institute, Head, Department of International Cooperation, Yeonsu-gu, Korea, Republic of

The Forum of Arctic Research Operators, FARO, was initiated by 24 operators from 11 countries in August 1998. Now, in 2018, FARO has 20 member countries with Arctic research activities. It acts as an international forum for information exchange, establishment of cooperation and development of new ideas. It aims to encourage and optimize logistics and operational support for scientific research in the Arctic. It is closely associated with the International Arctic Science Committee (IASC) and holds its annual meeting during Arctic Science Summit Week (ASSW).

Over the last 20 years Arctic research has changed in many ways driven by changing needs and stunning changes in technology, but the underlying need for collaboration and information exchange across national boundaries remains critical to the success of research endeavours. This is particularly true when a large infrastructure commitment is needed or many observing sites are involved.

As FARO celebrates 20 years of dialogue and information exchange, we will review the past, consider the present and anticipate the future of international collaborative Arctic research.

Geoscientific research often occurs via community-instigated bursts of activity. Successful attainment of research goals thus requires skilful scientific project management. In addition to usual matching scientific ambitions to limiting resources and on-going coordination, polar science confronts additional challenges. Planning and implementation of polar science projects often involve many uncertainties caused by, for example, unpredictable weather, ocean and sea ice conditions, or large-scale logistical juggling. Large amounts of funding are needed to procure the considerable infrastructure and technical equipment required for interdisciplinary and international polar expeditions; or permissions to enter certain regions must be requested. Assessment of risk is key to successful polar science project management as failure can be extremely costly. There is thus an increasing demand to employ professional project and community managers able to support their colleagues’ operations in the field. Project managers in polar science need to have comprehensive expertise in polar sciences themselves in order to understand requirements, structures and funding schemes that drive interdisciplinary polar research. Polar science community managers must understand the science and the institutional landscapes that polar researchers work within. In this presentation, we provide an overview of specific challenges of project and community management in polar sciences.
Co-designing a European Research Programme and the Lessons Learned along the Way

Kristina Charlotte Baer¹ (kbaer@awi.de), Nicole Biebow¹, Kirsia Latola², Annette Scheepstra³
¹Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, International Cooperation, Bremerhaven, Germany, ²Thule Institute, University of Oulu, Oulu, Finland, ³Arctic Centre, University of Groningen, Groningen, Netherlands

The EU-PolarNet consortium has been tasked by the European Commission to develop an integrated European polar research programme, which is co-designed with the European science community, international partners and relevant polar stakeholders. Well into its fourth year and with one and a half years left to deliver the programme, the consortium can look back on many boundaries it has bridged - to various level of success. This presentation aims at illustrating how the members of EU-PolarNet have navigated the challenges of “transdisciplinarily” identifying polar issues that are of high interest to the European society, and where the outcomes of future research could have social, economic and environmental benefits. It will give insight to how the consortium has successfully managed to get social and natural scientists to cooperate; to its efforts of meaningfully involve stakeholders from indigenous communities, industry and national administrations; and to its objective to provide European policy makers with relevant information on the changes affecting both the Arctic and the Antarctic. Within this framework, different engagement strategies will be presented, which have led to a steep learning curve within the project and which provide valuable lessons learned for researchers seeking to connect polar research across boundaries, including online consultations, European policy briefings and a transdisciplinary polar white paper workshop.
Making the Connection: A Path to Connecting Researchers and Indigenous Peoples

Meredith LaValley¹ (mlavalley@arcus.org), Carolina Behe², John Pearce³
¹Interagency Arctic Research Policy Committee, Anchorage, United States, ²Inuit Circumpolar Council- Alaska, Anchorage, United States, ³USGS, Anchorage, United States

The US Interagency Arctic Research Policy Committee’s (IARPC) Coastal Resilience Collaboration Team (CRCT) has made progress bridging boundaries between researchers and Indigenous Peoples. As an interagency body with a large Federal base but functionally open to all, IARPC is in a unique position to bring Arctic community and Indigenous voices into the discussion of Federal research initiatives. The CRCT is a case study for others interested in bridging boundaries between researchers and Indigenous Arctic communities in order to encourage involvement of Indigenous voices more fully in the discourse on Arctic research. This will take long-term consistent effort. The CRCT has made progress bridging boundaries by (1) devoting time and space for Indigenous Peoples to ask questions and become familiar with IARPC; (2) continuous outreach through Indigenous networks, setting aside specific time for engagement, and including Indigenous speakers regularly in meeting agendas; and (3) listening and taking action. These efforts have resulted in active Indigenous participation in several CRCT meetings and a focus placed on Indigenous concerns. Yet, uncertainty remains about the value to Indigenous Peoples of participation in IARPC. This presentation will demonstrate IARPC’s efforts to bridge the boundary between Federal research efforts, academia, and Indigenous people and explore ways to make further advances. It will include the Federal, academic and Indigenous community perspective.
A Nine-year Emperor Penguin Population Assessment from VHR Satellite Imagery

Peter Fretwell¹ (ptf@bas.ac.uk), Phil Trathan², Rod Downie³
¹British Antarctic Survey, Mapping And Geographic Information Centre, Cambridge, United Kingdom, ²British Antarctic Survey, Ecosystems, Cambridge, United Kingdom, ³WWF, Godalming, United Kingdom

Emperor penguins are a key study species if we are to understand change in the Southern Ocean. Their dependencies upon sea-ice as a breeding platform and as a foraging environment makes them vital for providing insights into this key part of the marine ecosystem. However, the logistical challenges of working in the sea-ice zone means that there are few long term studies for the species. In 2012, the first census of emperor penguins by satellite was published, assessing the major part of the population in a single breeding season. Satellite technology provides an insight into population state irrespective of logistical difficulties with ground-based methods. Since 2009 we have therefore continued to task Very High Resolution (VHR) satellites to take imagery of every colony and now, using the same methodology as our 2009 study, we report on population change at the 16 colonies located between 0° and 90° West. This nine year study of emperor populations shows there is high inter-annual variability at most colonies, highlighting colony movements, colony dispersal and occasional complete breeding failures. Our goal is to relate the population data, at the scale of a colony, group of colonies, or geographic region, to sea-ice, and other environmental conditions to better understand the relationship of emperor penguins with their environment. This will facilitate future models of regional population trajectories for this iconic species.
We developed a novel approach to incorporate the existing Landsat 4, 5, 7, and 8 imagery archive into models of Adélie penguins (Pygoscelis adeliae) distribution and abundance in Antarctica. Building on sensor-specific algorithms to automatically retrieve Landsat pixels classified as guano, we constructed an observation model that accounts for satellite detection failures when converting pixels into nest abundances and their associated observation errors. Using these satellite-derived nest abundances, we refit a recently published Bayesian population dynamics model that includes process and observation error to all known Adélie penguin abundance data (1982-2015) in the Antarctic, covering >95% of their population globally. By comparing models with and without satellite data, we assess how satellite derived nest abundances reduce our uncertainty of population trends at the CCCAMLR sub-area and regional scale. In addition, our analysis of the historical Landsat archive finds that several newly discovered Adélie penguin colonies have been in existence at least as far back as the late 1980s. Based on these results, we believe the Landsat-8 will allow for the automated mapping of Adélie penguin colonies over the life of the Landsat 8 program.
Geographic Structure of Adélie Penguin Populations

David Ainley¹ (dainley@penguinscience.com), Jarrod Santora¹, Michelle LaRue²
¹H.T. Harvey & Associates, Los Gatos, United States, ²University of Minnesota, Minneapolis, United States

We hypothesize that regional spatial organization of Adélie Penguin colonies is dependent on proximity and size of adjacent colonies, availability of coastal, snow-free terrain, and proximity of polynyas and submarine canyons. The hypothesis of Furness & Burkhead (1984) was tested previously before the availability of extensive biologging results to quantify colony foraging areas and when assessments of colony size was a compendium of historical counts. These critical data sets are now available following 20 years of biologging and real-time satellite assessment of colony locations and sizes continent-wide. We collated colony counts from Schwaller et al. (2013) and Lynch and LaRue (2014) and literature on foraging ranges to determine the relative importance of the three factors reviewed above. Indeed, colonies occur in clusters and in general large colonies do not exist adjacent to one another, with a zone of ~180 km being the critical distance, i.e. the outer edge of the foraging area of large colonies. Results are relevant to assessing effects of climate and other factors on penguin population trends, it being necessary to consider entire colony clusters rather than individual colonies.

Intraseasonal Variability of Remotely Sensed Penguin Colony Counts

Osama Mustafa\textsuperscript{1} (osama.mustafa@think-jena.de), Jan Esefeld\textsuperscript{2}, Max Firla\textsuperscript{1}, Martin Senf\textsuperscript{2}, Hans-Ulrich Peter\textsuperscript{2}, Christian Pfeifer\textsuperscript{1}
\textsuperscript{1}ThINK - Thuringian Institute of Sustainability and Climate Protection, Jena, Germany, \textsuperscript{2}Friedrich Schiller University, Institute of Ecology, Jena, Germany

In recent years significant progress was made in the field of satellite based detection of penguin colonies. As single penguin nests cannot be detected reliably, the coverage of the breeding area by guano is used as a proxy for the population size. Due to the frequent cloud coverage at Antarctic coasts, satellite images often cannot be acquired at the desired time related to the breeding phenology of a colony. Aim of this study was to understand how much the extent detected the guano cover changes during the breeding season. We studied the relation between guano coverage and breeding pair numbers in the course of the breeding seasons 2014/15, 2015/16, 2016/17 and 2017/18 in a colony of pygoscelid penguins at Ardley Island (South Shetland Islands). Data from multitemporal remote sensing images of different satellite sensors and from drones were collected as well as data on breeding phenology. Additionally, the colony was mapped on ground for its precise spatial extent and to obtain the exact breeding pair numbers. The analysis of this data shows that the extent of guano coverage in a Pygoscelid penguin colony undergoes significant intraseasonal changes. Hence, the timing of satellite image acquisition matters for the analysis of penguin populations and should be considered during the analysis.
Monitoring Pack-ice Seal Populations from Space with Deep Learning

Bento Collares Gonçalves¹,² (bento.goncalves@stonybrook.edu), Heather Lynch¹,²

¹Stony Brook University, Ecology and Evolution, Stony Brook, United States; ²Institute for Advanced Computational Science, Stony Brook, United States

Antarctic pack-ice seals are a fundamental component of the Southern Ocean (SO) foodweb and, as key krill consumers (CCAMLR, 2008), reflect the spatial and temporal distribution of krill stocks. Despite their importance to Antarctic ecology, mapping Antarctic pack-ice seals at large scale has proven challenging. In this talk, we demonstrate how high-resolution (sub-meter) satellite imagery in concert with automated detection algorithms provides a feasible and cost-efficient alternative to aerial surveys. Our computational pipeline involves two Convolutional Neural Networks (CNNs) trained using TensorFlow (Abadi et al 2016) on a set of manually-labelled images. Our training set contained two seal target classes -

1. seals on pack-ice, and
2. seals on fast-ice - and three additional target classes -
3. empty pack-ice,
4. non-pack-ice empty substrate, and
5. emperor penguin.

Our pipeline is > 95% accurate at classifying images when compared to manual classification of images. In addition to being immediately applicable to ongoing international efforts to monitor pack-ice seals, this approach can be easily adapted for other large-bodied species visible from satellite imagery. Automated “scanning” of the SO for pack-ice seals has the potential to radically expand the scale and frequency at which we can track their populations, and demonstrates the use of deep learning methods that have not been fully exploited for the interpretation of high-resolution satellite imagery.
Environmental Factors Influencing Presence of Weddell Seal Populations

Michelle LaRue¹ (larue010@umn.edu), Leo Salas², Nadav Nur², David Ainley³
¹University of Minnesota, Minneapolis, United States, ²Point Blue Conservation Science, Petaluma, United States, ³HT Harvey and Associates, Los Gatos, United States

Weddell seals are an important indicator of Southern Ocean health, yet are difficult to study at regional- to continental-scales due to their reliance on inaccessible areas of fast ice particularly in the springtime. Here, we combined citizen science with remote sensing to, for the first time, learn about the environmental factors that explain Weddell seal presence across Antarctic regions. We employed the crowd-sourcing platform Tomnod at Digitalglobe to select and host high-resolution satellite imagery (VHR) of the Antarctic coastline during November 2010 and 2011 --- images made available to volunteers, who were asked to categorize maps into seal presence and absence. We then created a 5km grid of seal presence within the extent of fast ice per year, and determined environmental variables that explained presence. We modeled habitat suitability of seals using a generalized linear model (GLM). Our best models included the positive influence of cracks in the fast ice, fast ice width, distance from the continental shelf break, and proximity to emperor penguin colonies, though covariate influence varied across regions. Our results represent an important step toward disentangling the factors that may influence Weddell seal populations around the Antarctic coast.
In general, Caucasus glaciers lost approximately one-third of the area and half of the volume during the 20th century. Prediction of their further degradation in changing environment is a challenging task because rivers fed by glacier melt water provide up to 70% of the total river run-off in the adjacent piedmont territories. Therefore accurate assessment of future glacial run-off is a key problem of sustainable development in the regions where hydrological regime is dependent on glacial run-off. The problem is solved by dynamical modeling of mountain glaciers. It is feasible to focus on several reference glaciers in the region and to further extrapolate modeling results on the whole glaciated area.

We employ a 3D higher-order ice flow model coupled with a surface mass-balance model with treatment of debris-covered areas to perform prognostic numerical experiments aimed at simulation of future dynamics of the reference Djankuat Glacier. It is a typical valley glacier on the northern slope of the main Caucasus chain. It is one of the most well studied glaciers in Russia (and, perhaps, in the World) which has been monitored during the last fifty years.

To validate the model, we utilize observations from the nearest weather stations, as well as flow velocity, radio echo-sounding, accumulation and ablation measurements.

Predictions until the end of the 21st century are performed by downscaling of global climate modeling results according to various climate change scenarios.

Oleg Rybak1,2,3, Elena Rybak1,2, Victor Popovnin4, Polina Morozova5
1Sochi Research Centre, Sochi, Russian Federation, 2Institute of Natural and Technical Systems, Sochi, Russian Federation, 3Vrije Universiteit Brussel, Earth System Sciences & Departement Geografie, Brussels, Belgium, 4Lomonosov Moscow State University, Department of Geography, Moscow, Russian Federation, 5Institute of Geography, Russian Academy of Sciences, Moscow, Russian Federation
Glaciation exists on the territory of Russia for thousands of years. At present mountain glaciers are widespread on continental part of the country where it currently covers the area of about 3,480,000 km$^2$. There are 18 glacier regions. Five out of twelve Atlantic regions (Khibiny, Urals, Putorana, Byrranga and Orulgan) are situated within subarctic latitudes and seven (Caucasus, Altai, Kuznetsk Alatau, East Sayan, Kodar, Barguzin and Baikal Ridges) - within mid-latitudes. Six Pacific glacier regions (Chukotka, Koryak and Kolyma Plateaus, Chersky Mts., Suntar-Hayata Mts., Kamchatka) are located relatively close to the Pacific Ocean within 68° - 62° N.

All recent data available indicate that during the last few decades almost all glaciers in mountain areas were retreating that manifested in decrease of their size, volume and ice mass. The paper presents the review of results of evaluation common factors and regional features of changes in glaciation of continental Russia based on satellite imagery interpretations and field surveys, analysis of the USSR Glaciers Inventory, topographic maps and aerial photographs as well as published research papers.

**Acknowledgements:** The paper includes the results of research project № 0148-2014-0007 of the Research Plan of the Institute of Geography, RAS and research project supported by the Russian Geographical Society (grant number 05/2017/RGS-RFBR).
Regional heterogeneity of glacier elevation and mass changes in high-mountain Asia (HMA) is well known. However, the changes in individual glaciers located in the same region can also be different primarily due to supraglacial features (debris-cover, ponds, lakes and ice cliffs). These features coexist on glacier ablation zones and affect the energy available for ice melt. While few studies have reported similar thinning rates of debris-covered and debris-free glacier areas in HMA, other studies provided evidences of debris insulation and enhanced melt due to supraglacial water bodies and ice cliffs. In order to contribute to this ongoing scientific debate, we derive spatially detailed glacier elevation changes in the Karakoram-Himalaya regions for the period 2000-2012. For this, we employ SRTM and TanDEM-X digital elevation models. Our regional scale altitudinal distribution of elevation change indicates the insulating effects of debris cover, whereas the debris-covered glaciers show two different patterns. First pattern shows maximum thinning upstream indicating the insulating effects of thick debris-cover at lower altitudes. The second pattern shows maximum thinning at the glacier terminus, which is most likely because of enhanced ice melt due to supraglacial water bodies and ice cliffs. To validate our assumptions, we combine debris thickness and the extents of supraglacial ponds of Satopanth Glacier, central Himalaya. These variables were measured in the field.
The Tien Shan and Pamir-Alay are among the largest mountain ranges on earth, hosting more than 15000 glaciers. These glaciers are important water sources for the downstream populations. Most studies focus on region-wide, decadal mass changes and only a few address seasonal/annual mass balance series for Central Asia. Here, we use a mass balance model coupled with repeat snowline observations throughout the melting seasons to infer daily mass balance series over a multi-decadal study period (2000 - 2017). By integrating snowline observations into the mass balance modelling, we produce an improved estimate at high temporal and spatial resolution. Snowline mapping is carried out automatically based on Landsat, ASTER and Sentinel images. We derive spatially distributed shortwave broadband albedo for the glacierized area of each scene to discriminate snow-covered and bare-ice surfaces using an automated, multi-step classification scheme. The mapped snowlines are used to calibrate an accumulation and temperature-index melt model.

We validate these results through comparison with geodetic mass balances calculated from ASTER images covering the entire region. To compute digital elevation models the MicMac ASTER (MMASTER) package, an enhanced method to process ASTER data, was used.

In this study, we present daily mass balance series supported by sub-seasonal snowline observations of glaciers located in the Tien Shan and Pamir-Alay, validated with region-wide geodetic mass changes.
Ice Flow Modeling to Constrain SMB and Ice Discharge in Patagonia

We simulate the ice dynamics of San Rafael Glacier located in the Northern Patagonia Icefield (46.7oS/73.5oW). The model is initialized using an inverse method to infer the basal friction coefficient from observed surface velocity. These observations are given by previous studies based on multiple synthetic aperture radar and optical satellite data collected between 1994 and 2014. Low values of basal shear stress (< 100 kPa) are obtained at the glacier front and are in agreement with values from other ice streams. These values are reasonable considering the high surface velocities in this zone (up to 7.5 km/a). The modeled ice flow results suggest that the horizontal velocities are quasi-independent of depth in the lowest zone of the glacier.

We force the 3D full-Stokes model Elmer/Ice based on San Rafael Glacier surface mass balance (SMB) given by previous studies. We use geodetic elevation changes during the study period (2000-2012). We analyze the influence of different SMB distributions on the glacier dynamics, ice discharge and mass balance. The analysis of different SMB scenarios suggests that the average SMB for the entire glacier is 0.08±0.05 Gt/a and that previous SMB estimations for San Rafael Glacier significantly overestimated the accumulation. The ice discharge is estimated as 0.77±0.29 Gt/a representing the main source of glacier wastage.
Fast Recession of Patagonian Glaciers Dynamically Modulated by Calving Activity

Andres Rivera¹,² (arivera@cecs.cl), Francisca Bown¹, Daniela Carrion¹, Sebastian Cisternas¹, Jorge Hernandez¹, Felipe Napoleoni¹, Jonathan Oberreuter¹, Pablo Paredes¹, Sebastian Pulgar¹, Jose Andres Uribe¹, Rodrigo Zamora¹

¹Centro de Estudios Científicos, Glaciology, Valdivia, Chile, ²Universidad de Chile, Geography, Santiago, Chile

The Southern Patagonia Icefield (SPI) is the second ice mass in the Southern Hemisphere outside Antarctica. With only a couple of exceptions, all its glaciers have experienced substantial frontal retreats, high thinning rates of the ablation zones and ice flow acceleration, a pattern that is climatically triggered, but dynamically modulated by calving activity, since the great majority the SPI outlet glaciers are calving into tidewater fjords or freshwater lakes, where the bathymetry is playing a critical role in controlling ice dynamics. In spite of the importance of calving in explaining recent glacier changes, very little is known about the lake or fjord waters nearby the main glaciers fronts, especially the bathymetry, sedimentation rates, temperatures and the consequent subaquatic melting. In recent years we have studied this problem by conducting several on the ground and airborne campaigns to Glaciares Jorge Montt, O’Higgins, Chico, Viedma and Upsala. In these surveys we have detected very deep fjords of up 600 m in areas recently occupied by glaciers, water temperatures with contrasting vertical structures and high subaquatic melting rates. Also, we have measured high ice velocities with satellite feature tracking techniques as well as time lapse videos. The most dramatic event recently captured with these techniques was the collapse experienced by Glaciar O’Higgins between May and June 2017 when it front lost 2 km² of ice in a sequence of huge calving events.
Challenges Associated with the Protection of Antarctic Geological Features

Jeronimo Lopez-Martinez1 (jeronimo.lopez@uam.es), Luis Carcavilla2, Kevin Hughes3, Juan Jose Duran2
1University Autonoma of Madrid, Faculty of Sciences, Geology and Geochemistry, Madrid, Spain, 2Geological Survey of Spain-IGME, Madrid, Spain, 3British Antarctic Survey, Cambridge, United Kingdom

Increased visitation, easier access, infrastructure construction and collection of samples for scientific purposes can all impact the conservation of Antarctic geological features. Therefore, there is a need to identify geological features that merit protected and possible ways to do it. The geographic location of Antarctica, its distinctive environmental conditions and the existing system for protection of values present a unique context for geoconservation in comparison with other regions of the world. Therefore, an adaptation of the criteria usually used to identify and protect geological heritage in other continents may be necessary. Given the existence of vulnerable geosites in Antarctica, the establishment of procedures to catalog and protect the Antarctic geological heritage may be recommended. This work analyses the components involved in the identification of Antarctic geological values and the associated risk of possible loss of values should some features not be identified. The advantages, difficulties and viability of identifying Antarctic geological heritage are discussed within the framework of existing experience and global protection mechanisms, including the management of geological heritage in existing protected areas. This work is a contribution to the ongoing work of the SCAR Action Group on Geological Heritage and Geoconservation, which aims to recommend possible measures to protect geological heritage in Antarctica.
Informing Conservation Planning for Terrestrial Antarctica

Aleks Terauds¹ (aleks.terauds@gmail.com)
¹Australian Antarctic Division, Antarctic Conservation and Management, Kingston, Australia

Antarctic Specially Protected Areas (ASPAs) are an important conservation mechanism of the Protocol on Environmental Protection to the Antarctic Treaty. While most ASPAs protect values that are consistent with those outlined in the Protocol, several recent assessments have questioned the efficacy of the current set of ASPAs. Concomitant with the increasing scrutiny of ASPAs, and sometimes critical assessment, is a suite of research into the provision of an evidence-base for the designation of protected areas in terrestrial Antarctica. Much of this research is underpinned by a strong focus on more holistic approaches to protected area designation, typically incorporating continental or large-scale data and analyses.

I will provide examples of empirical, continental scale analyses for terrestrial Antarctica with a focus on two key areas - species and ecosystems. For species I will report on i) a recent synthesis of continental scale species distribution modelling for over 30 taxa, and ii) a snapshot of Antarctic biodiversity protection. For ecosystems, my focus will be on i) a new assessment of Antarctic terrestrial habitats, and their potential as proxies for biodiversity and ii) the application of the IUCN Red List of Ecosystems process to terrestrial Antarctica. I will conclude with a summary of how these analyses, both individually and together, can contribute to the foundation of a more integrated and systematic protected area network for terrestrial Antarctica.
Conservation and Historical Research in the McMurdo Dry Valleys, Antarctica

Adrian Howkins¹ (adrianhowkins@hotmail.com), Andrew Fountain²
¹University of Bristol, Bristol, United Kingdom, ²Portland State University, Portland, United States

With particular attention to sites of past human activity, this paper explores how historical research can inform environmental conservation efforts in the McMurdo Dry Valleys, Antarctica. Since the late 1950s scientists have worked in the Dry Valleys every summer season making the region one of the most intensive sites of scientific activity anywhere on the Antarctic continent. Historical research can provide information about the location of field camps, the duration of occupation, and the nature of activities being conducted. This historical information has then been used to inform field observations and sampling conducted as part of the work of the McMurdo Dry Valleys Long Term Ecological Research site to provide insights into the long-term legacy of human activity in the McMurdo Dry Valleys. Alongside a presentation of results, this paper will also consider the challenges and opportunities of interdisciplinary conservation work in the polar regions.
A Multi-discipline Assessment of Foot Traffic Impacts in the McMurdo Dry Valleys

Kurt Joy¹ (kurtj@waikato.ac.nz), Jayne Belnap², Charles Lee¹, Stephen Cary¹
¹University of Waikato, International Centre for Terrestrial Antarctic Research, Hamilton, New Zealand, ²USGS, Southwest Biological Science Center, Moab, United States

The McMurdo Dry Valleys are recognised as a unique environment in which landscape and biodiversity are protected as an Antarctic specially managed area. The management plan associated with such areas allow tourist and scientific operations to occur with the minimum of environmental impact. Yet the magnitude and longevity of impacts associated with human foot traffic are poorly quantified, particular in respect to the identification and mapping of soils sensitive to such impacts. Therefore, gaining a greater understanding of how Antarctic soils respond to trampling is key to ensuring such protected areas remain as undisturbed as possible.

We present preliminary results of a combined near-target remote sensing and soil study of geomorphological units in the McMurdo Dry Valleys and their resilience to trampling. Using structure from motion photogrammetry and tension infiltrometry, 140 sites in the MDV ASMA have been visited, and their response to a range of human impacts measured. Our results show that the style of foot traffic, whether it be single or multiple pass, plays an important role in the magnitude of physical and visual disturbance observed at these sites.

It is hoped that this technique will identify soils in polar desert regions sensitive to disturbance. By providing environmental managers a tool to plan science and tourist visitation into ice free areas, human impacts can be assessed and management plans to mitigate then implemented prior to visitation.
Assessing Risks to Polar Ecosystems: The IUCN Red List of Ecosystems Criteria

David Keith1,2 (david.keith@unsw.edu.au), Rebecca Miller3, Emily Nicholson4, Graeme Clark5
1University of New South Wales, Centre for Ecosystem Science, Sydney, Australia, 2NSW Office of Environment and Heritage, Hurstville, Australia, 3IUCN Ecosystem Management Programme, Cambridge, United Kingdom, 4Deakin University, Centre for Integrative Ecology, Melbourne, Australia, 5University of New South Wales, Evolution and Ecology Research Centre, Sydney, Australia

Polar ecosystems face an uncertain future, with threats posed by exploitation of minerals, fossil fuels, fish and wildlife, shipping, tourism, invasive species and climate change. Understanding the relative risks to different ecosystems is fundamental to well-informed ecosystem management. The IUCN Red List of Ecosystems (RLE) protocol is an international standard enabling systematic assessment of ecosystems at risk of large detrimental changes involving loss of biodiversity and functionality. Several qualities make it well suited for application to polar ecosystems. First, it provides an adaptable and consistent framework for risk assessment across terrestrial, subterranean, freshwater and marine ecosystems. Second, RLE assessments may be framed to accommodate data of varying quality and abundance. Third, the RLE assessment process mobilises experts to compile and critically review available data, identifying gaps to support strategic investment in data acquisition. Finally, it enables scenario analysis, given plausible alternative futures for polar environments. We will briefly explain the assessment process and review applications to selected polar ecosystems. We will explore the potential for developing systematic Red List assessments of polar ecosystems to support decisions about design and management of protected areas, indigenous peoples' interests, industry development, impact assessment, reporting against global targets and climate change mitigation and adaptation.
Conservation Issues in the High Arctic and Pole-to-Pole Comparisons

Warwick F. Vincent\textsuperscript{1} (warwick.vincent@bio.ulaval.ca), Annick Wilmotte\textsuperscript{2}
\textsuperscript{1}Université Laval, Centre d’Études Nordiques (CEN), Québec City, Canada, \textsuperscript{2}University of Liège, InBios-Centre for Protein Engineering, Liège, Belgium

With the increasing impacts of global change, conservation activities are more important than ever to protect and preserve high latitude environments and their biota. Efforts to date in the Arctic have focused on higher plants and animals; for example, the Red List of threatened Arctic plants is currently limited to vascular species, and no attention has been given to lower plant and microbial communities that are often dominant features of far northern ecosystems. One of the largest northern conservation zones in Canada is Quttinirpaaq National Park, a 37,775 km\textsuperscript{2} region that extends to the northern coast of Ellesmere Island, Nunavut. Studies over the last two decades at the northern coastline of this park have shown that the land, lake and fjord environments contain diverse microbial assemblages and functions (‘environmental microbiomes’) and that these are responding strongly to the current trend of accelerated warming at these extreme high latitudes (82-83N), leading to the extinction of certain ecosystem types. In Antarctica, increased (albeit still limited) attention is being given to protection measures for microbial ecosystems (e.g., ASPAs and SCAR codes of conduct for activities and research in terrestrial, geothermal and subglacial aquatic environments) and a similar level of stewardship is needed for analogous High Arctic microbial ecosystems. A Red List of vulnerable microbiomes in High Arctic and Antarctic environments may help inform conservation efforts.
C. Christensen and C. Larsen: A Comparative Analysis of Two Whaling Entrepreneurs

Bjørn L. Basberg\(^1\) (bjorn.basberg@nhh.no)
\(^1\)Norwegian School of Economics, Economics, Bergen, Norway

Chr. Christensen and C.A. Larsen are usually considered among the most important pioneers in the transfer of whaling to Antarctic waters in the early 20\(^{th}\) century. After a period of close cooperation during the 1890s, they took different courses and built up their Antarctic enterprises independently of each other. While Larsen initiated the foundation of shore station whaling at South Georgia, Christensen sent a floating factory ship to the South Shetland Islands.

The main aim of the paper is to make a systematic comparison of the two entrepreneurs and their companies, and focus explicitly on the considerations and decisions they made when whaling was transferred from North to South. They obviously chose different strategies, but we will ask how different they really were in their thinking about how Southern whaling was going to develop.

Both entrepreneurs brought along their experiences from how whaling had been undertaken in the Northern waters. It was not obvious what organizational patterns that would work in the South, and we shall study how familiar and new ways of organizing the industry were combined - as is often the case in entrepreneurial innovations.
The Transfer of Sledging Technology from the Arctic to the Antarctic

Michael Pearson¹ (mike.p@ozemail.com.au)
¹Independent Scholar, Canberra, Australia

Sledges have been used by northern cultures for millennia, and were adapted and modified for exploration expeditions through the nineteenth century. When exploration in the Antarctic began, the experience of northern explorers was drawn on in the selection of sledges best suited to Antarctic conditions. The Nansen sledge proved to be the most popular, and the influence of Fridtjof Nansen as a model and mentor was immense, but other designs were also used. The paper looks at the development and the sledge for northern exploration, and its transfer to the Antarctic in the late nineteenth and early twentieth centuries.
After the successful use of ponies on Shackleton's 1907-09 *Nimrod* expedition, Scott wasn't the only explorer who wanted to do likewise. In Japan Lt Shirase's original plan had also been to use horses, but when his Antarctic Expedition finally found a ship it was much smaller than he envisaged. Horses were abandoned in favour of sledge dogs from the Japanese sub-Arctic Prefecture of Karafuto on the island now known as Sakhalin in the Russian Far East. Just days before the Expedition sailed the 36 dogs and their handlers arrived to join the Japanese expedition members in Tokyo. Yasunosuke Yamabe and Shinkichi Hanamori were from the indigenous Ainu community on Sakhalin. The Ainu were discriminated against and impoverished by Japanese settlers who flocked to develop the north of the country after the Meiji restoration in 1868. So why did these two men volunteer for such a dangerous mission so far from home? Why did they go so far as to risk their lives for the glory of their oppressors?

Little is known outside Japan about Lt Shirase's Heroic Age expedition, and even less about the Ainu who set Antarctic dog-sledging records, but never knew it. However, when they got back to Tokyo in 1912 Yamabe took the time to write his autobiography before returning to his community in the far north. Starting with his earliest memories and finishing with his experiences in Antarctica, his book gives us insights into the thoughts of a leader of an indigenous sub-Arctic community.
Historical Exchanges and Precedence in the Production Ice Sheet Knowledge

Jean de Pomereu¹ (jean@jeandepomereu.com)
¹University of Cambridge, Scott Polar Research Institute, Cambridge, United Kingdom

The cultural and scientific history of ice sheets cannot be considered from the point of view of just Greenland or Antarctica. Although they are located at opposite poles, both regions have played central roles in the interconnected, but not always synchronous production of ice sheet knowledge. Through examples of surface exploration, seismic sounding, radio echo sounding (RES) and ice coring, this paper examines the processes of exchange and precedence that have constructed our perception and understanding of ice sheets from their earliest physical exploration in the second half of the 19th century, up until the early 1980s. In mapping the history of where, when and how new methodologies and technologies were deployed in the study of the Greenland and Antarctic ice sheets, it demonstrates how ice sheet knowledge was shaped as much by scientific priorities, as by questions of accessibility, institutional and budgetary constraints, geopolitical interests, and individual or institutional leadership. This history also provides us with new insights into collaborative mechanisms, directions of exchange, and polar interdependence from both an exploratory and an Earth System perspective.
Established in 1958, SCAR has a much longer history of coordinating polar research than its Arctic equivalent, IASC, which was established decades later in 1990. By using new material from the recently opened SCAR archive, this paper sets out to investigate the events that led to the creation of an Antarctic research committee far earlier than one for the Arctic.

I will argue that we can understand this disparity in light of the different systems of governance existing in the Arctic and the Antarctic in the Cold War years. So, whilst for many years polar research developed in similar ways at both poles and often through coordinated efforts (Baker, 1982), there was only one agency devoted to its coordination. The disparity also originates in SCAR’s relationship with the Antarctic Treaty System, which was unparalleled in the Arctic. In particular, although there are specific cases in the Arctic (e.g. Svalbard) for which sovereignty was decided, upon on the basis of international treaties (Lüdecke, 2011), the Cold War prevented extending such legislation to the entirety of the Arctic Circle. This meant that whilst a body coordinating Antarctic research was needed to further strengthen the ATS, the same was not possible at the North Pole. It is thus no surprise that the potential of coordinating research in the Arctic, and also such research as a vehicle of international diplomacy, emerged only towards the end of the Cold War.
Polar Art and Climate Change: Perceptual Shifts in Polar History Mediated by Art

Lisa Bloom¹ (lbloom2@mindspring.com)
¹University of California, Gender and Women's Studies, Berkeley, United States

This paper draws on writing done for my book project Polar Art and the Climate Crisis: Witnessing the Anthropocene. It brings together the Arctic and Antarctic by asking in the context of climate change how we can imagine the shift in perception from the last spaces of heroic exploration to the first places of global decline. And how does this shift from space to place and the heroic to the climatic specify a shift in perception and history of both these polar regions mediated by art?

Through a discussion of the work of Judit Hersko, Annie Pootoogook, and Subhankar Banerjee on both the Arctic and Antarctic, I examine the shift from polar fantasies of the old flag-planting heroism of explorations to “the ends of the earth” of an earlier epoch to the new critical realities of place in the present. I focus on how these very different polar histories as mediated by art intersect and play an enormous part in replacing the sublime aesthetic of the polar heroic regions with an alternative aesthetic that is ant-heroic, feminist and indigenous (Inuit) one. More especially, the paper argues that art and visual culture about the polar regions in their most capacious aspects play a very key role in our thinking on the Anthropocene.
2017
Arctic Sea Ice Volume Variability over the Past 40 Years

Jean-Claude Gascard\textsuperscript{1} (jga@locean-ipsl.upmc.fr), Jinlun Zhang\textsuperscript{2}
\textsuperscript{1}University Pierre & Marie Curie, LOCEAN, Paris, France, \textsuperscript{2}University of Washington, Polar Science Center, Seattle, United States

We compared Arctic sea ice volume estimated from PIOMAS (Pan-Arctic Ice-Ocean Modelling and Assimilation System; Zhang and Rothrock 2003) and Arctic sea ice volume estimations based on observed freezing conditions expressed as Freezing Degree Days (FDD; Harpaintner et al 2001) deduced from ERA-Interim reanalysis (Dee et al 2011, Gao 2013) for the past 40 years. During the early 80s the amount of sea ice calculated from FDD was significantly lower than sea ice volume produced by PIOMAS in winter. This was due to the abundance of multiyear ice (MYI) during the early 80s that FDD could not account for. During more recent years, PIOMAS and FDD estimations are both producing a similar amount of sea ice. This is a remarkable result due to the disappearance of MYI during recent years. But the similarity between PIOMAS and FDD sea ice volume winter production including the long-term trend as well as the interannual and interdecadal variability is striking. This suggests that in the northern hemisphere as a whole, the surface air temperature driving freezing is a major factor for the sea ice volume production in winter. Since the 1980s the ice cover has shrunken by half in both extent and thickness, leading to a total sea ice volume reduction of 75 per cent in summer. It should only take one or two decades at most to melt away the remaining 25% of Arctic sea ice at the end of the summer season. Most of the Arctic Ocean would then refreeze during the following winter season.
Assessing Internal Variability of Arctic Sea Ice Thickness and Volume

Alexandra Jahn¹ (alexandra.jahn@colorado.edu), David M. Hall², Kerrie Dochen³

¹University of Colorado Boulder, Atmospheric and Oceanic Sciences and INSTAAR, Boulder, United States, ²University of Colorado Boulder, Computer Sciences, Boulder, United States, ³University of Colorado Boulder, INSTAAR, Boulder, United States

Satellite-based remote-sensing measurements of Arctic sea ice thickness provide important new constraints on the sea ice changes in the Arctic for the last 1.5 decades. However, ICESat and CyroSat-2 campaigns did not overlap, they (so far) provide only a short timeseries in terms of climate records, and they have sampled an unprecedented period of rapid sea ice decline in the Arctic. Given all of these constraints, how do we best use these sea ice thickness products for model assessment? By analyzing the variability of sea ice thickness from the CESM large ensemble, CMIP5 (and if possible CMIP6) models, and the satellite data in novels ways, we will show how we can interpret these short but crucial records of Arctic sea ice change in the light of natural variability, and which insights they allow about sea ice thickness and volume biases and their sources in climate models.
Spatial and Temporal Patterns of Arctic and Antarctic Sea-ice Leads, 2003 - 2016

Sascha Willmes¹ (willmes@uni-trier.de), Günther Heinemann¹, Fabian Reiser¹
¹University Trier, Environmental Meteorology, Trier, Germany

The occurrence of leads represents a key feature of the polar sea ice cover. Leads promote the flux of sensible and latent heat from the ocean to the cold winter atmosphere and are thereby crucial for air-sea-ice-ocean interactions and feedbacks. We use the thermal signature of leads in the MODIS ice surface temperature product and a subsequent cloud artefact filter to infer daily and monthly composite lead maps for the sea ice area in both hemispheres during wintertime, 2003-2016. For the Arctic, our results highlight the marginal ice zone in the Fram Strait and Barents Sea as the primary region for lead activity. The spatial distribution of the average pan-Arctic lead frequencies reveals distinct patterns of predominant fracture zones along the Arctic Boundary Current, in the Siberian sector of the Arctic Ocean as well as in the well-known polynya and fast-ice locations. For the Antarctic, we present results for the most active sea-ice regions with respect to lead occurrences and their inter-annual variability. Hemispheric and regional peculiarities as well as methodological issues are discussed. Results are compared to passive-microwave lead products and the potential of this data set for an operational high-resolution sea-ice monitoring is investigated.
Arctic sea ice has displayed significant thinning as well as an increase in drift speed in recent decades. Both buoy observations and satellite microwave radiometer based sea ice speed estimates show a strong increase in the Arctic-wide sea ice drift speed for the period 1979-2007 and 1992-2009, respectively. For the satellite data, the strongest ice speed increase was observed between 2004 and 2009. During these time periods changes in wind speed cannot explain the ice drift speed increase overall and sea ice thinning is the main driver for the ice speed changes. During the last ten years 2007-2016, however, the ice drift speed increase got reduced and became spatially more variable. Now the ice and wind speed trend patterns are in better agreement, and changes in the wind forcing can explain a larger fraction of ice drift changes. At the same time the ice thickness is at a very low level and therefore the ice drift got more susceptible to wind forcing, which is supported by a higher correlation between the two. The sea ice thickness, however, also did not change during recent years. The CryoSat-2 time series since 2010 shows thin ice and high inter-annual variability but no further overall thinning. The Arctic might have reached a new state with thin ice and higher ice drift speeds. The MOSAiC experiment in 2019/2020 will allow to observe this new Arctic for a complete seasonal cycle and can provide new insights to the coupling between sea ice dynamics and ice thickness.
A New Time Series of Sonar-based Sea-ice Draft Records from the Siberian Shelf

H. Jakob Belter¹ (jbelter@awi.de), Ed Ross², Stefan Hendricks¹, Markus Janout¹, Stephan Paul¹, Robert Ricker¹, Thomas Krumpen², Christian Haas¹,³
¹Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, ²ASL Environmental Sciences Inc., Victoria, Canada, ³Institute for Environmental Physics, University of Bremen, Bremen, Germany

The Laptev Sea is an important region for net ice production and a major contributor to the Transpolar Drift System. Seasonal and interannual ice thickness variability in this shallow shelf sea is primarily controlled by ice dynamics. Recent studies have shown increasing sea-ice area and volume export from the Laptev Sea, which is likely related to increasing drift speeds. This increased export accelerates summer sea-ice retreat and has far-reaching consequences for the entire Arctic sea-ice mass balance.

In order to increase the limited knowledge about seasonal and interannual variability of sea-ice thickness on the Laptev Sea Shelf, a set of moored Ice Profiling Sonars (IPS5, ASL Environmental Sciences Inc.) were deployed from September 2013 to September 2015. Here we present this comprehensive sea-ice draft data set for the first time. Observed seasonal changes in ice draft are linked to atmospheric and oceanic processes and used to validate different satellite-based sea-ice thickness products from altimeter and radiometer missions like CryoSat-2 and SMOS. Based on the comparison between ice thickness time series obtained from IPS and Acoustic Doppler Current Profiler (ADCP) bottom track data, we are able to extend the ice thickness time series even further back in time. This may provide us with the opportunity to compare our data sets to sea-ice thickness estimates obtained from ENVISAT radar altimeter data.
The ESA CCI Radar Altimeter Sea-ice Thickness Data Set: Some Evaluation Results

Stefan Kern1 (stefan.kern@uni-hamburg.de), Louisa Bell2, Kirill Khvorostovsky3, Stephan Paul4, Henriette Skourup5, Stefan Hendricks4, Stein Sandven3

1University of Hamburg, Center for Climate System Research and Sustainability (CEN), Hamburg, Germany, 2University of Hamburg, Hamburg, Germany, 3Nansen Environmental and Remote Sensing Centre, Bergen, Norway, 4Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, 5Danish Technical University, Lyngby, Denmark

Sea-ice thickness (SIT) is a key to quantify variability in the hemispheric sea-ice volume. Polar-orbiting satellite altimeters, in operation since the early 1990ties, permit to derive hemispheric-scale SIT from elevation measurements. Unlike for sea-ice concentration, changes in sensor characteristics and data coverage are substantial and complicate creation of a SIT climate data record (CDR) from altimeter data. We present evaluation results for the new ESA CCI SIT CDRs based on Envisat RA-2 (RA2) and CryoSat-2 SIRAL (CS2) satellite radar altimeter observations. The CDRs include monthly radar freeboard, ice freeboard (FB) and SIT at 25 km (Arctic, winter only) and 50 km (Antarctic, entire year) grid resolution. The CDR’s parameters are mostly consistent across the RA2 - CS2 sensor change. Regionally, however, FB and SIT from RA2 often exceeds that from CS2, particularly in early winter; the Ross Sea, Antarctic, seems to be especially problematic. We find a linear regression of 0.88x+0.03 m between Arctic CS2 SIT and airborne total (sea ice + snow) thickness, RMSE=0.73m; regression is 0.26x+1.45 m for RA2 SIT, RMSE=0.90m. Agreement between Antarctic SIT and airborne total thickness is worse than in the Arctic. Arctic sea-ice drafts measured by BGEP ULS and estimated from RA2 and CS2 SIT agree within ~0.5 m depending on ice type, month and snow-depth. On average, Arctic RA2 SIT underestimates ICESat SIT by ~0.4 m, with wide-spread differences > 1.5 m on 25 km grid scale.
Different Propagation Characteristics of Gravity Waves over Syowa and Davis

Masaru Kogure¹ (kogure.masaru@nipr.ac.jp), Takuji Nakamura², Yoshihiro Tomikawa², Mitsumu K. Ejiri², Takanori Nishiyama², Masaki Tsutsumi², Michael J. Taylor³, Yucheng Zhao³, P.-Dominique Pautet³, Damian Murphy⁴

¹SOKENDAI (The Graduate University for Advanced Studies), Department of Polar Science, Tokyo, Japan, ²National Institute for Polar Research, Tokyo, Japan, ³Utah State University, Center for Atmospheric and Space Sciences, Logan, United States, ⁴Australian Antarctic Division, Kingston, Australia

Source, propagation and intermittency of gravity waves are only poorly understood because of the lack of observations. To understand their source and propagation, our group has observed gravity waves over Syowa (69°S, 40°E), Davis (69°S, 79°E) and other stations using various instruments [Kogure et al., 2017; Matsuda et al., 2017].

We will show the ground-based horizontal phase speed spectrum over the two stations derived from OH imagers. We analyzed the OH airglow imager data obtained from March to October in 2016 with the M-transform [Matsuda et al., 2014]. We analyzed the data without clouds and aurora contaminations continuously for at least one hour. The numbers of nights with such data sets are 40 at Syowa and 55 at Davis. The seasonal variations of the nightly mean variance were very similar with winter maximum, but the variance over Syowa was larger than that over Davis in September. In 2016, clear sky and aurora free data were available at both station on ten nights. Comparison of phase velocity spectrum obtained on the same night showed similarities on only one night out of ten nights. At five nights, the spectra were different. At the other four nights, the spectral peaks with slow westward phase velocity were commonly observed but additional spectral peaks were found over Davis and not over Syowa. We will also present comparisons of kinetic energy and propagation direction of gravity waves derived from MF radars, and compare with the results from OH imagers.
Dynamics of Extreme Stratospheric Positive Heat Flux Events in a Simple Model

Etienne Dunn-Sigouin1 (etienne.dunn-sigouin@uib.no)
1University of Bergen & Bjerknes Centre for Climate Research, Geophysical Institute, Bergen, Norway

Extreme stratospheric positive wave-1 heat flux events are coupled to significant variability in the polar troposphere. In particular, the events are associated with large amplitude wave-1 geopotential height anomalies, near surface cooling over Eurasia and warming over Northern Canada. Here a dry dynamical core is used to investigate the dynamical mechanisms driving the events. Ensemble spectral nudging experiments are used to isolate the roles of specific dynamical components:

i) the tropospheric wave-1,
ii) the stratospheric zonal-mean flow and
iii) the higher-order planetary wavenumbers.

Nudging tropospheric wave-1 partially reproduces the events whereas they are not reproduced when nudging stratospheric wave-1, supporting the role of upward wave coupling from the troposphere to the stratosphere during the events. Nudging tropospheric wave-1 and the zonal-mean flow largely reproduces the events whereas they are not reproduced when nudging the latter alone, showing that the zonal-mean flow is a necessary but not sufficient condition in driving the upward wave coupling. Nudging the higher-order wavenumbers and the zonal-mean flow also largely reproduces the events. Mechanism denial experiments, whereby one component is fixed to the climatology and others are nudged to the event evolution, show that higher-order wavenumbers play a key role in driving the tropospheric wave-1 source during the events.
Stratospheric Polar Jet Oscillation Events and their Surface Predictability

Daniela Domeisen, Peter Hitchcock, Mikhail Dobrynin, Wolfgang A. Müller, Johanna Baehr

ETH Zurich, Institute for Atmospheric and Climate Science, Zurich, Switzerland, Laboratoire de Météorologie Dynamique, Ecole Polytechnique, Paris, France, Institute of Oceanography, Center for Earth System Research and Sustainability (CEN), University of Hamburg, Hamburg, Germany, Max-Planck-Institute for Meteorology, Hamburg, Germany

The surface impacts of stratospheric sudden warming (SSW) events tend to extend up to several weeks. It is however unclear which mechanisms lead to the long lifetime of the surface impacts on seasonal timescales. About half of all SSW events are associated with so-called Polar Jet Oscillation (PJO) events, which are characterized by an extended recovery of the stratospheric flow and long-lasting temperature anomalies in the lower stratosphere. It is here investigated if this extended recovery may in part be responsible for the extended duration of the surface impact of SSW events (though PJO events may also occur independently of SSW events) - and therefore a possible improvement in winter predictability in the extratropical troposphere.

The hypothesis is tested using a 30-member ensemble of seasonal hindcasts initialized on November 1st of each year from 1979 to 2014 from the seasonal prediction system based on the Max Planck Institute Earth System Model (MPI-ESM). Evidence is found that the ensemble provides improved statistical predictability for both SSW and PJO events in the stratosphere. In addition, the surface impact of PJO events is well represented in the model as compared to reanalysis, and it is significantly stronger and longer-lived than for SSW events. Prediction skill over the North Atlantic and the Arctic is significantly enhanced during years with SSW or PJO events.
Arctic System Reanalysis Provides High-resolution Accuracy for Arctic Studies

David Bromwich¹ (bromwich@polarmet1.mps.ohio-state.edu), Aaron Wilson¹, Lesheng Bai¹, Zhiquan Liu²
¹Ohio State University, Byrd Polar and Climate Research Center, Columbus, United States, ²National Center for Atmospheric Research (NCAR), Boulder, United States

To detect and diagnose rapid climate changes occurring in the Arctic, a state-of-the-art assessment and monitoring tool is imperative. The Arctic System Reanalysis is a university-led reanalysis of the Greater Arctic region using blends of the polar-optimized version of the Weather Research and Forecasting (Polar WRF) model and WRF three-dimensional variational data assimilation system. The latest is a comprehensive integration of the regional Arctic climate for 2000-2016 (ASRv2.1). ASRv2.1 features 15 km horizontal resolution, updated model physics including sub-grid scale cloud fraction interaction with radiation, and a dual outer loop routine for more accurate data assimilation. Analysis reveals superior reproduction of near-surface and tropospheric variables. Forecast precipitation and downward radiative fluxes demonstrate significant improvements over earlier versions. The high-resolution topography and land surface, including weekly-updated vegetation and realistic sea-ice fraction, sea-ice thickness, and snow cover depth on sea ice, resolve fine-scale processes. This allows in-depth investigations of topographically-forced wind events, marine cold air outbreaks, and polar lows, all important components of the Arctic climate. Thus, ASRv2.1 permits a reconstruction of the contemporary changes in the Arctic, complements global reanalyses, and may be used in environmental models, to verify regional processes, or aid in the siting of future observation networks.
How Well Do we Know the Polar Energy Budgets?

Tristan L’Ecuyer (tristan@aos.wisc.edu)
University of Wisconsin - Madison, Madison, United States

While the underlying theory behind polar feedback mechanisms has been known for a long time, current climate models still struggle to capture observed rates of sea ice decline and ice sheet mass. This may be explained, at least partially, by a lack of observational constraints on polar energy budgets and, in particular, the roles clouds and precipitation play in modulating them. One solution to the challenges of making sustained, high quality atmospheric measurements in this inhospitable region, is to turn to satellites. This presentation will introduce a new multi-satellite, multi-model dataset for probing the state of the Arctic and Antarctic climates and documenting its representation in predictive models. Recent satellite-based reconstructions of the polar energy budgets and their annual cycle from this dataset will be used to demonstrate that atmospheric reanalyses and global climate models exhibit significant biases in several key energy flows at both poles. These biases, in turn, lead to discrepancies in both the magnitude and seasonality of the implied surface heat storage and heat transport into polar regions from lower latitudes. The significance of these biases is illustrated by examining their influence on ice sheet dynamics and the surface mass balance of the Greenland Ice Sheet.
The Variations of Tropopause and TIL in the Arctic Region during SSW2009

Rui Wang1 (wangrui@pric.org.cn)
1Polar Research Institute of China, Shanghai, China

The mechanism to explain the variations of tropopause and tropopause inversion layer (TIL) in the Arctic region during a sudden stratospheric warming (SSW) in 2009 was studied with MERRA reanalysis data and GPS/COSMIC temperature data. During the prominent SSW in 2009, the cyclonic system changed to the anticyclonic system due to the planetary wave with wavenumber 2 (wave2). The GPS/COSMIC temperature data showed that, during the SSW in 2009, the tropopause height in the Arctic decreased accompanied with the tropopause temperature increase and the TIL enhancement. The variations of the tropopause and TIL were larger in higher latitudes. A static stability analysis showed that the variations of the tropopause and TIL were associated with the variations of the residual circulation and the static stability due to the SSW. Larger static stability appeared in the upper stratosphere and moved downward to the narrow region just above the tropopause. The descent of strong downward flow was faster in higher latitudes. The strong downwelling in the stratosphere was mainly induced by wave2, which led to the tropopause height and temperature changes due to the adiabatic heating. Around the tropopause, a pair of downwelling above the tropopause and upwelling below the tropopause due to wave2 contributed to the enhancement of static stability in the TIL immediately after the SSW.
Sea-ice Properties Derived from Ice Mass-balance Buoys using Machine Learning

Louisa Tiemann¹ (louisa.tiemann@awi.de), Marcel Nicolaus¹, Mario Hoppmann¹, Marcus Huntemann¹,², Christian Haas¹
¹Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Bremerhaven, Germany,
²University of Bremen, Institute of Environmental Physics, Bremen, Germany

Sea ice in the polar regions determines the energy, mass and momentum exchange between the atmosphere and the ocean. However, remoteness of the polar oceans as well as the harsh weather conditions make observations challenging and expensive. Sea Ice Mass-balance Buoys (IMBs) are autonomous instruments, consisting of a thermistor chain, measuring vertical temperature profiles extending from the air through snow and sea ice into the upper ocean. So far, deriving the respective interfaces between the media to investigate the local sea ice energy and mass balance is a crucial challenge. Here we present a semi-automatic algorithm based on supervised machine learning techniques that is capable of reliably identifying the interfaces between atmosphere, snow, sea ice and ocean from IMB temperature and heating data. We use a random forest classifier, based on a number of subsets of the training set to fit an ensemble of decision trees. The classification is achieved by averaging over the ensemble and the algorithm is applied to IMBs deployed in the Arctic and Antarctic since 2012. Our results show time series of sea-ice growth/melt, snow accumulation/ablation, snow-ice formation and thermal conductivities. We discuss the time series and the spatial variability in order to improve our understanding of seasonal variations in the energy and mass budgets of sea ice and its impact on the climate system.
Arctic sea ice retreat has been observable since 1950 and is reaching a stage where the summer ice cover will soon disappear. The rapidity of change was masked because the decline in area (easily mapped by satellite) was accompanied by a rapid decrease in mean thickness (less easily mapped by submarine sonar). We begin by surveying how sonic range probing of the ice underside has developed, from use in wave recording to single-beam then multi-beam mapping. We go on to survey the implications of the observed volume decrease, since the retreat has feedbacks on other aspects of the climate system. The feedbacks involve

1. albedo - as sea ice and snow on land retreat, the average albedo of the Earth is reduced, now equivalent to adding 50% to the emissions of CO2;
2. sea level - the retreating sea ice warms the atmosphere around Greenland in summer, speeding its melt rate and increasing the rate of global sea level rise;
3. methane - increasing quantities are being emitted from the Russian continental shelves, and this could accelerate into a methane pulse with major climate implications;
4. weather - extreme weather changes relate to the ice retreat and these threaten global food supply;
5. weakening of the Atlantic thermohaline circulation due to a loss of sea ice from the Greenland Sea, which reduces the warming rate of Europe while increasing that of the tropical Atlantic.

We estimate the magnitudes of the five feedbacks and their total impact on the global climate.
The morphology of sea ice deformation is important for the representation of deformation in sea ice models and interpreting satellite observations of ice thickness. Deformation features in the Antarctic differ from those in the Arctic, yet we have limited understanding of how deformation drives ice morphology. In this study, sea ice deformation is characterized and quantified with relevant statistics using high-resolution three-dimensional observations of ridges collected during the 2017 PIPERS cruise in the Ross Sea in early winter. These observations primarily consist of ice draft from multibeam sonar on an autonomous underwater vehicle (AUV) and are supplemented with terrestrial lidar for surface elevation and manual MagnaProbe for snow depth. We quantify ridge statistics such as roughness, symmetry (skew) and linearity using computer vision techniques and model the thickness distribution using generalized extreme value distributions. To understand how deformation processes determine these morphologies, ridge spatial statistics are verified using a three-dimensional Discrete Element Model, which also allows for investigating the effects of different initial floe statistics on resultant ridge morphology. This yields improved estimates of sea ice thickness redistribution due to ridging that will ultimately improve sea ice dynamic models, algorithms for remote sensing of ice thickness distribution and parameterizations of ice-ocean drag.
Observations of Sea-ice Mediated Upwelling and Downwelling in the Beaufort Sea

Gianluca Meneghello¹ (gianluca.meneghello@gmail.com), John Marshall¹, Mary-Louise Timmermans², Jeffery Scott¹
¹MIT, Cambridge, United States, ²Yale, New Haven, United States

We present observational estimates of Ekman pumping in the Beaufort Gyre region. Averaged over the Canada Basin, our results show a 2003-2012 average of 2.5m/y downward with strong seasonal and interannual variability superimposed: monthly and yearly means range from 30m/y downward to 10m/y upward. A clear seasonal cycle is evident with intense downwelling in autumn and upwelling during the winter months. Wintertime upwelling is associated with friction between the large scale Beaufort Gyre ocean circulation and the surface ice pack, and contrasts with previous estimates of year-long downwelling; as a consequence, the yearly cumulative Ekman pumping over the gyre is significantly reduced. The spatial distribution of Ekman pumping is modified as well, with the Beaufort Gyre region showing alternating, moderate upwelling and downwelling, while a more intense, year-long downwelling averaging 17.5m/y is identified in the northern Chukchi Sea region. Implications of our results for understanding Arctic Ocean dynamics and change are discussed.
The Impacts of El Niño on the Observed Sea Ice Budget of West Antarctica

James Pope1 (japope@bas.ac.uk), Paul Holland1, Andrew Orr1, Gareth Marshall1, Tony Phillips1
1British Antarctic Survey, Cambridge, United Kingdom

We assess the impact of El Niño induced wind changes on seasonal West Antarctic sea ice concentrations using reanalysis data and sea ice observations. A novel ice budget analysis reveals that in autumn a previously identified east-west dipole of sea ice concentration anomalies is formed by dynamic and thermodynamic processes in response to El Niño generated circulation changes. The dipole features decreased (increased) concentration in the Ross Sea (Amundsen and Bellingshausen Seas). Thermodynamic processes and feedbacks make a substantial contribution to ice anomalies in all seasons. The eastward propagation of this anomaly is partly driven by mean sea ice drift rather than anomalous winds. Our results demonstrate that linkages between sea ice anomalies and atmospheric variability are highly nonlocal in space and time. Therefore, we assert that caution should be applied when interpreting the results of studies that attribute sea ice changes without accounting for such temporally- and spatially-remote linkages.
Cooling and Freshening of the Southeast Pacific Driven by Sea Ice Export

Ivana Cerovecki¹ (icerovecki@ucsd.edu), Andrew Meijers², Matthew Mazloff¹, Sarah Gille¹, Veronica Tamisitt¹
¹Scripps Institution of Oceanography, University of California, San Diego, CA, United States, ²British Antarctic Survey, Cambridge, United Kingdom

Strong cooling and freshening was observed in the southeast Pacific in 2008-2010 and 1998-2000, affecting both the Southeast Pacific Subantarctic Mode Water (SEPSAMW) and the Antarctic Intermediate Water (AAIW) density ranges. Both 1998 and 2008 experienced an exceptionally low Amundsen Sea Low, a strong positive Southern Annular Mode, and a negative El Niño Southern Oscillation. In both years two varieties of SEPSAMW were formed: a colder, fresher, denser variety in the immediate vicinity of the Subantarctic Front (SAF), and a warmer, saltier, lighter variety further north. Results of analyses of an ocean-sea ice data-assimilating Southern Ocean State Estimate (SOSE) and other products suggest that this bimodal structure of SEPSAMW is associated with strong zonal wind forcing in the vicinity of the SAF and sea ice influences further poleward. In both 1998 and 2008, anomalously strong meridional winds drove strong sea ice export from the Ross Sea. The sea ice melt propagated eastward in the subsequent two year time period, causing destruction of water in the AAIW and SEPSAMW density ranges. Particles released along the sea ice edge in 2008 and advected by SOSE velocities confirmed that on timescales up to three years, the strongest influence on the AAIW and SEPSAMW comes from water that originates in the Ross Sea. Thus strong sea ice export from the Ross Sea can play an important role in modifying the AAIW and the SEPSAMW properties during subsequent years.
The Effect of Wind Direction on air Temperature Variability on James Ross Island

Klára Ambrožová¹, Kamil Láska¹ (laska@sci.muni.cz), Filip Hrbáček¹, Jan Kavan¹, Jakub Ondruch¹
¹Masaryk University, Faculty of Science, Department of Geography, Brno, Czech Republic

The western and eastern parts of the Antarctic Peninsula are quite different, especially due to frequent atmospheric blocking or foehn events induced by the mountains. In order to study the influence of topographic modification on atmospheric circulation and its impact on cryosphere, the air temperature measurements from the northern part of James Ross Island were evaluated with respect to surface wind direction. Meteorological parameters from 2013–2016 were observed in one-hour interval by multiple automatic weather stations, while 1000-hPa pressure level data from the ERA-Interim reanalysis were used to assess the surface wind effect. Furthermore, near-surface temperature lapse rates were calculated and linked to boundary layer processes. The results were analysed with respect to topographic conditions, separately for ice-free parts and glaciers of the Ulu Peninsula. The seasonal and inter-annual variation of the selected near-surface atmospheric variables was emphasized in the study.

A Satellite Perspective of Summer Warm-air Advection over Melting Sea Ice

Cheng You¹ (cheng.you@misu.su.se), Michael Tjernström¹, Abhay Devasthale²

¹Stockholm University, Department of Meteorology, Stockholm, Sweden; ²Swedish Meteorological and Hydrological Institute, Research Department, Remote Sensing Group, Norrköping, Sweden

Some very special conditions apply in summer warm-air intrusions as compared to in winter. As long as significant melting sea ice is present, surface temperature must remain at the melting point, in contrast to winter when the surface temperature can respond to changes in the heat surface fluxes. Strong surface inversion forms often accompanied by fog and the high temperature of the fog and its large longwave emissivity brings positive net longwave surface radiation, while the inversion conditions bring a downward turbulent heat flux. Studies based on data from the 2014 Arctic Clouds in Summer Experiment (ACSE), on the Swedish icebreaker Oden, indicate that while low clouds and fog reduce the net solar radiation at the surface, the combined effect on all terms in the surface energy budget leads to additional heat flux to the surface in these conditions; the net outgoing longwave radiation at the top of the atmosphere also increases. We hypothesize that cloud-top cooling and cloud-induced along with surface mixing eventually erodes the surface inversion downstream and the boundary layer transforms into the often-observed well-mixed cloud-capped boundary layer; the extra surface energy is concentrated to a zone inside the ice edge. To evaluate the hypothesis, and to determine the time/length scales involved in the transition, we use a combination of reanalysis, back trajectories and satellite products to extend the view from the local column observations from the icebreaker.
The observations from the Surface Heat Budget of the Arctic (SHEBA) campaign revealed the presence of two preferred states of wintertime Arctic boundary layer, a radiatively clear state and a cloudy state with low-level mixed-phase clouds (Persson et al. 2002). Both of these states have distinct impacts on radiative and turbulent heat fluxes of the Arctic boundary layer. The clear state is being characterized by strong longwave cooling under the clear sky or ice clouds and, the cloudy state by little to no surface longwave cooling (Stramler et al., 2011). However, most climate models lack a realistic representation of the cloudy state of the Arctic boundary layer (Pithan et al. 2013).

We examine what leads to the formation of these boundary layers. In order to study that, we calculate the back trajectories from the radiosondes data obtained from the SHEBA Ice Camp. For the calculation of these trajectories, we use the Hybrid Single Particle Lagrangian Integrated Trajectory Model (HYSPLIT) by NOAA Air Resource Laboratory. The various back trajectories provide us with an overall evaluation of the air mass formation in the Arctic boundary layer. Furthermore, the case studies can be used to design Single Column Experiments and Large-Eddy Simulation Models to improve the biases in climate models representing the Arctic boundary layer. It will also help us to inform the setup of the future observational campaigns in the context of YOPP and MOSAIC.
CMET balloons can fly for multiple days in the lower troposphere while changing altitude on demand. Around 20 CMET balloons have been launched from Svalbard and Antarctica during 2010-2017. In May 2011, one balloon launched from Ny-Ålesund, Svalbard achieved a suite of 18 continuous soundings that probed the Arctic marine boundary layer (ABL) over a period of more than 10h. Profiles were compared to model output from ECMWF Era-Interim reanalysis (ERA-I) and to a high-resolution (15 km) Arctic System Reanalysis (ASR) product. To the east of Svalbard over sea ice, the CMET observed a stable ABL profile with a temperature inversion that was reproduced by ASR but not captured by ERA-I.

In January 2013, two balloons were launched from the Aboa station in Dronning Maud Land, Antarctica. They were airborne for 60 and 106 hours with trajectory lengths of 885.8 km and 2367.4 km, respectively. The most interesting feature detected was a mesoscale anticyclone over the Weddell Sea and the coastal zone, which was reproduced by the WRF model with reduced intensity. Another balloon launched from Aboa in January 2017 was airborne for 157 hours and made a trans-Antarctic flight before it landed in the Ross Sea. It made multiple deep soundings to the surface over the interior of the continent.

The results above demonstrate that CMET balloons are a valuable approach for profiling the free atmosphere and boundary layer in remote regions such as Polar Regions.
Surface Temperature Inversions (STIs) are typical features of the polar atmosphere. They are principally due to a) the imbalance between outgoing longwave radiation from the surface and downwelling shortwave and longwave radiation, leading to a surface cooling, and/or b) the advection of warm air over a cooler surface layer. Recently, it has been suggested that STIs play an important role in the Arctic winter warming damping the infrared cooling of the lower atmosphere, and thus constituting a positive warming feedback contributing to the Arctic Amplification.

The present study show and discusses the variability of the vertical temperature profile retrieved by a RPG Humidity And Temperature PROfiler (HATPRO-G2) installed at the Thule High Arctic Atmospheric Observatory (THAAO, 76.5° N, 68.8° W, http://www.thuleatmos-it.it/, Northern Greenland) in July 2016. A statistical retrieval is used to estimate the temperature profile from the brightness temperatures measured by HATPRO. The retrieval accuracy in the Arctic environment is studied by comparing the obtained profiles with radiosondes launched in summer and wintertime. The temperature evolution and vertical structure of the atmosphere at THAAO in the period July 2016-March 2018 is discusses together with the occurrence and intensity of STIs. The relationship between and STIs and cloud occurrence is also investigated.
Observations and the Source Investigations of Boundary Layer BrO at Ny-Ålesund

Yuhan Luo\(^1\) (yhluo@aiofm.ac.cn), Fuqi Si\(^1\), Haijin Zhou\(^1\), Yi Liu\(^2\), Wenqing Liu\(^1\)
\(^1\)Chinese Academy of Sciences, Hefei Institutes of Physical Science, Hefei, China, \(^2\)University of Science and Technology of China, Hefei, China

Bromine monoxide is a reactive halogen species which has profound impact on the chemistry of the tropospheric polar boundary layer. A considerable challenge for understanding enhanced BrO and the associated ODEs is the difficulty of real-time observations. In this study, we found a typical process of enhanced bromine and depleted ozone in Ny-Ålesund boundary layer using ground based differential optical absorption spectroscopy (DOAS) techniques in late April 2015. BrO was observed as high as \(6 \times 10^{14}\) molecular cm\(^{-2}\), while the in-situ ozone and gaseous mercury reduced by 85\% and 90\% separately at the same period. The largest BrO column densities were found at elevation angle of 2° above the horizon. The vertical distribution of BrO was present at 0.5-1km layer using radiative transfer model simulation. Although the HYSPLIT model and satellite data showed air masses coming from the High Arctic area, which was enriched in bromine, the sea ice in the Kings Bay area, occurred only for a short period exactly during the enhancement, was considered as the main local source of this bromine enhancement event. The key role of bromine on the atmospheric oxidation and the ecosystem will be further discussed.
Multi-scale Modeling and Measurements of Arctic Clouds

Ben Hillman¹ (bhillma@sandia.gov), Dari Dexheimer¹, Erika Roesler¹
¹Sandia National Laboratories, Albuquerque, United States

Arctic clouds are important to the radiative budget, but they are difficult to represent in atmospheric general circulation models (AGCMs). Three approaches to improving Arctic clouds in models are presented. First, a cloud system resolving model (CSRM) is embedded into each gridcell of a traditional AGCM to explicitly simulate more cloud processes. Second, a variable resolution AGCM is used to understand modeled cloud response to increasing horizontal resolution. Third, stand-alone large eddy simulations (LES) are used to explicitly resolve cloud processes. The AGCM simulations have a negative low cloud amount bias when compared with multi-year satellite retrievals. The Atmospheric Radiation Measurement program’s (ARM) third ARM Mobile Facility (AMF3) and the restricted airspace associated with it at Oliktok Point, Alaska, are used to operate a tethered balloon system (TBS). Sensors deployed on the TBS are compared with the ground-based instrumentation also at the site, and with the AGCM and LES simulations previously described. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525. SAND2017-12294 A.
The Canadian Arctic Weather Science Project: An Overview

Stella Melo\textsuperscript{1} (stella.melo@canada.ca), Zen Mariani\textsuperscript{1}, Gabrielle Gascon\textsuperscript{2}, Barbara Casati\textsuperscript{3}, William Burrows\textsuperscript{2}, Armin Dehghan\textsuperscript{1}, Paul Joe\textsuperscript{1}, David Hudak\textsuperscript{1}

\textsuperscript{1}Environment & Climate Change Canada, Science and Technology, Meteorological Research Division, Toronto, Canada, \textsuperscript{2}Environment & Climate Change Canada, Meteorological Services of Canada, Edmonton, Canada, \textsuperscript{3}Environment & Climate Change Canada, Science and Technology, Meteorological Research Division, Montreal, Canada

ECCC established two supersites at western and Eastern Arctic for understanding weather and climate, testing suitable observation technology and support validation of space-borne observations of wind, aerosols, cloud and precipitation from ADM-Aeolus, EarthCARE and Global Precipitation Mission. Winds can be localized and impact the distribution of snow and ice affecting human activity and navigation. Aerosols from mid-latitudes can impact the cloud/precipitation distribution affecting the radiation balance and resulting in intensification of cold air outbreaks that affect mid-latitudes. The weather in Whitehorse is at the confluence of the Pacific Ocean, the Western Cordillera, the North American continent and the Arctic Ocean and is challenge to predict. Iqaluit is at the center of different Arctic large scale weather systems and Eastern seaboard of North America. Observations at the Iqaluit (64°N, 69°W) revealed high frequency (40% daily occurrence) of multiple (4-10) wind layers (0.2 to 4.4 km in depth) from surface to 7.2 km. These stratified wind layers are visible as shifting wind directions with height in Doppler lidar and dual-polarization Ka-band radar range-height scans and in the Doppler lidar and radiosonde data. Analysis showed that NWP surface variables were inaccurately predicted during wind layer events. Surface-based inversions can exceed 10 K with depths as large as 1 km the model appears to underestimate their intensity or fail to predict any inversion.
The Surface wind Circulation over a Complex Terrain of Central Spitsbergen

Kamil Láška1,2 (laska@sci.muni.cz), Zuzana Chládová2,3, Jiří Hošek2, Josef Elster2

1Masaryk University, Brno, Czech Republic, 2University of South Bohemia, České Budějovice, Czech Republic, 3Institute of Atmospheric Physics, Czech Academy of Sciences, Prague, Czech Republic

Better understanding of the Svalbard climate conditions requires a comprehensive knowledge of atmospheric boundary-layer processes including the effects of local topography and ground surface properties. The atmospheric boundary layer often includes large vertical gradients in air temperature, humidity as well as wind speed, which is mainly generated by a complex interaction of a large-scale circulation and small-scale processes. The aim of the study is to 1) compare surface wind measurements and reanalysed low-level geostrophic winds in the period of 2013-2016, and 2) evaluate a role of topography on spatiotemporal variability of winds within a fjord. For studying near-surface wind characteristics in central Spitsbergen (Billefjorden area), we chose three sites differing in terrain elevation and local surface properties: Petuniabukta terrace (15 m a.s.l.), Mimerbukta terrace (20 a.s.l.), and the top of Mumien Peak (773 m a.s.l.). Patterns of atmospheric circulation were identified using 1000-, 925- and 850-hPa geopotential heights and geostrophic winds based on the ERA5 reanalysis data provided by the ECMWF. Our results indicate that a large-scale flow was often modified by channelling and drainage effects accompanied by an increase in wind speed and wind direction frequency at the coastal sites. On the other hand, the near-surface wind at the top of the Mumien Peak was most similar to the geostrophic wind, irrespective of the circulation type.
In climate and weather prediction models the near-surface turbulent fluxes of heat and momentum and related transfer coefficients are parameterized on the basis of Monin Obukhov similarity theory (MOST). Its application requires an iterative solution of the MOST equations. To avoid iteration many models determine the transfer coefficients using the Louis method relating the stability parameter $\zeta = z/L$ (L is the Obukhov length and $z$ is height) to the bulk Richardson (Rib) number. However, the presently used methods are valid only for larger surface roughness and weaker stability than observed over the polar oceans. In contrast to the popular methods of polynomial fitting we propose an approximate solution that results in $\zeta$ as a function of Rib and of the surface roughness. For the stability functions we use those based on SHEBA data (Grachev et al. 2007) and thus on the most modern data over sea ice. Using the new $\zeta$ approximation, bulk transfer coefficients for momentum and heat are obtained without iteration depending on stability and surface roughness. It is shown that these coefficients reproduce the coefficients obtained by the classical, iterative solution of the MOST equations with a mean accuracy of 5% for Rib between 0 and 0.3 for a large range of surface roughness. At large Rib the new bulk transfer coefficients are much smaller than those currently used. The new non-iterative parametrization can be easily implemented in climate and weather forecast models.
 Boundary-layer Structure during Super-cooled Fog Events at Summit, Greenland

Christopher Cox1,2 (christopher.j.cox@noaa.gov), William Neff1,2
1Cooperative Institute for Research in Environmental Sciences, Boulder, United States, 2NOAA/Earth System Research Laboratory/PSD, Boulder, United States

Persistent stable stratification of the boundary layer at Summit, Greenland (72.58ºN, 38.48ºW, 3210 masl) drives the development of liquid fogs by surface radiative cooling. These fogs are most common from June through October and are super-cooled, typically ~ -20 ºC. We present case studies from June 16th and 23rd, 2013 that are associated with the diurnal development of surface-based temperature inversions during clear skies, each lasting ~10 hours. We analyze measurements collected by meteorological sensors, cloud particle probes, and isotopic vapor composition from a 46 m tower, as well as a nearby high resolution minisodar and other remote sensors. The common driving mechanism and the typical transition in the boundary-layer from stable stratification to a shallow convective layer led to similarities between the cases in the evolution of the fog microphysics. There were important differences too, such as in the liquid water path, which was larger on the 16th and suppressed the surface cooling. We explore how these differences may be related the boundary-layer structure, including Kelvin-Helmholtz instability identified on the 16th while the liquid water path was high, and transient disturbances of the boundary layer at 10 to 20 minute intervals during the 22nd and 23rd. Improved understanding of the physical processes that govern fogs will inform on the importance their representation in the models used for ice sheet surface energy and mass balance projections.
The Role of Atmospheric Rivers and Summer Surface Melting in Greenland

William Neff1,2 (william.neff@noaa.gov), Mathew Shupe1,2, Gilbert P. Compo1,2
1NOAA/Physical Sciences Division, Boulder, United States, 2University of Colorado, CIRES, Boulder, United States

Past work implicated atmospheric rivers (ARs) in the melting of the surface of the Greenland Ice Sheet (GIS) in 2012 and 1889 (Neff et al. 2014). In this work we examine the degree of melt along the western slopes of the GIS from 2000 to 2012. We compare three different reanalyses (ERA-I, NCEP, and 20CR) in their ability to detect the northward transport of moisture to the west of the GIS and then compare such events with the degree of melt for the period June-August (available through NSIDC). We assessed the three reanalyses at four locations to the west of the GIS, between 50N and 66N, comparing wind speed and direction at 850 hPa and total integrated water vapor (IWV). Events were detected using thresholding of wind speed and IWV at 60N and 66N. These events were compared with the fraction of melt observed in two geographical regions west of the highest topography: from -55W to -43W and south to north 63N to 68N and 68N to 73N. Two case studies will also be presented: One will be an AR on 18 August 2000 with extensive melt inland and temperatures just below freezing at Summit Station and one on 24 August 2011 that produced significant rain along the coastal glaciers (Doyle et al. 2015) with more limited melt inland. We will also explore the potential of identifying the impact of ARs on the GIS using the 20CR back to 1880.
The Meteorology and Chemistry of High NO Concentrations at the South Pole

William Neff1,2 (william.neff@noaa.gov), James Crawford3, Marty Buhr4, John Nicovich5, Gao Chen3, Douglas Davis5
1University of Colorado, CIRES, Boulder, United States, 2NOAA/Physical Sciences Division, Boulder, United States, 3NASA Langley Research Center, Science Directorate, Hampton, United States, 4Air Quality Design, Golden, United States, 5Georgia Institute of Technology, Earth & Atmospheric Sciences, Atlanta, United States

This presentation summarizes key results from a recent paper submitted to ACPD (doi.org/10.5194/acp-2017-812). Our study examined the effect of the seasonal cycle in meteorology from November through December and the effect of stratospheric ozone depletion on the photochemical production of nitrogen oxide (NO) from nitrate in the snow at the South Pole. We found a systematic evolution of the large-scale wind system at 300 hPa over the ice sheet from winter to summer that controls the surface boundary layer and its effect on NO: Initially in Early Spring (Days 280-310) the transport of warm air and clouds over West Antarctica dominates the environment over the South Pole; In Late Spring (Days 310-340), of significance to NO, the winds at 300-hPa exhibit a bimodal behavior alternating between NW and SE; In Early Summer (Days 340-375), the flow aloft is dominated by winds from the Weddell Sea. During Late Spring, winds aloft from the SE are strongly associated with clear skies, shallow stable boundary layers, and light surface winds from the east: it is under these conditions that the highest NO occurs. We also found that ozone depletion which now extends into late November-early December coincides with optimum conditions (clear skies, strong surface temperature inversions, and light winds) for high concentrations of NO to accumulate at the surface.
An Evaluation of the WRF Model for the Antarctic Peninsula

Elcin Tan\textsuperscript{1} (elcin.tan@itu.edu.tr)
\textsuperscript{1}Istanbul Technical University, Department of Meteorological Engineering, Istanbul, Turkey

The near-surface wind field of Antarctica is determined by Katabatic winds which is originated by the occurrences of the strong temperature inversion zone, whose intensity is driven by the temperature gradient between surface and the atmospheric layer above it. Numerical weather prediction studies show that large and mesoscale circulation pattern can be captured with reasonable accuracy by having small biases (Turner et al., 1996; Van Den Broeke, 1997; Wilson et al., 2012). In this study, The Polar WRF model is used to simulate the atmospheric conditions of selected days of 2016 for each season. The model is configured with three nested domains to provide high-resolution model outputs which are compared to in situ observations of the Antarctic Peninsula. The finest domain resolution of the model is 1 km. The model offers multiple physics options for microphysics, radiation, cumulus parameterization, boundary layer, snow surface physics and sea-ice treatment. MODIS land use/cover data is adapted to the model to determine the snow surface characteristics of the model more accurate. The WRF configuration is designed to have 45 terrain-following vertical levels. Initial and boundary conditions are obtained from NCEP/NCAR Reanalysis data. The results of the WRF model are compared to the available temperature and wind data of automatic weather stations on the Antarctic peninsula to discuss katabatic wind patterns and their relations with temperature gradients.
This study investigates characteristics of the atmospheric boundary layer (ABL) observed over continental Antarctica during the Concordiasi campaign in spring 2010. The Concordiasi dropsondes are high-resolution atmospheric profile measurements, valuable for studying the ABL. The surface air temperature is in good agreement with collocated 2 m air temperature from the Antarctic Mesoscale Prediction System (AMPS). Regional analyses show that the ABL is often well-mixed in the west and southeast regions of the continent. Increased temperature and wind speed shear associated with synoptic disturbances is the likely cause for the high frequency of well-mixed ABLs in West Antarctica. Higher temperatures and wind speed shear are also associated with well-mixed ABLs in northern Antarctica. In other regions, thermal effects appear to dominate over mechanical mixing in the ABL. Solar heating plays an important role in eroding surface-based inversions and mixing the ABL in higher latitudes (south of 80°S). A similar effect is observed along the slopes of the east Antarctic plateau, where adiabatic warming associated with downsloping winds appears to increase surface air temperatures and reduce boundary layer stability. Although we do not measure cloud properties, the dewpoint depression profiles suggest that the most pronounced saturation differences (and associated longwave feedback) between stable and well-mixed ABLs may occur along the eastern coastal regions of Antarctica.
The contrasting geographies of the Southern and Northern hemispheres play a significant role in the observed Rossby wave regimes. In addition to differences in the continental distribution and the location of major north-south mountain chains, the mean equator-to-pole temperature difference is significantly larger in the Southern Hemisphere (around 70 K) than in the Northern Hemisphere (around 40 K). The evolving nature of these wave regimes have been extensively studied in climate models and re-analyses. Planetary wave amplitude is a challenging measurement compared to parameters such as wave propagation speed, jet strength and location, and wavenumber. In this study, the evolution of planetary wave amplitudes over the 20th Century are analyzed using a novel implementation of the quasi-geostrophic wave activity parameter. The trajectories of change are distinctive between the hemispheres and can be linked to sea ice properties.
A key issue to be resolved in cryospheric science is to fully understand and explain the contrast between Antarctic and Arctic sea ice change: Why Antarctic sea ice has been stable or even slightly increased while Arctic sea ice has been reduced drastically in the past several decades? We discuss multiple interactions and processes controlling the polar sea ice covers. We present results from SeaWinds scatterometer aboard the QuikSCAT satellite and from aircraft acquired during the NASA’s Operation IceBridge (OIB). Results indicate that Antarctic sea ice cover is encapsulated by a band of circumpolar frontal ice zone (FIZ) containing older, rougher, and thicker sea ice in the zone adjacent to the sea ice edge. This is in a stark contrast to Arctic sea ice where the marginal ice zone (MIZ) consists of young and thin sea ice along the ice edge, which is easily reduced by melt and by wind and wave effects. For Antarctic sea ice, topography and bathymetry, which are stable geological factors, can have a significant role in sea ice processes that must be considered in explaining the overall stability of Antarctic sea ice. Finally, we will describe the 2017 OIB/TanDEM-X Antarctic Science Campaign (OTASC) to obtain extensive observations in characterizing Antarctic sea ice, by coordinating NASA Operation IceBridge (OIB) aircraft with DLR TanDEM-X satellite SAR data acquisitions together with other multi-sourced remote sensing data and surface field measurements.
The Warm Arctic-Cold Siberia Temperature Pattern: Has it Happened before?

Martin Wegmann\textsuperscript{1,2} (martin.wegmann@univ-grenoble-alpes.fr), Yvan Orsolini\textsuperscript{3}, Olga Zolina\textsuperscript{2,4}
\textsuperscript{1}Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Bremerhaven, Germany,
\textsuperscript{2}University of Grenoble, Institut des Géosciences de l’Environnement, Grenoble, France,
\textsuperscript{3}Norwegian Institute for Air Research, Kjeller, Norway,
\textsuperscript{4}P.P. Shirshov Institute of Oceanology, Moscow, Russian Federation

The Warm Arctic-Cold Siberia surface temperature pattern during recent boreal winter is suggested to be triggered by the ongoing decrease of Arctic autumn sea ice concentration and has been observed together with an increase in mid-latitude extreme events and a meridionalisation of tropospheric circulation. However, the exact mechanism behind this dipole temperature pattern is still under debate, since model experiments do not support this sea ice forcing. We use the early Twentieth Century Arctic warming as a case study to investigate the link between September sea ice in the Barents-Kara Sea and the Siberian temperature evolution. Analysing a variety of long-term climate reanalyses, we find that the overall winter temperature and heat flux trend can be largely attributed to a reduction of September BKS sea ice. Tropospheric conditions show a strengthened atmospheric blocking over the BKS, strengthening the advection of cold air from the Arctic to Central Siberia on its eastern flank, together with a reduction of warm air advection by the westerlies. This setup is valid for both, the early and the current Arctic warming period.
Impact of Permafrost Melting on the Hg Cycling in Thermokarst Pond

Martin Pilote¹ (martin.pilote@canada.ca), Joao Canario², Christian Gagnon¹
¹Environment and Climate Change Canada, Aquatic Contaminants Research Division, Montreal, Canada,
²University of Lisbon, Department of Chemical Engineering, Lisbon, Portugal

Mercury naturally occurs as elemental mercury (Hg⁰) and organic and inorganic species as well. Microorganism can transform inorganic Hg to methylmercury (MeHg), and thus easily bioaccumulated in biota and biomagnified in the food web. Melting permafrost has the potential to release a large proportion of previously stored Hg and organic carbon that could alter the Hg cycling in permafrost zone and subarctic region. The aim of this study is to characterize Hg levels and carbon contents in thermokarst ponds during the cold and the growing season, to assess the contribution of allochtonous input of Hg and to evaluate their potential transport towards the aquatic system. Thaw ponds are formed by the collapse of peat mounds in discontinuous permafrost, eastern Canadian subarctic region. Our results suggest a strong link between MeHg production, nutrient status and the importance of anaerobic methylation. Winter results will be compared to summer measurements in order to assess the biogeochemical cycle of Hg in warmer months and to evaluate the potential Hg transport towards the aquatic system. Quantifying the Hg source originating from melting permafrost and soil leaching in subarctic and Arctic region in a changing climate is crucial of interest to assess the Hg dynamic in the aquatic ecosystem and the food chain.

Arctic Precursors of Changing Eurasian Storm Tracks and Surface Climate

Pawel Schlichtholz1 (schlicht@iopan.gda.pl)
1Institute of Oceanology, Polish Academy of Sciences, Sopot, Poland

Since synoptic eddies forming midlatitude storm tracks shape the day-to-day weather and several aspects of surface climate, seasonal predictability of their seasonal mean activity is of paramount importance to society. While some seasonal predictability of the Pacific storm track and related climate variations in North America is provided by atmosphere-ocean coupling in the tropics, seasonal predictability of Eurasian storm track variations has not been demonstrated yet. Here statistical analyses of atmospheric reanalysis (NCEP/NCAR) data and observed Arctic sea ice concentration (SIC) in the era of satellite observations (1979-2017) are used to identify linkages of a dominant mode of interannual variability in wintertime upper-tropospheric storm tracks over Eurasia to the concurrent surface climate anomalies and pre-winter Arctic SIC variations. This mode explains an exceptionally large fraction (about 70% of the variance) of the North Atlantic Oscillation (NAO) and of a leading mode of Eurasian surface air temperature variations. As more than 50% of its variance is found to be accounted for by October SIC anomalies in the Barents/Kara Sea, we conclude that wintertime Eurasian climate variability is to a large extent predictable. It is further shown that the predictability of the storm track/NAO system from Arctic sea-ice anomalies might have increased after the acceleration of the Arctic sea-ice decline in the 2000's.
The Arctic is regarded as one of the most vulnerable regions to climate change. Retreat and thinning of glaciers is a prominent response, which, in turn, alters the functioning and importance of processes in proglacial and periglacial zones. When deglaciated, fluvial (along with slope) processes substantially determine the evolution of landscape and thus represent an important topic in climate change studies. Despite the progress in an understanding of fluvial systems over the past decades, lack of empirical studies in various environmental conditions has limited to address handul of questions such is the difference in importance of controls on hydrological response of streams across catchments. In the study, we focus on a description of relationship between meteorological factors and hydrograph during two ablation seasons in three catchments (Elsa, Ferdinand, Bertil Streams) in Billefjorden, Svalbard. These have similar geology, geomorphology and climate; however, they differ in an extent of glaciers. Meteorological variables are represented by air and ground temperatures, global radiation, precipitation, wind speed and direction, all measured by automatic weather stations with one-hour interval. Discharges were obtained in stable gorges near the outlet into the sea by applying discharge - water stage rating curve using continuous hydrostatic pressure sensors and handheld Acoustic Doppler Velocimeter.
Sea Ice Influence onto Eurasian Snow Revealed by Model Sensitivity Experiments

Maria Santolaria-Otin¹ (maria.santolaria-otin@univ-grenoble-alpes.fr), Olga Zolina¹, Fumiaki Ogawa², Ho Nam Cheung², Noel Keenlyside²

¹Université Grenoble-Alpes, Institut des Géosciences de l’Environnement, Saint Martin d’Hères, France,
²University of Bergen & Bjerknes Centre, Geophysical Institute, Bergen, Norway

Snow is a critical element of the Arctic system and is rapidly changing due to global warming with unexpected impacts on environment, society and economy. Snow variations affect the atmosphere via changes in their reflectance of shortwave solar radiation (albedo), emissivity of longwave radiation, insulation of the atmosphere from the soil below and latent-heat and water-release in association with melting. Understanding snow processes is a crucial need. Here, we show an intercomparison of an ensemble of CMIP5 models with observations for snow-related variables over the Arctic climate system for historical runs and future projections in different RCP scenarios. Moreover, we perform two different sensitivity experiment prescribing SIC and SST with two atmospheric model CAM4 (low-top) and WACCM (high-top) to investigate the influence of sea ice on Eurasia regarding variability and trends of snow cover and on the atmospheric circulation on the North Atlantic sector.
A Climatology of Strong Large-scale Ocean Evaporation

Franziska Aemisegger1,2 (franziska.aemisegger@env.ethz.ch), Lukas Papritz3,4
1ETH Zurich, Institute for Atmospheric and Climate Science, Zurich, Switzerland, 2Centre for Environmental and Climate Research, Lund University, Lund, Sweden, 3Geophysical Institute, University of Bergen, Bergen, Norway, 4Bjerknes Centre for Climate Research, Bergen, Norway

In this presentation an object-based, global climatology (1979-2014) of strong large-scale ocean evaporation (SLOE) is presented. This study is based on the reanalysis data set ERA-Interim from the European Centre for Medium-Range Weather Forecasts (ECMWF). The mechanisms underlying the frequent occurrence of SLOE are discussed as well as the typically associated climatic properties. In polar regions more than half of the total wintertime evaporation is associated with SLOE. An analysis of the past history and fate of air parcels involved in cold season SLOE in the North Atlantic and the Southern Indian Ocean shows that cold advection is the main mechanism that induces these events. Extratropical cyclones thereby play an important role in setting the necessary equatorward synoptic flow. An analysis of the interannual variability of SLOE associated with the North Atlantic Oscillation and the Southern Annular Mode shows that SLOE is very sensitive to the location of the storm tracks in both hemispheres. This study highlights the strong link between transient synoptic events and the spatio-temporal variability in ocean evaporation patterns. The possible implications of this study for our understanding of the water cycle at mid- to high latitudes and for the interpretation of deuterium excess as a proxy for changes in climatic conditions are highlighted.
Oceanic and atmospheric warming of Greenland and surrounding areas has led to increased ice sheet spatial melt extent and decreased sea ice coverage during the summer months. The last two decades have witnessed increased warm air and moisture advection into the region from Greenland blocks and transient synoptic patterns that have exasperated the background warming signal and led to several melt season anomalies and isolated extreme melt events. The scope of the melt season is also evolving rather rapidly, particularly throughout much of Baffin Bay and adjacent portions of the western Greenland Ice Sheet, where melt (freeze) is occurring earlier (later) within the annual melt cycle. Less is known, however, about processes driving ice sheet and sea ice changes at the temporal boundaries of the melt season and how these ice environments physically interact during times of melt and freeze onset. Utilizing observational data from passive microwave satellite sensors, in situ weather stations, and reanalysis products we look to better understand the local sea/land ice interactions by 1) assessing relationships between the timing of melt and freeze onset, and 2) evaluating preconditioning factors, such as heat and moisture intrusions, that influence subsequent melt responses. Emphasis is placed on the autumn freeze onset period and how processes leading to a fluctuating freeze date influence ice sheet and sea ice melt during the subsequent spring.
Reason for Accelerated Decline in Arctic Sea Ice in Recent Decades

Leijiang Yu1 (yuleijiang@pric.org.cn)
1Polar Research Institute of China, Shanghai, China

In recent decades, the Arctic sea ice has been declining at a rapid pace along with a significant warming in the region at a rate of twice the global average. The underlying physical mechanisms for the Arctic warming and accelerated sea ice retreat are not fully understood. We present evidence that the anomalous autumn Arctic intrinsic atmospheric modes could explain as much as 50% of autumn sea ice decline for the 1979-2016 period. The Arctic atmospheric circulation anomalies associated with anomalous sea surface temperature patterns over the North Pacific and North Atlantic influence sea ice concentrations primarily through anomalous water vapor advection and associated radiative feedback.
The influence of global warming on the Arctic sea-ice exhibits a profound declining trend as expected. In contrast, sea-ice around Antarctica exhibits an overall expansion with regional heterogeneity that comprises of increasing and decreasing pattern in different sectors. Regional sea-ice variability in the Indian Ocean sector of the Antarctica (IOSA) during 1979-2015 revealed significant expansion of sea-ice extent at an average annual rate of 2.4%±1.2 per decade. The sea-ice expansion trend in this sector has a substantial seasonal variability which peaks in summer (10.6%±4.1 decade$^{-1}$), followed by autumn (4.0%±1.6 decade$^{-1}$), winter (1.9%±0.9 decade$^{-1}$) and spring (1.7%±1.2 decade$^{-1}$). Result showed robust features of sea surface freshening and cooling trend (up to ~100m depth) in the IOSA region which is conducive for expansion in sea-ice. The spatial trend map of sea surface temperature (SST) shows wide spread cooling throughout all seasons. Analysis of Ocean Reanalysis System 4 (ORAS4) and Met office EN4 observations shows sub-surface warming trend below ~100m depth, possibly from advection of modified circumpolar deep water which advects warm water onto the ice-shelf. In the present work, the mechanism of observed sea-ice expansion is analysed with respect to SST, winds, current, heat flux, vertical thermohaline structures, and leading climate oscillator of ocean-atmospheric coupled phenomenon.
Bi-Polar Sea-ice Trends - An Overview of Possible Teleconnections

Girija Kalyani Burada¹ (girija.kalyani18@gmail.com), Alvarinho J Luis¹
¹National Center for Antarctic and Ocean Research, Polar Sciences, Vasco da Gama, India

Currently, Arctic sea ice extent for Sep 2017 was 4.87 million sq km, 7th lowest in the entire satellite record since 1979 and was 1.67 million sq km (1.24 million sq km) below (above) the 1981-2010 average (Sep record low-2012). Antarctic sea ice has reached its maximum extent on Sep 15, at 17.98 million sq km among the earliest maxima on record. If this extent holds, it will be second lowest daily maximum in the satellite record at 20000 sq km above 1986 record. Antarctic sea ice extent has been record low since Sep 2016 though it has recorded highest until 2014-15. What is causing these drastic inter-annual changes? These changes are definitely causing on longer temporal forcing of multiple teleconnections. Depending on which teleconnection is strong on a particular time-period, which is weakening the other whilst together influencing sea-ice. We explain how multi-decadal scale teleconnections are acting on inter-decadal, inter-decadal on decadal, thereby annular modes and local factors. Study addresses how Pacific Decadal Oscillation (20-30 years)-Inter decadal Pacific Oscillation(15-30)-Atlantic Multi-decadal Oscillation-North Atlantic Oscillation-El Nino Southern Oscillation(2-7), Indian Ocean Dipole (1-2)-Annular Modes (North & South) had affected the polar climate over a period; thereby enhancing local factors. Since both the poles are behaving anomalously in terms of sea-ice, we focus on outlining the changes driving these on a broader scale with possible evidences.

Response to the Arctic Sea Ice Decline in a Regional Climate Model

Vladimir Semenov1,2 (vasemenov@mail.ru), Mikhail Varentsov3
1A.M.Obukhov Institute of Atmospheric Physics, Russian Academy of Sciences, Moscow, Russian Federation,
2Institute of Geography RAS, Moscow, Russian Federation, 3Lomonosov Moscow State University, Moscow, Russian Federation

Record high global temperatures in the beginning of the 21st century were accompanied by more frequent anomalously cold spells during winter in the Northern Eurasia. A number of previous studies based on empirical data analysis and global atmosphere general circulation models revealed a link between negative surface air temperature anomalies and rapid Arctic sea ice reduction. A mechanism of such a link is under discussion. The major hypothesis is based on interaction between large-scale atmospheric circulation and anomalous wave activity induced by low troposphere heating in the areas of sea ice retreat. The response can also be explained by regional circulation response to the modified local temperature contrasts. In order to test a possibility of the regional response, we performed ensemble simulations with COSMO regional atmospheric model for the region covering a part of the Northern Eurasia and Eastern Arctic. Simulations were performed for high and low sea ice concentrations in the Barents Sea and strong and weak zonal circulations for the both low and high sea ice cases. The model reproduced anticyclonic circulation anomaly in the southern Ural region accompanied by negative temperature anomalies as a response to the sea ice reduction only under conditions of a weak zonal flow. The results support a possibility of the regional response independent on interaction with stratosphere and/or circumpolar circulation modes and highlight a role of background circulation.
The Impacts of Greenland Ice Sheet Collapse on the Tides in Hudson Bay

Anna Hayden1 (anna-mireilla.hayden@mail.mcgill.ca), Natalya Gomez1, Sophie-Berenice Wilmes2, J.A. Mattias Green2

1McGill University, Earth and Planetary Sciences, Montreal, Canada, 2Bangor University, School of Ocean Sciences, Menai Bridge, United Kingdom

In Hudson Bay, sea level changes associated with Greenland ice loss vary across the bay and differ significantly from the change in global mean sea level equivalent due to gravitational effects. Changing water depths give rise to changes in ocean tides, for which tidal energy dissipation and tidal amplitudes are directly linked to ocean bathymetry (Green, 2010). In the present study, we investigate the impact of sea level changes on tides in Hudson Bay, Canada - a region where tidal energy dissipation is strongly sensitive to bathymetry (e.g. Egbert and Ray, 2000), and the bathymetry is in turn highly uncertain in some parts of the bay. Recent work by Wilmes et al. (2017) indicates that regional variability in future sea level changes as a consequence of ice sheet collapse will impact tides globally, in particular in Hudson Bay. We present simulations of the sea level changes associated with a suite of Greenland ice loss scenarios using a gravitationally self-consistent sea level model (Gomez et al., 2010) and consider the impact of these sea level changes on tides in the Hudson Bay using the OTIS tidal model. We also investigate the sensitivity of our tidal calculations to uncertainty in regional bathymetry. Our results aid in constraining the response of Hudson Bay tidal dynamics to projected sea level changes, elucidating the feedbacks between energy dissipation and shoreline migration, and assessing the impact of climate change on coastal regions in the Hudson Bay.
Predicting Arctic Sea Ice Extent using Causal Effect Networks

Sha Li¹ (ariel14.lis@gmail.com), Muyin Wang², Jiping Liu³, Yuqi Bai¹, Shiming Xu¹, Bin Wang¹,²
¹Tsinghua University, Department of Earth System Science, Beijing, China, ²University of Washington, Joint Institute for the Study of the Atmosphere and Ocean, Seattle, United States, ³State University of New York at Albany, Department of Atmospheric and Environmental Sciences, Albany, United States, ⁴Chinese Academy of Sciences, State Key Laboratory of Numerical Modeling for Atmospheric Sciences and Geophysical Fluid Dynamics (LASG), Institute of Atmospheric Physics, Beijing, China

Chukchi and East Siberian seas play a vital role in the polar resource exploration and ship transportation. In this study a novel data-driven approach named causal effect networks (CEN) was applied to explore the potential factors triggering the sea-ice loss in this region. The CEN is an adjusted causal discovery method, which can reduce data dimension by initially selected regional mean time series and avoid false correlations by conditionally independence tests. We took September sea-ice extent (SIE) as an example to know how it correlates with potential predictors including downward short- and long-wave radiation, sea surface temperature, and winds. It is shown that the predictors from selected lower-latitude regions are more closely related to September SIE than that from the local areas. The results are sensitive to parameters in the algorithm, such as significance level, temporal resolution, and max leading time. On the monthly scale, $R^2$ values for all the models exceed 0.97 when the max leading time is less than nine months with other parameters fixed. If the max leading time is seven months, the best prediction model can explain 98.7% of September SIE variance by Leave-One-Out Cross-Validation. We found the earlier zonal winds at 10 m height near the tropical eastern Pacific and Inner Mongolia are both the most significant predictors, while the downward long-wave radiation to the south of Greenland is an important heat source associated with September sea-ice loss.
Large-scale Atmospheric Teleconnection Related to Pan-Arctic Wildfire Activity

Jin-Soo Kim¹ (jinddu@gmail.com), Jong-Seong Kug¹, Gabriela Schaepman-Strub²
¹Pohang University of Science and Technology, Division of Environmental Science and Engineering, Pohang, Korea, Republic of, ²University of Zurich, Department of Evolutionary Biology and Environmental Studies, Zurich, Switzerland

The pan-Arctic has the potential for positive carbon-climate feedbacks by releasing a substantial amount of carbon buried in the permafrost zone. Wildfires can rapidly transfer carbon to the atmosphere, thereby playing an important role in the pan-Arctic terrestrial carbon cycle. One expected response to recent pan-Arctic warming is an increase in wildfire activity, but satellite-based observations suggest that the interannual variability of wildfires is much higher than a linear increase. We found diverse large-scale atmospheric teleconnections with wildfire activity in East Siberian and North American permafrost regions. However, dipole structures in sea-level pressure between Arctic and pan-Arctic commonly drive temperature anomalies in the pan-Arctic region and directly modulate wildfire activity. This dipole pattern is consistent with previous studies that showed teleconnections related to Arctic temperature variation via Rossby wave propagation. Furthermore, some large-scale atmospheric teleconnections lead few months later to wildfire activity; therefore, these climate variabilities could be a possible predictor for the pan-Arctic wildfire activity.
Landscape and Climate Interaction on sub-Antarctic Marion Island

Werner Nel\(^1\) (wnel@ufh.ac.za)

\(^1\)University of Fort Hare, Department of Geography and Environmental Science, Alice, South Africa

Marion Island in the southern ocean has a hyper-maritime climate and an environment where diurnal processes dominate the landscape. In a diurnal soil frost environment like Marion Island, the impact of climate change on the landscape occur at a higher resolution than for seasonal and permafrost environments and needs investigation at the synoptic time scale. Results from automated and manual measurements of the abiotic characteristics of a variety of habitats show that the passage of synoptic scale weather systems dominated the landscape on Marion Island. These systems influences the thermal characteristics of soil, intensity of rainfall, snowfall, soil frost dynamics, needle ice development, aeolian erosion, the hydrochemistry of stream water and a host of other abiotic processes and its direct and indirect interactions with the ecosystem. This presentation reviews the current knowledge on the interaction between climate and the landscape, the current methodologies employed to investigate these interactions and specifically addresses the possible landscape responses under a future climate.
Atlantic Multidecadal Oscillation Modulates the Impact of Arctic Sea Ice Decline

Fei Li¹ (lifei715@163.com), Yvan Orsolini²
¹Norwegian Institute for Air Research, Oslo, Norway

Arctic sea ice cover has been rapidly declining in the last two decades and the connection between the sea ice decline and the Arctic Oscillation (AO) remain unclear. Here we use both observations and model simulations to investigate how the Atlantic Multi-decadal Oscillation modulates the connection between the sea ice decline and the AO. We find that the sea ice decline during the AMO|− induces increased Ural blocking activity and southward-extended snowpack over Eurasia in December through enhanced cold air advection and moisture transport from the Arctic. The increased Ural blocking activity and extended Eurasian snowpack strengthen the upward wave propagation over the Siberia-North Pacific in the lower stratosphere and hence lead to weakened stratospheric polar vortex and to the negative AO at the surface in February. However, corresponding to the sea ice decline during the AMO|+, one finds extended Arctic warming, less Ural blocking activity, and reduced snowpack over northern Eurasia in December. The stratosphere-troposphere coupling is suppressed in early winter and no negative AO anomaly is found in February. We suggest that the AMO|− is important to regulate the atmospheric circulation response to the Arctic sea ice decline and our study provide insight to the ongoing debate on the connection between the Arctic sea ice decline and the AO.
Causal Effect Networks in Arctic-midlatitude Teleconnections

Peter Yu Feng Siew¹,² (yu.siew@uib.no), Xinshu Fu³, Camille Li¹,², Stefan Sobolowski²,⁴, Martin King²,⁴
¹University of Bergen, Geophysical Institute, Bergen, Norway, ²Bjerknes Centre for Climate Research, Bergen, Norway, ³Nanjing University, Nanjing, China, ⁴Uni Research Climate, Bergen, Norway

Mid-latitude variability can affect and be affected by Arctic climate change. Evidence exists for mechanisms operating in both directions, for example, sea ice decline causing cold winters in Eurasia (Mori et al. 2014), and moisture transport from the mid-latitudes driving sea ice decline (Park et al. 2015). An essential difficulty in investigating Arctic-midlatitude teleconnections is demonstrating causal links in a system with large internal variability. Here, we use causal effect network analysis (Kretschmer et al. 2016) to identify robust causal links between the mid-latitudes and Arctic, and to elucidate the characteristics of their lead-lag behavior. This approach allows us to test a range of pathways within the same framework, using variables such as poleward moisture transport, downward longwave radiation, surface turbulent heat fluxes, Barents-Kara seas ice cover, vertical wave activity, and polar vortex strength. This network analysis builds a clearer picture of the physical mechanisms linking the Arctic and mid-latitudes, as well as their relative importance in today’s climate.

Impacts of Arctic storms on Atlantic Water Transports into the Arctic Ocean

Zhenxia Long1 (longz@dfo-mpo.gc.ca)
1Bedford Institute of Oceanography, DFO, Dartmouth, Canada

The impacts of Arctic storms on the Atlantic water transports into the Arctic Ocean are investigated using a coupled atmosphere-ice-ocean model (NEMO). In the Nordic Sea, Arctic storms play an important role on the air-sea interactions. To understand the impacts of the Arctic storms on the water volume transports through Fram Strait and the Barents Sea Opening, NEMO is implemented in the Arctic Ocean, forced by PHC temperature (salinity), GLORYS currents and CORE II surface fields. Compared to PHC data, NEMO can reliably reproduce the upper layer water temperature and salinity, suggesting a warm layer at intermediate depths. In addition, the model simulations exhibit significant decadal variations of water volume transports through Fram Strait and the Barents Sea Opening. Moreover, the storm activity in the eastern Arctic Ocean plays an important role in the variability of Atlantic water inflows. In the early 1990s and 2000s, while increased storm activity in the Greenland Sea tended to enhance the Atlantic water transport through Fram Strait, the increased Atlantic water inflow through the Barents Sea Opening was mainly associated with the storm activity in the northern Barents Sea. Furthermore, our results also show that the decadal variability in the storm activity is related to decadal variations of atmospheric baroclinicity.
The Atmospheric Circulation Response to Sea Ice Change in an Aquaplanet AGCM

Caroline Holmes\textsuperscript{1} (calmes@bas.ac.uk), Tim Woollings\textsuperscript{2}, David Brayshaw\textsuperscript{3}, Len Shaffrey\textsuperscript{3,4}

\textsuperscript{1}British Antarctic Survey/NERC, Cambridge, United Kingdom, \textsuperscript{2}University of Oxford, Department of Physics, Oxford, United Kingdom, \textsuperscript{3}University of Reading, Department of Meteorology, Reading, United Kingdom, \textsuperscript{4}National Center for Atmospheric Science, Reading, United Kingdom

Despite considerable modelling efforts, there remains uncertainty about the magnitude and nature of the sensitivity of the atmospheric circulation to sea ice change. Here, the impacts of sea ice loss on the global atmospheric circulation are investigated using equilibrium simulations in an aquaplanet AGCM with prescribed, zonally symmetric, sea ice.

Responses can be separated into two broad categories; for sea ice constrained to poleward of 60°, the difference relative to a simulation with no ice is a moderate acceleration on the poleward flank of the eddy-driven atmospheric jet stream which projects increasingly onto the annular mode. For larger extents, anomalies are much larger relative to the magnitude of the forcing and a shift in circulation regime is evident, with the jet and storm tracks shifting polewards and intensifying.

This is consistent with previous work in which sea ice reductions are connected to equatorward shifts in the jet. Moreover, the apparent nonlinearity in the magnitude of the response aids our understanding of the range of responses found in previous studies with models of varying complexity.

It is also demonstrated that jet latitude variability increases as ice extent increases, and that certain features of changes in the jet speed are masked by looking only at the time-mean picture. These results have implications for understanding the impact of different sea ice extents in paleoclimate, as well as the twentieth and twenty-first centuries.
Recent springtime climate extremes have been observed along the northern coast of Alaska. The dates when snow melted at Barrow in 2015 and 2016 were the 4th and 1st earliest recorded, respectively, since 1901. These early years were followed in 2017 by the latest date of snow melt since 1988, nearly seven weeks later than in 2016. Previous work implicates the northward advection of warm air circulating around the Aleutian Low during years of early melt and blocking by the Beaufort High during years of later melt. The same circulation patterns have been linked to the timing of the onset of ice melt in the Chukchi Sea. Here, we further investigate how the transport of Pacific air to the Arctic is linked to the position of the Aleutian Low and its juxtaposition with the Beaufort High. Using reanalysis, satellite and surface-based data sets we analyze how the spatial distribution of air temperature is modified by variability in the atmospheric circulation. Anomalies are further investigated by analysis of the resulting spatial patterns in the timing of snow melt over land areas and melt onset over the sea ice. We introduce a new climate index that explains some of the variance in those variables. This index is suitable for monitoring changes in regional circulation and may be useful for developing seasonal-scale predictive tools.
Variability of Circulation Eddy Energy Components in High Latitudes of Siberia

Elena Kharyutkina¹ (kh_ev@mail2000.ru), Sergey Loginov¹, Yuliya Martynova¹²
¹Institute of Monitoring of Climatic and Ecological Systems SB RAS, Tomsk, Russian Federation, ²Siberian Research Hydrometeorological Institute of Roshydromet, Novosibirsk, Russian Federation

Acceleration of warming in the Arctic region over last decades causes reduction of sea ice cover and intensification of heat exchange between ocean and atmosphere. Observed changes in atmospheric circulation processes lead to climate change in the adjacent regions, for instance, winter cooling in the midlatitudes of Eurasia.

Main goal of this study is the investigation of seasonal variability in energetic characteristic of atmospheric circulation in West Siberia (50°-70°N, 60°-90°E), where special attention paid for its Arctic part. Statistical estimations of climatic variables and energy characteristics (zonal and eddy components of available potential and kinetic energy), were derived using reanalysis data (ERA-Interim, JRA-55) and climate system model INMCM 4.0. The calculation of baroclinic instability parameter fields allowed us to reveal baroclinity zones, to define the changes in its intensity and, as a result, to get an overview about the variability of advection over the region of under study. It was revealed that in the beginning of XXI century the variability of eddy kinetic energy has significant contribution to temperature variability over the territory of West Siberia. Moreover, constructed temporal variability of relative vorticity value (anticyclonic type) showed the increase of this parameter in winter months.

The work is supported by the grant of the RF President MK-2018.2017.5 and by RFBR, according to the research project No.16-35-60088 mol_a dk.
Inter-seasonal Temperature Teleconnections in the Northern Hemisphere

Natalia Gnatiuk¹² (natalia.gnatiuk@niersc.spb.ru), Timo Vihma³, Leonid Bobylev¹⁴
¹Nansen International Environmental and Remote Sensing Centre, St. Petersburg, Russian Federation,
²Ukrainian Hydrometeorological Institute, Kiev, Ukraine, ³Finnish Meteorological Institute, Helsinki, Finland,
⁴Nansen Environmental and Remote Sensing Centre, Bergen, Norway

On the basis of ERA-Interim reanalysis we analysed relationships between Earth surface temperature (Ts) in the Northern Hemisphere (on grid 1.5°-1.5°) and 2-m air temperature (T2m) in 13 selected study regions in Europe, Greenland, and parts of Asia and North Africa for the period 1979-2016. Applying detrended data we eliminated spurious correlations resulting from similar trends in the two variables.

We detected significant correlations between the surface temperature over the Labrador Sea, Canadian archipelago and North Atlantic and 2-m air temperature in different study regions for inter-seasonal spring - summer (MAM-JJA) and autumn - winter (SON-DJF) relationships.

Among the strongest correlations between the spring Ts and summer T2m were the positive correlations found between Ts in the North Atlantic and T2m in Scandinavia, Ts in the Labrador Sea and T2m in Northwest Africa, and Ts in Norther Sahara and T2m in Urals.

As well, among the strongest correlations between the autumn Ts and winter T2m were the positive correlations found between Ts in the North Atlantic and the Labrador Sea and T2m in Scandinavia and Northwest Africa; and the negative correlations found between Ts in the Labrador Sea and the North Atlantic and T2m in Scandinavia, Northeast Europe, Urals, Black Sea region and Northcentral Asia.

Coupled Modes of Barents Sea Ice and Atmospheric Anomalies in Autumn and Winter

Martin King\textsuperscript{1,2} (martin.king@uni.no), Stefan Sobolowski\textsuperscript{1,2}, Camille Li\textsuperscript{2,3}
\textsuperscript{1}Uni Research Climate, Bergen, Norway, \textsuperscript{2}Bjerknes Centre for Climate Research, Bergen, Norway, \textsuperscript{3}Geophysical Institute, University of Bergen, Bergen, Norway

Recent studies report linkages of late autumn Barents-Kara sea ice and winter atmospheric circulation anomalies but it is unclear what the zero-lag feedbacks and higher coupled modes do. Here, we revisit the problem using Maximum Covariance Analysis (MCA), examining not only the first modes but also higher modes that contribute significantly to the squared covariance fraction (SCF). Besides sea ice concentration, SLP, and geopotential height, we also analyse heat advection and surface temperature to elucidate the climate impact on Europe. In reanalysis/observational data, the first two atmospheric modes at zero lag advect cold/warm air southward/northward over the Arctic-Atlantic sector, and are associated with positive/negative sea ice anomalies. Additionally, the atmospheric modes at zero lag can cancel or reinforce, depending on the regions, the lagged atmospheric responses to sea ice reported previously. Applying the same analysis to coupled model simulations, we find that models can reproduce the first MCA modes, but they are far too dominant (SCF > 60%) compared to those in observational data (SCF ~ 40%). This suggests that coupled modes in models are not as diverse as in the real world, and that the lagged coupled modes are underestimated by models. By considering all the leading modes, we can have more complete understanding of the lagged and zero-lag feedbacks. Additionally, examining MCA beyond the first modes can be used to assess coupled modes simulated by models.
The catchment of the Ob, Yenisei and Lena rivers covers stretch from 46°N to 71°N and cover 7.95 million square kilometers. The water cycle over these basins is sensitive to rising temperatures due to melting permafrost, reduction in snow cover, increased atmospheric moisture and possible circulation changes. Downstream, the river discharge is a major contributor to the Arctic Ocean freshwater budget. Changes in the regional water cycle are constrained upstream by the quantity of water vapour transported by winds into the domain, which can be monitored with atmospheric reanalyses.

Our study builds upon the work of Zhang et al. [Nature Climate Change 3.1 (2013): 47-51.] using NCEP NCAR R1. We evaluate the robustness of their conclusions using state of the art reanalyses (ERA-Interim, NCEP CFSR, JRA 55 and MERRA 2) and prolonging the reference period from 2008 to 2015. The increasing trend in NCEP NCAR R1 is found to be sensitive to the start and end points and is weaker or absent in the other datasets. We confirm that the variability of the moisture convergence is a consequence of changing winds rather than increasing moisture. Finally, we contrast this behaviour with moisture fluxes into the High Arctic (north of 70°N) where winds and humidity show opposite trends.
What If Paris Works: Ice Sheet Surface Melting in Low and High Warming Worlds

David Reusch1,2 (david.reusch@nmt.edu)
1New Mexico Institute of Mining and Technology, Earth & Environmental Science, Socorro, United States,
2University of Washington, Earth & Space Science, Seattle, United States

Surface melting on the Greenland ice sheet has seen dramatic change with increasing global air temperatures, e.g., recent melt extent often exceeds the 1981-2010 median through much of the melt season. To evaluate potential future change, we investigate surface melting drivers under both low (~1.5 °C) and high (RCP 8.5) warming scenarios including differences in scenario outcomes.

Melt-relevant climatologies are developed from two publicly available ensembles of CESM1-CAM5-BGC runs: the 30-member Large Ensemble (CESM LE; Kay et al. 2015) for historical calibration and RCP 8.5 scenario and the 11-member Low Warming ensemble (CESM LW; Sanderson et al. 2017) for the 1.5 °C scenario. For higher spatial resolution (15 km) and improved polar-centric model physics, we also apply the regional forecast model Polar WRF to decadal subsets (1996-2005; 2071-80) with ERA-Interim Reanalysis (ERAI) & GCMs for boundary conditions.

Models are skill-tested against ERAI and AWS observations. For example, CESM LE tends to overpredict both maximum (above-freezing) and minimum daily average surface temperatures vs GC-Net Swiss Camp AWS observations.

Future (2081-2100) Greenland warms even in the LW scenario, but positive changes vs ERAI are mostly coastal (2-3 °C) with the interior showing only minor change. Under RCP 8.5, the entire ice sheet has warmed by 2-6 °C, or a median increase of ~5 °C vs LW. Adjusting for the CESM cold bias pushes these values closer to more frequent melting conditions.
Reconstruction of Autumn SIE during 1289-1993AD for Barents-Kara Seas, Arctic

Qi Zhang¹, Cunde Xiao² (cdxiao@bnu.edu.cn), Minghu Ding³, Tingfeng Dou⁴

¹Chinese Academy of Meteorological Sciences, China Meteorology Administration, Haidian District, China, ²State Key Laboratory of Earth Surface Processes and Resource Ecology, Beijing Normal University, Beijing, China, ³Chinese Academy of Meteorological Sciences, China Meteorology Administration, Beijing, China, ⁴College of Resource and Environment, University of Chinese Academy of Sciences, Beijing, China

Using high resolution ice core and tree ring proxies for sea ice extent (SIE), we reconstructed robust time series of autumn SIE over the Barents-Kara (B-K) sector of Arctic during 1289-1993 AD. After inter-comparison of the results and statistical parameters of the Ordinary Least Squares Regression (OLSR), Principle Components Regression (PCR) and Partial Least Squares Regression (PLSR) methods, the SIE time series are synthesized into a more convincing one using weighted average method with the explained variance as the weight. The result shows that during 13th to 18th century, autumn B-K SIE is in a high level with high oscillations and has a slight trend of expanding. It reflects significant multidecadal oscillations during the little ice age (LIA) background. B-K SIE starts to decline since the end of 18th century and the shrinking trend becomes very significant during the second half of the 19th century lasting to 1930s-1940s. 1930s-1940s is a period of relative low SIE in B-K sea and the SIE has a short period of expansion during 1940s-1970s. However, the B-K SIE has continuously been shrinking significantly since 1970s with industrial activities may be a dominant factor. B-K SIE retreats significantly since 1970s with the speed 6.18 times as the former mean retreating speed, the Arctic SIE in recent years may be the lowest one over the last millennium.

Analyses of Explosive Cyclones Reaching the Antarctic Coast in 2017

Luciana Bassi Marinho Pires¹ (luciana.pires@worldenvironmentalconservancy.org), Marcelo Romão¹,², Ana Carolina Vasques Freitas¹,³

¹World Environmental Conservancy, Atlanta, United States, ²National Institute for Space Research (INPE), Sao José dos Campos, Brazil, ³Federal University of Itajubá, Itabira, Brazil

Explosive cyclones or meteorological bombs are a kind of mesoscale cyclones known for their rapid intensification, but are not necessarily short-lived. They can produce strong winds, heavy rainfall and dangerous oceanic conditions as a result of rapid change of central pressure. It is likely that climate change is causing an increase in this type of event in the Antarctic coast and, if this increase is confirmed, the regime of winds and temperatures may be changing. In the northern portion of the Antarctic Peninsula a decrease in temperature has been recorded over the last 15 years, with a higher incidence of explosive cyclones over the region having been noted during this period. Explosive cyclones, which change the wind patterns when they reach certain areas, therefore may be contributing to this change in the Antarctic climate. This study is part of the “Explosive Cyclones on the Antarctic Coast” (EXCANC) Project conducted by the World Environmental Conservancy organization which analyzes data from 13 meteorological stations strategically scattered throughout the coast and operated by various international Antarctic programs, and also utilizes satellite images. Results show that through October of 2017, 96 cases of explosive cyclones in the Antarctic continent have occurred with around 100 cases being expected through the end of the year; the greatest number of events have been recorded at the Australian Casey station (16 cases). Intensity analyses also are shown.
Black carbon (BC), light-absorbing impurities plays an important role in Earth's cryosphere due to its strong absorption of visible light. Direct absorption of solar radiation by BC leads to atmospheric warming, while BC deposition on snow increases the fraction of solar energy absorbed accelerating in turn melting.

In this context, we focused our efforts on the measurement of the BC concentration and other light-absorbing impurities as well as algae in snow. In the last two years, we sampled in the snow across a north-south transect of almost 2000 km of the Chilean Andes: from at 8 locations from King George Island (62°S) to the southern Ellsworth Mountains on the broad expanse of Union Glacier (79°S; 3030 km from the southern tip of Chile and just about 1000 km from the South Pole). The sampling methodology was the meltwater filtration (MF) technique, whereby our 235 snow samples (of about 2.5 liters each) were melted shortly after collection and passed through a 0.4 mm nucleopore filter.

As expected, we found significant geographical differences in the content of light-absorbing impurities. For surface snow, the estimate of BC-equivalent mass loading was found to be 5 ng/g on King George Island to 0.5 ng/g at Union Glacier Camp. Our measurements also showed that light-absorbing impurities as well as the effect of algae in the snow decreased as we went south.
The Arctic is warming twice as fast as the global mean, with the northern Barents Sea being the absolute warming hotspot. This region has seen the largest decline in winter sea ice and the strongest surface warming, with the warming signal extending deep into the water column and high into the lower troposphere. The mechanisms controlling the heat transfer from the sub-surface warm Atlantic layer, and thus the sea ice cover and the lower troposphere temperatures, are not well understood nor quantified. In this presentation, we explore some of the mechanisms that we believe are important in the Arctic warming hotspot.

Our analysis is based on an extensive observational hydrographic data set from late summer and early autumn 1970-2016 in the northern Barents Sea. Focus for the study is the relationships between the upper ocean stratification, vertical fluxes of heat and salt from the deep Atlantic layer, and influx of sea ice and fresh water to the region. Year-to-year changes in the distribution of heat and salt in the water column reveal substantial variations in vertical fluxes of heat and salt that is controlled by upper ocean salinity. Special focus is on the freshwater input to this region, its interplay with vertical mixing, and its role in the Arctic warming hotspot.
Intense precipitation events are important contributors both to the surface mass balance of the Antarctic ice sheet and Southern Ocean salinity. As they are typically associated with high wind speeds and whiteouts they also strongly disturb local operations. Here we analyse several precipitation events affecting the Mertz glacier region and Dumont D’Urville (DDU) station in February 2017 combining unique ship-based measurements performed during the Antarctic Circumnavigation Expedition (ACE) and DDU station measurements. Precipitation amounts and properties are obtained using a combination of techniques, including precipitation radars, photoelectric particle counters, and formvar imprints of snowflakes for microphysical characterization. Atmospheric profiles are analyzed using radiosonde measurements. The events were forecasted and closely monitored using operational analysis of the European Centre for Medium-range Weather Forecasts (ECMWF) model and the Antarctic Mesoscale Prediction System (AMPS)/Polar WRF model. A combination of ACE and DDU measurements provide a unique opportunity to evaluate model performance and assess predictability of the events at different forecast lead times.
Nitrogen uptake by Phytoplankton in the Indian Sector of Southern Ocean

Sarat Chandra Tripathy1 (sarat76@gmail.com), Sivaji Patra2, K Vishnu Vardhan2, A. Sarkar1, R.K. Mishra3, N. Anilkumar2
1ESSO-National Centre for Antarctic and Ocean Research, Ocean Sciences Group, Vasco-da-Gama, India, 2ESSO-Integrated Coastal and Marine Area Management-PD, Chennai, India

This study reports nitrogen uptake rate (using 15N tracer) of phytoplankton in surface waters of different frontal zones in the Indian sector of Southern Ocean (SO) during austral summer of 2013. The investigated area encompasses four major frontal systems, i.e., the Subtropical Front (STF), Subantarctic Front (SAF), Polar Front-1 (PF1) and Polar Front-2 (PF2). Analysis of nutrient ratios indicated potential N-limited conditions at the STF and SAF but no such scenario was observed for PF. In terms of phytoplankton biomass, PF1 was found to be the most productive followed by SAF, whereas PF2 was the least productive region. Nitrate uptake rate increased with increasing latitude, as no systematic spatial variation was discerned for NH4+ and urea. Linear relationship between nitrate and total N-uptake reveals that the studied area is capable of exporting up to 60% of the total production to the deep ocean if the environmental settings are favorable. Like N-uptake rates the f-ratio also increased towards PF region indicating comparatively higher new production in the PF than in the subtropics. The moderately high average f-ratio (0.53) indicates potentially near equal contributions by new production and regenerated production to the total productivity in the study area. Elevation in N-uptake rates with declining temperature suggests that the SO with its vast quantity of cool water could play an important role in drawing down the atmospheric CO2 through the “solubility pump”.

Plankton Production in Open Southern Ocean and Surrounding subantarctic Islands

Luca Stirnimann1 (luca.stirimann3@gmail.com), Tommy Bornman2,3, Heather Forrer1, Kolisa Sinyanya4, Hans Verheye5, Sarah Fawcett1
1University of Cape Town, Oceanography, Cape Town, South Africa, 2South African Environmental Observation Network (SAEON), Port Elizabeth, South Africa, 3Nelson Mandela Metropolitan University, Ocean Sciences Campus, Port Elizabeth, South Africa, 4University of Cape Town, Cape Town, South Africa, 5Department of Environmental Affairs, Oceans and Coastal Research, Cape Town, South Africa

The Southern Ocean supports a complex foodweb which is shaped by the many interactions occurring between the planktonic system and the physico-chemical conditions of the marine environment, which affect both primary production and net ecosystem production. Southern Ocean ecosystems are thought to be changing rapidly due to climate change, yet much remains unknown of the “baseline” state of trophic carbon fluxes, which is key to understanding the potential ecosystem response to ongoing or future perturbations. We investigated ecosystem production and plankton trophic dynamics in the waters surrounding the Subantarctic Prince Edward Island archipelago during two expeditions to the Southern Ocean - the Antarctic Circumnavigation Expedition (ACE) in December 2016 and a SANAP cruise to Marion Island in April/May 2017. We collected biological (e.g., plankton abundance, biomass, diversity) and chemical (e.g. dissolved organic carbon, nutrients, chlorophyll, carbon and nitrogen) samples and measured biogeochemical rates (e.g. primary and secondary production, net ecosystem production) in the open Subantarctic and in the vicinity of the islands. Trophic structure, rates of production, nutrient biogeochemistry and their interactions will be discussed, with a view to better understanding Subantarctic ecosystem carbon cycling.
Contribution of Small Cells to the Total Primary Production in the Amundsen Sea

Yu Jeong Lim¹ (yjlim@pusan.ac.kr), Sang Hoon Lee², Jisoo Park², Dabin Lee¹, Sang Heon Lee¹

¹Pusan National University, Department of Oceanography, Busan, Korea, Republic of, ²Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of

The warming ocean is anticipated to increase the importance of small phytoplankton. However, little information has been reported in the Amundsen Sea. To understand the seasonal variation of the small contribution to the carbon uptake rates, the $^{13}$C-$^{15}$N dual stable isotope tracer techniques were carried out during January-February 2016 and the small contributions were compared with the previous results in different seasons. The total daily carbon uptake rate and the small contribution to the primary production averaged in all stations were respectively 0.59 g C m$^{-2}$ d$^{-1}$ and 24.8 %. In the polynya region alone, the average total daily carbon uptake rate was 0.72 g C m$^{-2}$ d$^{-1}$ and the average small contribution was 24.2 %. The mean proportion of small cells to the total carbon uptake rates in the polynya region in this study was significantly different from previous results: 50.8 % in February-March 2012 and 14.9 % in early January 2014 (one-way ANOVA; F = 15.66, p < 0.01). Different bloom timings of large and small phytoplankton are suggested for causing the large seasonal variation of small contribution. The total daily carbon uptake rates and the euphotic depths were also changed largely along the season. A strong negative correlation ($r = -0.52$, p < 0.01) between the small contributions and the total daily carbon uptake rates was found in this study, whereas a strong positive correlation was found between the small contributions and the euphotic depths ($r = 0.75$, p < 0.01).
In-situ Carbon and Nitrogen Uptake Rates of Arctic Melt Pond Algae

Sang Heon Lee1 (sanglee@pusan.ac.kr), Ho Jung Song1, Kwanwoo Kim1, Jae Hyung Lee1, So Hyun Ahn1, Houngh-Min Joo2, Jin Young Jeong2, Eun Jin Yang2, Sung-Ho Kang2
1Pusan National University, Department of Oceanography, Busan, Korea, Republic of, 2Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of

Relatively little studies on melt pond ecosystems have been conducted in the Arctic Ocean although melt ponds are a ubiquitous feature of summer Arctic sea ice. Twenty two melt pond samples at ice camp 1 (146.17 °W, 77.38 °N) and 11 melt pond samples at ice camp 2 (169.79 °W, 76.52 °N) were obtained to measure uptake rates of carbon and nitrogen from various melt ponds in the western Arctic Ocean. The major nutrient concentrations were largely variable among melt ponds at the ice camps 1 and 2. The chl-a concentrations averaged from the melt ponds at the camps 1 and 2 were 0.02-0.56 mg chl-a m⁻³ (0.12 ± 0.12 mg chl-a m⁻³) and 0.08-0.30 mg chl-a m⁻³ (0.16 ± 0.08 mg chl-a m⁻³), respectively. The hourly carbon uptake rates at the camps 1 and 2 were 0.001-0.080 mg C m⁻³ h⁻¹ (0.025 ± 0.024 mg C m⁻³ h⁻¹) and 0.022-0.210 mg C m⁻³ h⁻¹ (0.077 ± 0.006 mg C m⁻³ h⁻¹), respectively. In comparison, the nitrogen uptake rates at the camps 1 and 2 were 0.001-0.030 mg N m⁻³ h⁻¹ (0.011 ± 0.010 mg N m⁻³ h⁻¹) and 0.002-0.022 mg N m⁻³ h⁻¹ (0.010 ± 0.006 mg N m⁻³ h⁻¹), respectively. These values obtained in this study are significantly lower than those reported previously. A large portion of algal biomass caught into new forming surface ice in melt ponds appears to be a main potential reason for the lower chl-a concentration and subsequently lower carbon and nitrogen uptake rates in this study.
Normally the Southern Ocean is characterized by its high nutrient availability and its low chlorophyll concentrations (High Nutrients Low Chlorophyll or HNLC). Discrepancy, which seems to be caused by the paucity of micronutrients (e.g. Fe). Nevertheless, this general pattern does not entirely apply in coastal areas (e.g. bays), where iron is more abundant due to meteoric water inputs (i.e. glacial melt). In the Western Antarctic Peninsula water column stability has been proposed as the main cause for massive phytoplankton blooms that attain very high primary production rates.

During the extremely warm summer of 2017 (January and February) we found huge phytoplankton blooms (chlorophyll > 15 mg m-3) inside Maxwell Bay (King George Island, South Shetland Islands) and South Bay (Doumer Island, Palmer Archipelago). Accordingly, primary production rates were very high (1.3 - 8.9 g C m-2 d-1) agreeing with concomitant measures of low pCO2 (< 200 µatm) near surface waters. Fast winds (>70 km h-1) mixed the water column, breaking the stability promoting phytoplankton blooms and diminishing chlorophyll concentrations, whereas its downward vertical flux increased.

These findings suggest that bays on the Western Antarctic Peninsula may act as biological “hot spots” (i.e. CO2 sinkholes) gathering phytoplankton, when they present a stable water column, that afterwards may be exported horizontally (nearby oceanic waters) or vertically (carbon sinking) due to fast winds forcing.
To obtain the monthly variation in macromolecular compositions (carbohydrates, proteins, and lipids) of phytoplankton, surface water samples were collected at the Jang Bogo Station (74° 37.4’ S, 164° 13.7’ E) located in Terra Nova Bay, Antarctica. Samplings were performed approximately once every second week from February to October, 2015. The total chlorophyll a (Chl-a) concentration was 0.32 µg L⁻¹ (S.D. = ± 0.88 µg L⁻¹) averaged from our observation period. The phytoplankton community was dominated by large-sized phytoplankton (> 20 µm) accounting for 58.9 ± 18.5 % (mean ± S.D.) of the total Chl-a concentration, followed by middle-sized (2-20 µm; 26.8 ± 10.5 %), and small-sized phytoplankton (0.7-2 µm; 14.3 ± 9.4 %). Overall, carbohydrates were dominant components of total phytoplankton with a mean of 69.3 % (± 13.8 %) and had an increasing trend over our study period except February 9, 2015. On the other hand, protein contribution was lowest (9.4 ± 11.0 %) except February, 2015 and had a decreasing trend from February to October. Lipids, however, did not show any specific trend with a few fluctuations (21.4 ± 4.4 %). In comparison, the overall contributions of carbohydrates, proteins and lipids of small phytoplankton were 68.8% (± 12.0 %), 6.5 % (± 9.2 %) and 24.6 % (± 5.9 %), respectively.
Carbonate Sensitive Phytotransferrin Controls High-affinity Fe Uptake in Diatoms

Jeff McQuaid1,2 (jmcquaid@jcvi.org), Adam B. Kustka3, Miroslav Oborník4, Aleš Horák4, John P. McCrow1, Bogumil J. Karas1, Hong Zheng1, Theodor Kindeberg2, Andreas J. Andersson2, Katherine A. Barbeau2, Andrew E. Allen1,2

1J. Craig Venter Institute, Environmental Genomics, San Diego, United States, 2Scripps Institution of Oceanography, UC San Diego, San Diego, United States, 3Rutgers University, Earth and Environmental Sciences, Newark, United States, 4Institute of Parasitology and University of South Bohemia, Biology Centre ASCR, Faculty of Science, Ceske Budejovice, Czech Republic

In large regions of the Southern Ocean the scarcity of iron controls the growth and productivity of phytoplankton. While most dissolved iron in the marine environment is complexed to organic molecules, picomolar amounts of unchelated ferric iron (Fe′) are maintained within the euphotic zone and are an important source of iron for eukaryotic phytoplankton, particularly diatoms. In the model diatom Phaeodactylum tricornutum, we show high-affinity Fe′ acquisition is mediated by phytotransferrin, a endocytosis-dependent functional analog of transferrin. Like transferrin, phytotransferrin coordinates the binding of iron with carbonate (CO32−), and manipulation of the carbonic acid system reveals that the synergistic binding of [Fe′] and [CO32−] occurs at environmentally relevant concentrations of seawater carbonate, and [CO32−] co-limits Fe′ uptake. We show phytotransferrin has broad phylogenetic distribution among marine eukaryotes and is abundant in Southern Ocean genomic and proteomic datasets, suggesting that ocean acidification and the decline in seawater [CO32−] will negatively impact this iron acquisition mechanism, with possible implications for carbon export rates and marine biogeochemical cycles.
Enhancing of Biological Pump in the Chukchi Sea Based on Chinese Arctic Cruises

Jianfang Chen1 (jfchen@sio.org.cn), Haiyan Jin1, Yanpei Zhuang1, Youcheng Bai1, Hongliang Li1
1Second Institute of Oceanography, State Oceanic Administration, Laboratory of Marine Ecosystem and Biogeochemistry, Hangzhou, China

With decreasing of sea ice cover there would the potential for deepening of nutricline and an increasing of annual biological pump in the Arctic Ocean because of more nutrients in the euphotic zone will be consumed in an ice free sea or open ocean. Since 1999 (in summers, 1999, 2003, 2008, 2010, 2012, 2014, 2016), seven Chinese Arctic Expeditions has been carried out in Chukchi Sea and Canadian Basin where upper ocean nutrients are abundant compared with European sector of the Arctic Ocean. During those cruises, we analyzed nutrients, DO, pH, chl a, opal and HPLC pigments in the water column, which allow us to look the variation of nutricline and biological pump after sea ice retreat since 1999. The results showed that size fractionation of chl a and opal, chl a-maximum depth, phytoplankton communities changed dramatically in the West Arctic Ocean, especially along the longitudinal 170°W section since 1999. A highlight of those changes is deepening of nutricline in summer and increasing of the depth of chl a-maximum in the shelf waters such as Chukchi Sea and ice edge in the Canadian Basin since 1999. Organic carbon, opal burial and biomarkers records in sedimentary cores in the Chukchi Sea also indicated that increasing of organic carbon burial and relative abundance of diatoms while the contributions of haptophytes decreased since last 250a. We will involve MOSAIC program and future Chinese cruises in the west Arctic Ocean focusing on biological pump observation.
In the present study, the surface sediments from Kongsfjorden-Krossfjorden, Arctic were examined for spatial distribution and biomarkers of benthic communities. Photosynthetic pigments (chlorophyll a and b), accessory pigments (fucoxanthin, zeaxanthin, alloxaithin, lutein etc.), and chlorophyll a decomposition products (chlorophyllide a, pheophorbide a, pheophytin a) from surface sediments were analyzed using high performance liquid chromatography. The distribution of pigments was found to be spatially variable with overall greater concentrations in Krossfjorden than Kongsfjorden. In both the fjords, the most abundant pigment was chlorophyll-a (0.1-0.8 µg g⁻¹) followed by pheopigments (0.06-0.6 µg g⁻¹) with greater concentrations recorded in mid-fjord stations, indicating the productivity distribution within the fjord. Similarly, the concentration of β-carotene (total algal abundance) & carotenoids like alloxaithin (cryptophyta), fucoxanthin (diatoms), lutein (Chlorophyta, Euglenophyta, Plantae) and zeaxanthin (cyanobacteria) recorded to be elevated at middle of fjord, but peaked at outer fjord stations. The ratio Chl-a:pheo was >1 in most stations, indicating that chlorophyll-a was preserved despite grazing and degradation pathways that accumulate pheopigments. The overall study outlines the spatial distribution of benthic communities in the two fjords and baseline for further ecological studies to be undertaken for the region.
The Effect of Climate Change on the Carbon Balance in Microalgae

Deborah Bozzato¹ (deborah.bozzato@uni-leipzig.de), Torsten Jakob¹, Christian Wilhelm¹
¹University of Leipzig, Plant Physiology, Leipzig, Germany

The Southern Ocean is an important sink for the atmospheric CO₂ due to the physical and the biological (photosynthetic) activity of phytoplankton. Some studies have investigated the photosynthetic activity of the benthic and pelagic producers, but there is only very scarce knowledge about the carbon losses due to respiration of phytoplankton. The reason for this lack of information is principally methodological limitations. In the light of expected changes of environmental conditions due to the climate change, the aim of the project is to investigate the range of variability of photosynthesis over respiration ratio (rP/R) in response to different growth conditions, namely: different temperatures, water salinity and in dependence on iron availability. In this respect, two key species of the Southern ocean are investigated: the diatom *Fragilariopsis cylindrus* and the prymnesiophyte *Phaeocystis antarctica*.
The “biological pump” (BP) plays a central role in the sequestration of carbon away from the atmosphere for long time. Sea ice change, slope transport, CDW upwelling and other climate change processes will change the Antarctic BP process and efficiency. Between 2009 to 2017, ten sets of mooring system with sediment trap were deployed in the Prydz Bay to study the seasonal variations of particle fluxes. 6 moorings with 7 sediment traps were successfully recovered. The annual average flux of organic carbon (OC) and biogenic silica (BSi) were comparable to other similar Antarctic seas. The summer flux is the main contribution of the whole year flux, ca. >80%. The major contributor to the total mass flux was BSi. Comparison of remote sensing data, there are significant inter-annual differences. The results of carbon and nitrogen stable isotopes show that, the lowest organic carbon flux during the summer of 2014/2015 may be caused by strong lateral transport from east, thereby in-situ production of high organic matter cannot settle down to the trap. In deep ocean, the upper fluxes were extremely low while the lower fluxes relatively high during winter, which may be explained by sediment suspension or lateral transport. High fecal flux during winter suggest that strong biological process would happened on the continental slope. This speculation requires further evidence, and it could improve a better understanding of the link between the BP and Antarctic ecological process.
Effects of Iron Bioavailability on Plankton Communities from the Southern Ocean

Damien Cabanes1 (damien.cabanes@unige.ch), Sonia Blanco-Ameijeiras1, Scarlett Trimborn2,3, Sonja Wiehmann2, Christian Volkner2, Dorothee Wilhelms-Dick2, Tina Brenneis2, Heike Simon4, Matthias Sieber5, Jasmin P Heiden2,3, Florian Lelchat1, Astrid Bracher2,3

1University of Geneva, Department F.-A. Forel for Environmental and Aquatic Sciences, Geneva, Switzerland, 2Alfred Wegener Institute, Bremerhaven, Germany, 3University of Bremen, Bremen, Germany, 4University of Oldenburg, Oldenburg, Germany, 5ETH Zurich, Zurich, Switzerland

Organic ligands such as saccharides and exopolymeric substances (EPS) are known to complex with iron (Fe) and influence Fe bioavailability to phytoplankton. In this work, we addressed how Fe enrichment associated to organic binding ligands influences productivity and biodiversity of natural phytoplankton communities from two sites of the Drake Passage and one from the Western Antarctic Peninsula. At each station, short- (24h) and long- (6d) term incubations were performed with the in-situ phytoplankton community without (control treatment) and after addition of different Fe-binding ligands including: the siderophore desferrioxamine B, two saccharides, two different bacterial EPS and a virally degraded EPS. While siderophores consistently decreased Fe uptake rates, effects of saccharides and EPS were variable the different plankton size fractions. Additionally, Fe speciation measurements allowed us to characterize the pool of Fe-binding ligands naturally present in the samples, and determine the impact of the added organic ligands on Fe bioavailability and phytoplankton productivity. Our results illustrate that the different organic ligands used have great capability to differentially modulate Fe bioavailability for different plankton groups. The simultaneous characterization of chemical and biological parameters provides valuable insights in the rarely carried out relationship between Fe chemistry and Fe bioavailability.

Seasonality of Carbon Cycling in the Kerguelen Bloom Reveals by Autonomous Tools

Stephane Blain\textsuperscript{1} (stephane.blain@obs-banyuls.fr), Jacqueline Boutin\textsuperscript{2}, Liliane Merlivat\textsuperscript{2}, Herve Claustre\textsuperscript{3}, Mathieu Rembauville\textsuperscript{4}
\textsuperscript{1}UPMC, LOMIC, Banyuls sur Mer, France, \textsuperscript{2}CNRS, Paris, France, \textsuperscript{3}CNRS, Villefranche sur Mer, France, \textsuperscript{4}UPMC, Banyuls sur Mer, France

The central Kerguelen plateau hosts a recurrent massive phytoplankton bloom essentially sustained by natural iron fertilization. During the past decade, this bloom has been extensively studied thanks to oceanographic cruises but a complete view of the seasonal dynamics was still missing. The SOCLIM project has filled this gap with the deployments of both instrumented moorings and biogeochemical Argo floats. The subsurface mooring (40 m) was equipped with biogeochemical sensors and a remote autonomous sampler. Two sediment traps were also deployed at 300 m at the same site. This 1D view was completed by 2 BGC argo floats that drifted close to the moorings and captured the export events. The data collected during SOCLIM will allow to understand the interplay between environmental factors (light, nutrients) and bloom dynamics, and how biological activity and ecological vectors contributes to the CO\textsubscript{2} sink and carbon storage in the deep waters.
Satellite Study on Particulate Inorganic Carbon Content within *E. huxleyi* Blooms

Dmitry Kondrik¹ (dmitry.kondrik@niersc.spb.ru), Dmitry Pozdnyakov², Lasse Pettersson²
¹Nansen International Environmental and Remote Sensing Centre, St. Petersburg, Russian Federation, ²Nansen Environmental and Remote Sensing Centre, Bergen, Norway

By implementing the developed methodologies of *E. huxleyi* blooms identification and special processing algorithms to the satellite data, multi-year time series of variations in occurrence, spatial extent, and content of particulate inorganic carbon (PIC) within *E. huxleyi* blooming areas in the North, Norwegian, Greenland, Barents, and Bering Seas were obtained for the time period 1998-2013. The analysis of obtained results permitted to reveal the specific features of *E. huxleyi* blooming events in the studied regions. During the intra-annual cycle, *E. huxleyi* blooms advance from temperate to higher latitudes along the pathways of the Gulf Stream propagation starting from North and Norwegian Seas (in early June), and ending in the Barents Sea (in late July-early September). The highest bloom areas in the North Atlantic-Arctic waters were registered in the Barents Sea (up to 250,000 km²). The same pattern holds for the total PIC content within *E. huxleyi* blooms: values of this parameter reached the amount of ~0.35 Mt in the Barents Sea. In the Bering Sea, the temporal and spatial dynamics of *E. huxleyi* development proved to be highly irregular: before and after the 1997-2001 period of high intensity of this phenomenon, the blooms are sporadic, their extent and PIC production are either very low or insignificant, whereas during 1997-2001, it even exceeded the values for the Barents Sea: up to ~0.4 Mt and, on one occasion (in 2001), even about ~0.7 Mt.
Dissolved CO\textsubscript{2} Increase within Coccolithophore Blooms in Subpolar and Polar Seas

Dmitry Pozdnyakov\textsuperscript{1} (dmitry.pozdnyakov@niersc.spb.ru), Dmitry Kondrik\textsuperscript{1}, Ola Johannessen\textsuperscript{2}
\textsuperscript{1}Nansen International Environmental and Remote Sensing Centre, St. Petersburg, Russian Federation, \textsuperscript{2}Nansen Scientific Society, Bergen, Norway

Coccolithophore \textit{E. huxleyi} cause less uptake of atmospheric CO\textsubscript{2} by the ocean. A global assessment of this phenomenon has so far not been quantified. We used Ocean Colour Satellite time series data for a 19-year period (1998-2016) to quantify the CO\textsubscript{2} partial pressure increase (\(\Delta p\text{CO}_2\)) within \textit{E. huxleyi} blooms in the North, Norwegian, Greenland, Barents, and Bering Seas. \textit{E. huxleyi} outbursts in the North Atlantic and Arctic Seas proved to occur annually, but their extent vary interannually. In the Bering Sea, during 1998-2001 there was a splash in blooming activity followed by a drastic drop. The bloom duration in the Bering Sea in 1997/98-2001 reached 10 months, in the North Atlantic seas it was \(\sim\) 1 month. The maximum inorganic carbon content in \textit{E. huxleyi} blooms in all seas varied over the 19 years between \(\sim\) 15 and 70 Kt. When normalized to \(p\text{CO}_2\) in the absence of bloom, the mean and maximum \(\Delta p\text{CO}_2\) values within the bloom areas varied in percent between 21.0 - 43.3 and 31.6 - 62.5, respectively. Utilizing OCO2 spaceborne data on columnar \(p\text{CO}_2\), we also quantified changes in atmospheric columnar CO\textsubscript{2} over \textit{E. huxleyi} blooms in the target seas and documented a reversion of CO\textsubscript{2} flux from ocean to atmosphere. As huge outbursts of \textit{E. huxleyi} also occur in the southern hemisphere, such blooms unfold in the world oceans across the entire year. Our data can serve as a baseline for assessing the importance of the phenomenon for climatology, marine chemistry and ecology on a global scale.
Zooplankton Mediate Faecal Pellet Fluxes across Southern Ocean Environments

Cecilia Liszka1,2 (ceclis56@bas.ac.uk), Carol Robinson2, Gabriele Stowasser1, Clara Manno1, Geraint Tarling1
1British Antarctic Survey/NERC, Ecosystems, Cambridge, United Kingdom, 2University of East Anglia, ENV, Norwich, United Kingdom

The Southern Ocean (SO) is the world’s greatest carbon sink and, via carbon uptake and sequestration, the SO Biological Carbon Pump exerts a strong control over global climate. Central to its efficiency is the production and fate of zooplankton faecal pellets (FPs), particularly the magnitude of, and processes governing, FP flux to depth. Primary productivity and seasonal ice cover vary considerably across the SO, impacting secondary consumption and FP production. Constraining this variability is crucial for improving SO representation in ocean biogeochemical models.

We address this by investigating the distribution and fate of FPs over 400m, the region where attenuation is potentially highest. We studied three sites within the Scotia Sea: i) ice-influenced; ii) comparatively oligotrophic; and iii) within a seasonally extended phytoplankton bloom. FPs obtained from CTD bottles and mesozooplankton from net samples were analysed to derive estimates of and investigate controls on FP flux from the epi- to mesopelagic. Within the top 200 m, FP fluxes varied by a factor of 6 but, at 400m, by < 3. We suggest that, whilst FP production in surface waters may vary between productivity regimes, zooplankton-mediated controls on remineralisation and FP lability can act to narrow differences in respective levels of export. This has implications for our understanding of carbon export at intermediate depths, and for resulting carbon sequestration to bathypelagic depths in differing regimes.
Low Mesoscale Kinetic Energy as a Precondition for Blooms in the Southern Ocean

Joseph Gradone¹ (jgradone@udel.edu), Matthew Oliver¹, Alexander Davies²
¹University of Delaware, Marine Science and Policy, Lewes, United States, ²United States Naval Academy, Oceanography Department, Annapolis, United States

In the Southern Ocean, surface waters are typically macro-nutrient rich in the austral summer, yet they are characterized by patchy, intense phytoplankton blooms within a generally unproductive environment. Due to the remoteness and harsh conditions, there are a dearth of in-situ chlorophyll observations in the Southern Ocean. Furthermore, persistent clouds and low sun-angle make remote sensing observations of chlorophyll comparatively rare. However, we have detected a hyperbolic relationship between satellite estimates of chlorophyll and radar-based satellite estimates of surface current kinetic energy. This is important because satellite derived estimates of kinetic energy, which are not hampered by cloud cover, and can possibly be used to improve estimates of total Southern Ocean biomass. While iron is a major limiting factor for Southern Ocean phytoplankton blooms, our analysis suggests there is a low-kinetic energy pre-condition before large phytoplankton blooms can occur. This is observed by both satellite and Argo biofloats, suggesting that kinetic energy estimates from space serve as a proxy for ecologically relevant mixing of phytoplankton populations in the Southern Ocean.
Carbon Uptake in Bi-polar Regions and their Responses to Climate Change

Zhongyong Gao¹ (gaozhongyong@tio.org.cn), Heng Sun¹, Liqi Chen¹, Di Qi¹
¹Third Institute of Oceanography, State Oceanic Administration (SOA), Key Laboratory of Global Change and Marine-Atmospheric Chemistry (GCMAC), SOA, Xiamen, China

Carbon uptake data sea were integrated from the 1999 to 2017 not only in the Antarctic, but also in the Bering Sea and the Western Arctic Ocean. Both were summer cruises of the Chinese National Arctic and Antarctic Research Expedition (CHINARE). Parameters including CO₂ system parameters etc., were well measured. Bering carbon sink, Arctic carbon sink, and the Southern carbon sink were all well calculated during the past two decades. Both Bi-polar carbon sink including Bering carbon sink were well compared with each other. Results showed distinguished differences between the bi-polar ocean carbon sink. The Bering Basin carbon uptake was almost remained stable compared with its adjoin spacious Pacific Ocean, however, those in Bering Slope Current region was coincide well with climate change. Due to rapid Arctic Change, Chukchi Sea's carbon sink was remained strong uptake during the past two decades, where nutrients was supplied well by the Pacific inflow, however, the other regions where there were not nutrients supply was different change. In Contrast, the Southern Ocean carbon sink was response to the climate change in December, however, there was negative feedback was observed during Astral Summer season due to the bio-production, especially in Prydz Bay, Antarctic.

Effects of High CO$_2$ on Pteropod Contribution to Carbonate Flux in the Ross Sea

Kirstie Jones-Williams$^{1,2}$ (kirnes79@bas.ac.uk), Clara Manno$^1$, Victoria Peck$^1$, Robert Upstill-Goddard$^2$, Laura Cutroneo$^3$, Marco Capello$^3$

$^1$British Antarctic Survey, Cambridge, United Kingdom, $^2$Newcastle University, Newcastle-upon-Tyne, United Kingdom, $^3$Università degli Studi di Genova, Genova, Italy

The Southern Ocean (SO) plays a key role in global climate and biogeochemical cycles. Thecosomate pteropods (calcareous molluscs) are the main planktonic producers of aragonite in the world's oceans and in the SO they can contribute to $>$ 50% of the total biogenic carbonate export. Pteropods are vulnerable to the forecasted increase in ocean acidification (OA), owing to their aragonite shell which is prone to dissolution. Understanding pteropod flux dynamics is crucial in order to predict how a drop in their population will impact the balance between Particulate Inorganic Carbon (PIC) and Particulate Organic Carbon (POC) export to the deep ocean. Here we present an investigation of pteropods collected from subsurface and deep moored sediment traps in Terra Nova Bay, Ross Sea for one year. In this region, the presence of CO$_2$-rich water masses promotes OA. Pteropod abundance and biomass were investigated to assess their contribution to deep carbonate export. Level of shell dissolution was estimated by scanning electron microscope (SEM) to evaluate the impact of OA on shell condition. Results highlight the significance of pteropods as a vector for carbon export, contributing up to 88% of the total carbonate flux. The observation of a mass mortality of larval stage pteropods along with extensive “in-life” shell dissolution amongst all individuals, highlights (with in situ evidence) the threat of OA to the key role of pteropods within the SO carbonate system.
The Southern Ocean plays an important role in moderating our climate through the biological carbon pump (BCP), in which atmospheric carbon is drawn down and sequestered into the deep ocean through a combination of biological and physical processes. The zooplankton community plays a key role in BCP both through their individual vertical migrations and also in the generation of waste matter that may rapidly sink, both of which contribute to a process termed active flux. Vertical migration in zooplankton is a well-described phenomenon where animals migrate on mass from depth to the surface layers to feed under the cover of darkness and return to depth during the daylight hours. However, recent studies suggest that individual zooplankton may also make several shorter migrations into shallow waters, termed forays, over the course of 24 hours. These forays may lead to an increase in active flux and could augment the BCP. Here we aim to use novel technology and traditional methods to look at migration behaviour at both the individual and population level. In particular, we have developed a 2-way net trap that can be deployed in open-ocean environments which can intercept individuals during their forays. We identify the main migrators that participate in foray behaviour in the Scotia Sea, which is a key region of carbon drawdown in the Southern Ocean.
Influence of Coccolithophore Species-specific Growth Rates on Calcite Production

Kyle Mayers1,2 (kyle.mayers@soton.ac.uk), Stephanie Allen1,2, Alex Poulton3
1University of Southampton, Southampton, United Kingdom, 2National Oceanography Centre Southampton, Southampton, United Kingdom, 3The Lyell Centre, Heriot-Watt University, Edinburgh, United Kingdom

Coccolithophores are single celled phytoplankton which produce an exoskeleton of calcium carbonate plates. The production and export of these coccoliths play a major role in ocean carbon cycling. The rates at which species produce coccoliths, as well as the calcite content of species can influence the flux of carbon from the euphotic zone.

In this study, we measured the abundance, biometry and species specific growth rates of coccolithophores on the extended Ellett line between Scotland and Iceland during June 2015. The coccolithophore community was dominated by *Emiliania huxleyi* and the larger species *Coccolithus pelagicus*. Abundances of *E. huxleyi* and *C. pelagicus* varied from 22-1,500 and 0.3-129 cells mL\(^{-1}\) respectively. However, *C. pelagicus* accounted for 20-95% of daily calcite production due to its larger calcite per cell content and similar growth rates to *E. huxleyi*. Across the entire cruise the average contributions to calcite production was 55 and 45% for *E. huxleyi* and *C. pelagicus* respectively.

This research highlights the importance of species specific rates when considering biogeochemical rates, as less abundant but larger species can dominate calcite production. How different species respond to environmental change will also impact on regional carbon dynamics.
The phytoplankton communities, adaptations and variations in the frontal ecosystems of the Indian sector of the Southern Ocean (IOSO) have been investigated along with the sea surface temperature (SST), sea surface wind (SSW), photosynthetically active radiation (PAR), and nutrients. The \textit{in situ}, model and satellite observations during austral summer 2013 indicates that the variability of chlorophyll a (Chl-a) and diatoms were primarily influenced by light and wind. The Chl-a was higher in the sub-Antarctic front (SAF) followed by the sub-tropical front (STF) and the polar front (PF). However, in throughout the period during 1998-2012, the diatoms concentration was higher at the SAF followed by the PF and STF. Dominance of diatoms at the PF may be attributed to their adaptability for low light conditions. During a time series (1998-2014) in austral summer the diatoms contribution to the Chl-a biomass was ≥80% at the PF. On the other hand, the chlorophytes to Chl-a biomass showed ≥70% at the STF and gradually decreased towards the PF mainly attributed to the temperate adaptation. The variability of flagellates and diatoms from the STF to PF is attributed to the variability of PAR, SST and SSW. The results from this study of the frontal ecosystems would help to understand the shifting of communities in the ecosystem, biogeochemical cycle of the IOSO.
Trends in Primary Production under the New Arctic Sea-ice Regime

Pedro Duarte1, Philipp Assmy2, Lasse M. Olsen1, Hanna M. Kauko1, Mar Fernández-Méndez1, Haakon Hop1,2, Mats A. Granskog1, Gunnar Spreen3, Harald Steen1

1Norwegian Polar Institute, Tromsø, Norway, 2Faculty of Biosciences, Fisheries and Economics, UiT The Arctic University of Norway, Department of Arctic and Marine Biology, Tromsø, Norway, 3Institute of Environmental Physics, University of Bremen, Bremen, Germany

Here we analyze trends in sea-ice primary production (PP) under the new thinner and more dynamic Arctic sea-ice regime using empirical data and various biogeochemical models, ranging from analytical to numerical and from one-dimensional vertically-resolved to three-dimensional. We argue that the traditional conceptual view of a spring phytoplankton and ice algal bloom in the Marginal Ice Zone (MIZ) following its progression as a PP “front”, should be replaced by a “network view”. This view does not contradict the existence of a frontal PP zone, but it merely acknowledges the effect of the thinner and more dynamic ice cover in creating a fractal network of refrozen light conduits, deep into the ice pack, along which phytoplankton and ice algal growth rates may be enhanced. We further argue that this network will lead to an increase in spring phytoplankton areal PP under the ice pack, ultimately limited by nutrient availability. However, the outcome of these light conduits is not so obvious for ice algae. In spite of the increased growth rates, nutrient and recruitment limitation in the expectably more frequent and extensive young sea ice along the light conduits may prevent standing stocks from reaching the levels observed in older ice types. These bottlenecks may be partly compensated by horizontal spreading of transmitted light to thick ice and ridges bordering the refrozen areas, where ice algal standing stocks are higher and not recruitment limited.
Arctic Ocean Carbon Cycle Response to Atlantification and CO2 Invasion

Tatiana Ilyina1 (tatiana.ilyina@mpimet.mpg.de), Hongmei Li1, Katharina Six1, Mikhail Dobrynin2
1Max Planck Institute for Meteorology, Hamburg, Germany, 2Universität Hamburg, Institute of Oceanography, Hamburg, Germany

Arctic Ocean carbon cycle is a hotspot for strong perturbations driven by rising CO2 emissions and concomitant climate change in future projections. We investigate these perturbations with the Max Planck Institute’s Earth System Model, focusing on the high CO2 scenario RCP8.5 extended until 2300. Model results project an SST increase in the Arctic Ocean by 4°C in 2100 and by 10°C in 2300, respectively, accompanied by the loss of summer and eventually also the winter sea ice. Warming enhances thermal stratification, but ice free water favors formation of convection cells. Intensification of the Atlantic water inflow leads to erosion of the halocline in the central basin of the Arctic Ocean. The carbon cycle responds to these complex hydrodynamic changes, but is also directly affected by the uptake of anthropogenic CO2. We will show that while future changes in the Arctic Ocean carbon cycle proceed at rates determined by atmospheric CO2 levels, the regional patterns are driven by shifts in the hydrodynamic regime.
Timing of Meroplankton in Different Arctic Primary Production Regimes

Janne E. Søreide¹ (janne.soreide@unis.no), Eike I Stübner², Tove M. Gabrielsen¹, Paul Renaud², Jørgen Berge³, Marit Reigstad³, Slawomir Kwasniewski⁴, Katarzyna Blachowiak-Samolyk⁴, Rafal Boehnke⁴
¹The University Centre in Svalbard, Department of Arctic Biology, Longyearbyen, Norway, ²Akvaplan-niva AS, Tromsø, Norway, ³UiT The Arctic University of Norway, Tromsø, Norway, ⁴Institute of Oceanology Polish Academy of Sciences, Sopot, Poland

Larvae of benthic organisms that temporarily inhabit the pelagic environment (meroplankton), are important contributors to coastal Arctic marine zooplankton communities. Their seasonal dynamics is, however, poorly described due to their small size and limited presence in the pelagic. Here we present high resolution meroplankton data from three different fjords in the Svalbard archipelago, one ice-free fjord and two seasonally ice covered fjords. Among the eight main meroplankton groups that were present the most important were Cirripedia and Bivalvia.

Based on 5 seasonal data sets from these three fjords with different primary production regimes, we conclude that the timing of meroplankton is mainly steered by the timing of the phytoplankton bloom, and less by ice algae and hydrography. Reduction in sea ice cover and thickness may lead to changes in the onset, duration and magnitude of the phytoplankton bloom, and eventually the meroplankton seasonal dynamics in a future warmer Arctic.
Metagenomic Analysis of Antarctic Communities of Thalassiosirales Diatoms

Mariela Guajardo¹ (mari.igm.bi@gmail.com), Mario Moreno¹, Rodrigo de la Iglesia², Nicole Trefault¹

¹Universidad Mayor, GEMA Center for Genomics, Ecology and Environment, Santiago, Chile, ²Pontificia Universidad Católica, Facultad de Ciencias Biológicas, Santiago, Chile

Antarctic coastal regions are highly productive ecosystems characterized by temperatures below the freezing point, complete darkness in winter and continuous day light and high UV radiation in summer. In these systems, photosynthetic microorganism, especially diatoms, are the base of the food web, contributing in great manner to carbon fixation and intake during spring and summer blooms. Thalassiosirales inhabiting this environment have adapted their physiology to maintain their basic functions in these extreme conditions. In this work, we aim to analyze the metagenomic features allowing Antarctic diatom communities to thrive in this environment.

Metagenomes corresponding to pico and nano-phytoplankton communities from a short diatom bloom were analyzed by standard bioinformatic analyses. Our results show that:

i) The major diatom group was Thalassiosirales order, representing 43 and 73 %, with members belonging to Detonula, Skeletonema and Thalassiosira genus.

ii) We observed a large number of genes related to photosynthesis and genetic information processing.

iii) Functional predictions of ORFs assigned to Thalassiosirales show a substantial number of heat shock proteins, DEAD-box, RNA helicases, fatty acid desaturases and other proteins involved in functions that are indicative of a low-temperature-adapted metabolism.

Our results remark the special characteristic of an important Antarctic community member as Thalassiosirales, who has a key role in this environment.
The export of particulate organic carbon (POC) from the sea surface is an essential part of the biological pump. POC from the upper layers is delivered to the deep ocean, which retains CO2 for a relatively long period compared with the epipelagic CO2 residence time.

This work summarizes POC fluxes measured in the past 25 years in the Ross Sea (Antarctica) and western Svalbard (Arctic) by using moored sediment traps. In the Ross Sea, fluxes of POC and total mass are well correlated implying that particle fluxes are dominated by biogenic debris. Annual POC fluxes to below 200 m average 4.4±3.3 g C m\(^{-2}\) y\(^{-1}\). Particle fluxes are relatively low when primary production is high (spring-summer) followed by enhanced sedimentation in late summer-fall.

The high degree of decoupling between production and sedimentation is unusual compared to records of Antarctic Peninsula and may represent low grazing rates.

In the past decades, the decrease of sea-ice in Fram Strait (NW Svalbard) is significant. From 2002, water temperature increases in general, while POC fluxes tend to decrease. Starting from 2010, moored sediment traps have been deployed also in SW Svalbard slope. Here, marine POC fluxes show the typical temporal variability of high latitudes with higher content of biogenic compounds in spring-summer linked to phytoplankton blooms. However, most of the POC is laterally advected in late winter by occasional intrusions of warmer, saltier, less dense and more oxygenated water.
Potential Primary Production of Microphytobenthos in the Changing Potter Cove

Ralf Hoffmann¹ (ralf.hoffmann@awi.de), Angela Wulff², Adil Yousif Al-Handal², Ulrike Braeckman³, Dolores Deregibus⁴, Frank Wenzhöfer¹

¹Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Deep Sea Ecology and Technology, Bremerhaven, Germany, ²University of Gothenburg, Biological and Environmental Science, Gothenburg, Sweden, ³Ghent University, Department of Biology, Ghent, Belgium, ⁴Instituto Antártico Argentino, Departamento de Biología Costera, Buenos Aires, Argentina

The retreating Fourcade glacier in Antarctic Potter Cove uncovered new space for primary production. Thought, pelagic and macroalgae primary production does not provide enough organic carbon to feed the benthic community. Benthic microalgae, the microphytobenthos (MPB), are proposed to partly provide the required organic carbon. To estimate the potential primary production from MPB, we incubated 12 intact sediment cores from three stations (8 m depth) at increasing light intensities (up to 70 µmol photons/m² s) and measured the oxygen exchange. Further, we measured in situ photosynthetic active radiation (PAR, 400-700 nm), chlorophyll a (Chl a), and the MPB composition. The diatom Gyrosigma fasciola was the most occurring species at all stations, while Chl a showed large intra- and inter station-specific variability. In situ PAR intensities partially exceeded the calculated light compensation point of the MPB, which indicates MPB as a potentially important carbon source for the heterotrophic benthic community. However, primary production differed strongly between the stations, following the general Chl a pattern. Further, PAR availability depends on turbidity, caused by melting related processes and its distribution in Potter Cove by wind and currents. Therefore, our study is a first step to reveal the contribution of microphytobenthic primary production in Potter Cove and thereby expand our understanding of how melting glaciers may alter Antarctic coastal primary production.
Monitoring changes in shallow-water benthic ecosystems requires baseline information against which any future changes can be assessed. This includes information on the existing spatial extent and physical habitat requirements of the different benthic communities.

A detailed study in shallow coastal waters of the Vestfold Hills has shown that seafloor geomorphology information provides a physical framework for understanding benthic habitats and a broad indication of the distribution of benthic communities in the region. Macroalgae is common in the coastal waters, inhabiting very shallow areas with hard substrate. Areas with extended sea ice cover are dominated by invertebrates and are devoid of macroalgae. Studies have shown that these shallow invertebrate-dominated ecosystems are vulnerable to changes in sea ice extent which will increase light availability and drive regime shifts towards macroalgae-dominated communities (Clark et al. 2013. DOI:10.1111/gcb.12337).

New high-resolution multibeam data collected over the broader Vestfold Hills region is being used to expand our understanding of the spatial extent of benthic habitats across the shallow coastal environment and identify potential habitat for macroalgae communities. Bathymetry derived from multispectral satellite imagery is used to fill data gaps in very shallow areas and areas under sea ice. This seafloor information is useful to guide further biological studies to determine if and when regime shifts occur.
Polynya Formation and its Associated Chlorophyll - A Variability in Antarctica

Jisoo Park¹ (jspark@kopri.re.kr), Edward Shin¹, Eunho Ko¹, Sanghoon Lee¹, Taewook Park¹
¹Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of

Antarctic coastal polynya is the most productive area in the Southern Ocean, therefore they play a significant role in polar ecosystem. Change in polynya phenology can alter, or even disrupt, the polar food web. As such, it is important to understand the polynya phenology. However, despite polynya's significance in the polar ecosystem, there are still many unfamiliar aspects of polynya and its associated changes in ecosystem. Our aim is to organize relevant polynya data, reveal insightful polynya characteristics: determine whether physical polynya features have an effect on phytoplankton dynamics. We investigated to what extent the physical polynya parameters affect polynya phenology. By looking for correlations between such parameters and chlorophyll-a concentration of each season and their respective dates, we hope to develop a thorough understanding of the relationship between the physical input and biological output. We focused on Antarctic polynyas, and we are especially interested in the types of environment that contribute to distinct correlations. We are also interested in the causation and the implications of our findings. Understanding the driving force behind the physical parameters of polynya would allow us to predict what sort of effect a polynya can have on its ecology. We will talk about how physical forcing could affect chlorophyll variability in Antarctic coastal polynyas in recent decades, and whether the relation has any connection with climate change.
Shelf Ice-associated Cryo-benthos and Environmental Features

Horst Bornemann¹ (horst.bornemann@awi.de), Christoph Held¹, Marthán N. Bester², Julian Gutt³, Boris Dorschel¹, Dieter Gerdes¹, Rainer Knust¹, Dominik Nachtsheim³, W. Chris Oosthuizen², Nils Owsianowski¹, Joachim Plötz¹, Claudio Richter¹, Svenja Ryan¹, Michael Schröder¹, Rainer Sieger¹, Daniel Steinhage¹, Christine Wesche¹

¹Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Bremerhaven, Germany, ²Mammal Research Institute, University of Pretoria, Pretoria, South Africa, ³Institute for Terrestrial and Aquatic Wildlife Research, University of Veterinary Medicine Hannover, Foundation, Büsum, Germany

Incidences of cryo-benthic communities beneath ice shelves are rare and recent discoveries. Combined seal- and ROV-borne imagery and novel sampling technologies allowed for a re-assessment and augmentation of earlier findings on a cryo-benthic isopod community (Antarcturus cf. spinacoronatus), being attached head-down to the underside of floating shelf ice at depths of around 80-150m. The shelf ice-associated cryo-benthos was discovered at Drescher Inlet (-72.83667 -19.15300), Riiser-Larsen Ice Shelf (eastern Weddell Sea). The inlet constitutes a 25km long and between 2 and 4km wide crack in the surrounding shelf ice, which is associated with certain environmental features. Here we compile all available local physical, biological, and biogeochemical data and discuss their relevance in the wider regional context for this faunal hotspot. These include data on shelf, sea and platelet ice, seafloor topography, hydrography and water chemistry, as well as associated pelagic and benthic marine life, in particular affinities of the cryo-benthic isopod community to related fauna occurring in nearby seabed communities using molecular barcoding.
Data on Antarctic coastal sites remain scarce and are generally limited to microscopy; the diversity of coastal Antarctic ecosystems has been long underestimated. The diatom-dominant community in the coastal sea waters of the Fildes Peninsula has been described according to traditional protocols. Molecular diversity of microbial eukaryotes (≤ 20 µm) from Great Wall Cove and Ardley Cove, Fildes Peninsula, has been determined by Illumina MiSeq2000 sequencing. Inferred metabolisms of summer phytoplankton in the two coves are characterised by autotrophy and heterotrophy. The frequent occurrence of such nanoflagellates as Dinoflagellates, Cryptophyta, Stramenopiles, Pyramimonas, Telonema, and Cryothecomonas, is predicted to be important in these Antarctic coastal communities. Seawater exchange exists between the two coves when high tide occurs, indicating that there appears to be mixing between the microbial communities in the two coves. Cluster analysis of the microbial eukaryote composition at the phylum and genus levels reveals a conservation of the community composition between the two coves. The inner stations of Great Wall Cove are clustered closely together, surrounded by islands and formed into a semi-closed body of water. The samples from the outer stations of Great Wall Cove, are more similar to the Ardley Cove samples. Sea water exchange between the outer basins might be the effect of their community compositions.
Lipid Composition of the Sea Ice and Water Column in Early Spring

Patti Virtue1 (virtue@utas.edu.au), Peter Nichols2
1University of Tasmania / Institute for Marine and Antarctic Studies, Hobart, Australia, 2CSIRO Oceans & Atmosphere, Hobart, Australia

To understanding the role of sea ice in the Southern Ocean ecosystem, we need to also understand the availability of key and essential nutrients to consumers. Baseline biochemical data are therefore required in order to gauge any impact the reduction of sea ice will have on the sea ice community. Here we compare lipid class, fatty acid and sterol content and composition of sea ice and water column samples collected during early spring in East Antarctica. The availability of key essential omega-3 long-chain (≥C20) polyunsaturated fatty acids, including - 20:5w3, eicosapentaenoic acid, EPA and 22:6 w3, docosahexaenoic acid, DHA - the major constituents of cell membranes, were found to be severely limited during late winter and early spring, particularly in the under ice water samples. The ramifications for sea ice obligate organisms such as larval krill are discussed.
Macrobenthic Communities along a Shelf-slope-Basin Transect in the Bering Sea

Heshan Lin¹ (linheshan@tio.org.cn), Kun Liu¹, Jianjun Wang¹
¹The Third Institute of Oceanography, State Oceanic Administration, Xiamen, China

The study analyzed the macrobenthic community and the spatial-temporal patterns of the Bering Sea based on a number of summer surveys. Polychaetes (Scoloplos armiger), crustaceans (Ceradocus capensis) and sea urchins (Echinarchnium parma) were the main dominant groups in the shallow shelves. The sea star (Ctenodiscus crispatus) and the brittle star (Ophiura sarsii) were the main dominant groups in the continental slope, whereas small polychaetes (Prionospio malmgreni) dominated the basin. Sediment type, water depth, and current were the major factors affecting the macrobenthic community and spatial distribution. The Bering shelves and slope showed an extremely high-standing biomass. In particular, the northern shelf, which is primarily controlled by Anand Water, is an undersea oasis. In contrast, a deficiency in the downward transport of particulate organic carbon has resulted in a desert-like seabed in the basin. Compared to previous studies, macrobenthic communities of this area have undergone significant structural changes in recent decades, resulting in a decrease in density and an increase in biomass. In addition, populations of amphipods and bivalves in the northern shelf have decreased significantly and have been gradually replaced by other species. These changes might be associated with advanced seasonal ice melting, changes in organic carbon input, and global warming, indicating that large-scale ecosystem changes have been occurring in the Bering Sea.
Dispersal is a key factor affecting the biogeography and connectivity of Antarctic benthic communities. The potential for planktotrophic larval dispersal is typically inferred from genetic data and current distributions of adult forms. However, these methods do not provide insights into the mechanisms behind observed patterns nor information on processes occurring on ecologically relevant time scales. In regions of complex topography and potentially limited circulation (e.g., in fjords), source-sink population dynamics may be very important in assembling communities. Fjords along the West Antarctic Peninsula are known to harbor rich and abundant benthic communities distinct from those on the open shelf and even adjacent fjords (Grange and Smith, 2013) and are therefore likely to exhibit limited connectivity and larval dispersal. We applied the Lagrangian TRANSport model (LTRANS) (North et al. 2005) to Andvord Bay, a fjord on the northern West Antarctic Peninsula, to address this key question: can the abundant megabenthic populations of Andvord Bay export larvae to adjacent fjords and the open continental shelf? The model tracked simulated larvae (i.e., particles) in a range of dispersal scenarios over time scales representative of PLDs for a range of organisms (14-120 days). Results indicate that Andvord Bay acts to retain larvae over 120-d time scales, and may not routinely export larva to adjacent fjords the open continental shelf along the West Antarctic Peninsula.
Decadal Population Trends of Two Pacific Arctic Clams as Related to Production

Christina Goethel¹ (cgoethel@umces.edu), Jacqueline Grebmeier³, Lee Cooper¹
¹University of Maryland Center for Environmental Science, Solomons, United States

Dynamic factor analysis of bivalve abundance and biomass, along with two covariates, sea ice extent and bottom water temperature, have identified time-series benthic macrofaunal changes in the Distributed Biological Observatory (DBO) in the Pacific Arctic. Station SLIP 5 in the northern Bering Sea (DBO region 1) was determined to be a transition point for abundance and biomass of the common deposit-feeding bivalve *Macoma calcarea* between three stations to the south and two to the north. In addition, an increase in the suspension-feeding bivalve *Serripies groenlandicus*, has been observed during field sampling (2014-2017) in the DBO 3 region. We determined the spatial and temporal resolution of abundance and biomass of *M. calcarea* and documented the increased abundance and biomass of *S. groenlandicus* north of Bering Strait. We also tracked changes in abundance and biomass of the two species at five additional sites in the DBO 3 region (north of Bering Strait) and over two additional years. We will present results relating the potential significance of sediment chlorophyll-a, integrated water column chlorophyll-a concentrations, and sediment parameters that include total organic carbon content and grain size as potential drivers for these changes. We will show that these additional covariates contribute to the assessment of abundance and biomass trends for these two Arctic bivalve species and reflect on the overall biological productivity of the system.
As sea ice retreats due to a warmer climate, habitats of seabirds, such as little auks (*Alle alle*), will change. To understand how this affects populations of little auks, it is essential to study the relations between them, their zooplankton prey and water mass characteristics. A study was carried out in NW Greenland in July-August, a period where little auks depend on lipid-rich zooplankton to feed their chicks. Results suggest that the abundance of prey integrated across the upper 50 m, which was what we were able to measure from net hauls, may only be important if the prey items are also concentrated in the vertical plane. The use of high-resolution acoustic echo sounders represents a method to study fine scale zooplankton distribution patterns in details and non-invasively. This approach was used in a similar study in NE Greenland where water mass characteristics, fine scale zooplankton distribution and little auk abundance were assessed across areas with different sea ice cover and stratification, from shelf to off-shelf areas. Here, we will present data on zooplankton fine-scale distribution in relation to sea ice cover, physical and biological oceanography, and furthermore discuss how this relates to the abundance of little auks.
Small-scale DVM of Zooplankton and Susceptibility to Light Pollution

Jørgen Berge¹ (jorgen.berge@uit.no), Martin Ludvigsen², Geir Johnsen², Maxime Geoffroy³, Jon Cohen⁴, Malin Daase⁵

Light is a major cue for nearly all life on Earth. However, most of our knowledge concerning the importance of light is based on organisms' response to light during daytime, including the dusk and dawn phase. When it is dark, light is most often considered as pollution, with increasing appreciation of its negative ecological effects. Using an Autonomous Surface Vehicle fitted with a hyperspectral irradiance sensor and an acoustic profiler, we detected and quantified behavior of zooplankton in an unpolluted light environment in the high Arctic polar night, and compared the results with that from a light polluted environment close to our research vessels. First, in environments free of light pollution, the zooplankton community is intimately connected to the ambient light regime, and perform synchronized diel vertical migrations in the upper 30 m despite the sun never rising above the horizon. Second, the vast majority of the pelagic community exhibits a strong light-escape response in the presence of artificial light, observed down to 100 m. This study underscores the need to adjust sampling platforms, particularly in dim-light conditions, to capture relevant physical and biological data for ecological studies. It also highlights a previously unchartered susceptibility to light pollution in a region destined to see significant changes in light climate due to reduced ice cover and increased anthropogenic activity.
As the Western Antarctic Peninsula (WAP) region responds to a warmer climate, the impacts of glacial meltwater on the Southern Ocean are expected to intensify. Because fjords provide an extreme in the meltwater’s spatial gradient from the glacio-marine boundary to the WAP continental shelf, Andvord Bay is an ideal study site to understand the impacts of environmental conditions, particularly glacial meltwater, on phytoplankton community composition and their spatial distribution. While meltwater processes are weaker in Antarctic fjords in comparison to the Arctic, they can still influence phytoplankton due to the direct entrainment into water column; meltwater is rich in macro-nutrients and iron, induces stratification, and impacts underwater light field, but the net effect of these factors is elusive. Fluorometric chlorophyll measurement indicates that the concentration range is ~1 order of magnitude higher in Dec. 2015, while significant deep chlorophyll and phaeo-pigment accumulations were found in Apr. 2016. Concurrent high-performance liquid chromatography samples were also collected; and in the context of environmental conditions, further analyses of these samples can illustrate the spatial distribution of phytoplankton community composition and their seasonal variability. The hypothesis being tested is the impact of meltwater presence can shift phytoplankton community to one that is dominated by cryptophytes due to reduction in salinity and mixed layer depth.

The Arctic Ocean is undergoing substantial warming and sea ice loss, which are likely to cause changes in primary production, export fluxes and productivity of the Arctic marine ecosystems. Yet, we lack sufficient information about the ecosystem productivity, organic carbon cycling and cryo-pelago-benthic coupling processes in the Arctic Ocean. Such information is particularly scarce for deep Arctic basins and during the spring to summer transition under seasonally ice-covered waters. Our aim was to provide carbon budget estimations under different environmental regimes and bloom development stages in the region north of Svalbard. We conducted ecological and biogeochemical early spring process studies in sea ice covered areas, from the shelf to the basins of the European Arctic margin and on the Yermak Plateau during the TRANSSIZ cruise PS 92 on the ice breaker R/V Polarstern in May/June 2015. We identified the potential characteristics of carbon production of primary producers in the sea ice and water column, and secondary production of zooplankton and benthos. We looked into the organic carbon production fate and export, including respiration and burial, as well as identified similarities and differences in ecosystem functioning along topography-, sea ice- and water mass-related gradients. This scientific initiative was undertaken by Arctic in Rapid Transition (ART) International Arctic Science Committee (IASC) network.
High Resolution Hydrographic Surveys: Fjord Ecosystem Experiment Results

Hank Statscewich¹ (hank.stats@alaska.edu), Peter Winsor¹, Martin Truffer¹, Craig Smith², Maria Vernet³
¹University of Alaska - Fairbanks, College of Fisheries and Ocean Science, Fairbanks, United States, ²University of Hawai`i at Manoa, School of Ocean and Earth Science and Technology, Honolulu, United States, ³Scripps Institution of Oceanography, University of California, San Diego, Integrative Oceanography Division, La Jolla, United States

Fjords with tidewater glaciers occur widely at temperate to polar latitudes, and extensively along the sub-polar Western Antarctic Peninsula (WAP). Fjord ecosystems can be heavily modulated by local conditions, causing ecosystem structure and function to differ from the open continental shelf and to be highly sensitive to climate warming. Fjord ecosystems remain very poorly studied along the WAP, and several lines of evidence suggest that WAP fjords are intense hotspots of biological productivity. In December 2015 and April 2016, a series of high resolution hydrographic surveys were conducted utilizing a towed undulating instrument platform and an autonomous underwater vehicle to investigate phytoplankton distributions, meltwater content, and sediment inputs to Andvord Bay, a sub-polar glacio-marine fjord on the WAP. The towed vehicle and glider completed several transects near glacier termini, over sills and along the length of Andvord Bay. Our observations reveal elevated chlorophyll values associated with a persistent upper water column frontal boundary near the mouth of the fjord and limited subsurface sediment plumes near glacier termini. We hypothesize that the high (benthic and pelagic) productivity in Andvord Bay may be facilitated by elevated turbulence associated with bathymetric features, fjord geometry and tidally driven flow and further aided by existing conditions of low meltwater content and the limited extent of glacial-derived sediment input.
Sediment traps may provide a useful tool to study Arctic zooplankton during the whole year, irrespective of environmental conditions or sea ice. Year-round sediment traps were moored in 2014/2015 and 2015/2016, in high Arctic fjords on Svalbard - Kongsfjorden and Rijpfjorden respectively, to monitor seasonal and inter-annual variability in zooplankton community. These fjords require enhanced monitoring, because of the progressive alteration of extent and dynamics of the relatively warm West Spitsbergen Current. Thus, fjords differ strongly in the amount of flowing Atlantic Water, which influences the composition and distribution of zooplankton species. Our study demonstrated the relationship between distinct water masses and zooplankton structure in fjords. The zooplankton community was divided into several groups, strictly related to hydrological shifts and advection in the fjords: spring, summer/autumn, and winter. The dominant species in the winter group in fjords consisted mainly of Arctic taxa such as *Oikopleura* spp, *Pseudocalanus* spp., *Metridia longa*, *Themisto libellula*, *Limacina helicina*, but also typical boreal species like *Limacina retroversa* and cosmopolitan *Oithona similis*. The spring and summer seasons in fjords were characterized by high numbers of Copepoda eggs and nauplii, small copepods and genus *Calanus* which differed in proportions within the fjords. Especially three species were linked to the advection events in the fjords - two pteropods and *O. similis*. 
ART Initiated TRANSSIZ - Transitions in the Arctic Seasonal Sea Ice Zone - Cruise

The TRANSSIZ ('Transitions in the Arctic Seasonal Sea Ice Zone') cruise PS92 was carried through by the “Arctic in Rapid Transition” (ART) International Arctic Science Committee (IASC) network on the German research icebreaker R/V Polarstern in May/June 2015. The overall cruise goal was to use a multidisciplinary approach to identify the potential characteristics in carbon production as well as to investigate similarities and differences in ecosystem functioning related to gradients in topography, sea ice and water masses, and to link past and present sea ice transitions in the Arctic Ocean. Thus, ecological, physical and biogeochemical early spring process studies were conducted across the shelf of the European Arctic margin and on the Yermak Plateau. At each station R/V Polarstern was anchored for 36 hours to an ice floe. Special emphasis was given to the quantification of the environmental preconditions for biological productivity (e.g. nutrients, stratification) under sea ice and in open waters. With this study we gained new insights for improving predictions of the potential annual primary production in the changing Arctic Ocean and the understanding of ecosystem functioning and biogeochemical cycles in the transition from spring to summer in the European Arctic margin. Investigations during TRANSSIZ will also enable reconstructions of productivity, food web carbon flux, and sea ice and ocean circulation across the few last glacial cycles.
Functional Patterns of Chukchi Sea Benthos

Renate Degen\textsuperscript{1} (renate.degen@hotmail.com), Bodil Bluhm\textsuperscript{2}, Katrin Iken\textsuperscript{3}
\textsuperscript{1}University of Vienna, Limnology and Bio-Oceanography, Vienna, Austria, \textsuperscript{2}Arctic University of Norway, Tromsø, Norway, \textsuperscript{3}University of Alaska - Fairbanks, Fairbanks, United States

Traits - i.e. the life history, morphological and behavioural characteristics of species - provide a link between species and multiple ecosystem-level processes, such as the fluxes of oxygen, energy and nutrients. In marine ecosystems, trait-based approaches are often applied to detect early responses of communities to environmental changes or stressors, to estimate ecosystem resilience or vulnerability, or to indicate overall ecosystem functioning. They are however still rarely applied in studies from polar marine regions, albeit these areas are facing dramatic and rapid environmental changes today. One reason is that biological trait information of polar species is often not ready at hand, and its collation requires a time and labor intensive survey of literature. The open access to trait databases is an important step in overcoming this obstacle. Here we demonstrate how trait information retrieved from the online accessible Arctic Traits database is used to analyze functional patterns of benthic communities in the Chukchi Sea, a shallow Arctic shelf sea characterized by tight pelagic-benthic coupling. The observed community patterns are further related to environmental parameters like water temperature and sea ice concentration in order to detect potential drivers of change in benthic ecosystem functions.
Sea Ice and Glacier Control of Antarctic Coastal Ecosystem Dynamics and its Fate

Hyoung Chul Shin¹ (hcshin@kopri.re.kr), Sung-Ho Kang¹, Hyoung Sul La¹, Tae Wan Kim¹, In-Young Ahn¹
¹Korea Polar Research Institute, Incheon, Korea, Republic of

Bays and coves in King George Island, Antarctica represent a sentinel embayment ecosystem in South Shetland Islands that is sea ice affected in a highly seasonal manner and subject to accelerating glacier retreats in the region. Oceanographic measurements mostly from fixed points and the station weather logs for nearly 20 years have been examined in order to determine the mechanisms of ecosystem responses and the critical governing factors. Sea ice formation and break-up in the Bay appear to be controlled by physical oceanography in offshore waters and sea ice trend in the wider region. In addition, yearly varying sea ice dynamics combined with local meteorology seem to determine the fate of the algal blooms and the major primary producer species. There is an inconspicuous yet consistent trend with the taxonomic group and size compositions. Moreover, glaciers receding at high paces (most recently, around 100 m per year) are opening up new waters and create new habitats both pelagic and benthic. This already provided for a new start of ecological successions but also would modify key environmental features that will shape the future ecosystems and determine the changing functions. Models that came out of this would greatly assist us in assessing the future changes in the ocean-cryosphere boundary along the Northern Antarctic Peninsula.
Changes in sea ice cover are affecting the bloom timing, quantity and quality of primary production, and thus quantity and quality of organic matter reaching the seafloor. Changes in organic matter export fluxes are predicted to influence structure and functioning of benthic communities, especially in the deep-sea. The aim of this study was to examine meio- and macro- benthic community structure and function in relation to sea ice cover, bloom stage and depth from the shelf to the basins of the European Arctic margin and on the Yermak Plateau, Svalbard fjords and in the Barents Sea. Material was collected during spring cruises PS92 - TRANSSIZ in May-June 2015, and ARCEX in May 2016, and included sediment and particulate Organic Matter (OM) samples. OM sources and trophic position of benthic animals were determined with use of stable carbon ($^{13}$C) and nitrogen ($^{15}$N) isotopes. Additionally bioturbation experiments were performed. The particulate OM concentrations in the water column decreased with depth, and increased with the bloom progress. Benthic density, biomass and intensity of bioturbation were the highest at the shelf stations where intensive bloom was observed and were related to higher concentrations of fresh OM input to the sea bottom. Low benthic infaunal diversity, abundance, and biomass were noted in fjords and deep stations where low concentrations of lower quality OM reaching seafloor were noted.
Mammalian species have been shown to shift life history event phenology in response to environmental change, but this response is highly variable across species. The replacement of hair (i.e. molt) is an intermediate life history event that may affect subsequent breeding attempts; however, the magnitude of its impact is poorly understood. Our aim was to understand the carry-over effects of molting and pupping phenology in Weddell seals. To do so, we conducted demographic surveys of 4,252 uniquely identified seals in Erebus Bay, Antarctica during the austral summers of 2013-2017. The start date of each animal’s molt was back-calculated based on hair loss progression, and pupping success and dates were obtained for the breeding season prior to and following the molt. The molt in Weddell seals lasted 29 ± 8 days. Within adult females, molt phenology was markedly different across reproductive and non-reproductive individuals, with non-reproductive seals beginning molt 16 days earlier than reproductive seals (mean start date Jan06 and Jan22, respectively, t-test $p<0.0001$). Animals that molted later were less likely to be seen in the breeding colonies during the following pupping period, suggesting they either did not pup that year or were deceased. By systematically manipulating estimated transition probabilities between pupping and molting categories using a simulation model, we demonstrate the importance of intermittent skipping of pupping to reset life history phenology.
How Do Hormones and the Skin Transcriptome Drive Molt in a Polar Pinniped?

Amy Kirkham1,2 (amy.kirkham@gmail.com), Roxanne Beltran2,3, Skyla Walcott2, Michelle Shero2, Donald Thompson, Jr4, Julie Avery5,6, Jennifer Burns2

Pinnipeds replace their fur each year in an annual pelage molt, the timing of which is tightly regulated to conserve energy. Recent cases of disrupted molt in Arctic seals have highlighted how little is known about the underlying mechanisms of this key life history event. To characterize the drivers of healthy molt in a polar phocid, we examined hair cycling in 121 prime-age female Weddell seals (Leptonychotes weddellii) during the Antarctic summer (Nov-Feb). At each handling (n=1 or 2 per female), skin biopsies were collected to determine hair cycle phase (i.e., anagen, catagen, telogen) by histology, and serum hormone levels and body composition were measured to test for endocrine and nutritional effects on molt. Hair follicles became active in Nov/Dec, at least a month prior to the onset of shedding, and did not complete growth until late Jan at the earliest. Elevated prolactin appeared to delay molt, while body condition did not impact molt timing. To identify gene expression changes between three hair cycle phases, skin transcriptomes were profiled using Illumina RNA-Seq (n=9). Over 4000 genes were differentially expressed between phases. These included hormone receptors and genes involved in wound healing, suggesting skin’s response to hormones and its healing capacity change across the molt. Our novel findings on endocrine and trancriptomic control of molt indicate how this process may be impaired, as well as how altered hair cycling may impact integumentary health.
Environmental Influences on the Thermal Flux of a Molting Polar Pinniped

Skyla Walcott¹ (skyla.walcott@gmail.com), Amy Kirkham¹,², Roxanne Beltran¹,³, Jennifer Burns¹
¹University of Alaska Anchorage, Department of Biological Sciences, Anchorage, United States, ²University of Alaska - Fairbanks, College of Fisheries and Ocean Sciences, Fairbanks, United States, ³University of Alaska - Fairbanks, Department of Biology and Wildlife, Fairbanks, United States

Antarctic pinnipeds face complex thermoregulatory challenges, as they must conserve heat in both air and water. Primary adaptations to reduce heat loss include a thick blubber layer and the ability to limit blood flow to the peripheries via vasoconstriction. These adaptations reduce heat flux by decreasing the temperature gradient between the animal and the environment. During the annual molt however, heat conservation may be compromised, as hair follicles may require more constant perfusion; this could result in higher rates of heat loss and higher metabolic costs. In warmer summer months, the thermal gradient between the animal and environment is reduced, providing optimal ambient conditions for molting.

Across a four-year study, surface temperature and heat flux were directly measured in-air, on adult female Weddell seals (n=77, Leptonychotes weddellii) across the progression of the molt. Surface temperatures increased significantly with increased ambient temperature and relative humidity and decreased wind speed and solar radiation. Heat flux was significantly higher during the molt than prior to its onset, resulting in greater overall heat loss in molting seals. This suggests that perfusion is increased during molt to support hair follicles at the expense of increased thermoregulatory costs. Correlations between time-activity budgets and ambient conditions will be measured to determine how environmental perturbations may influence summertime molting haul-out decisions.
Recent studies carried out by our research group revealed high levels of Cd, Pb, Cr and Se in the kidney and liver of three penguin species: Papua - *Pygoscelis papua*, Barbijo - *Pygoscelis antarctica* and Adelia - *Pygoscelis adeliae*. According to these results, the effects on the cell cycle have been studied, that the average concentrations found in chickens, juveniles and adults and the EC50 (effective concentration 50) provoke on the cell lines VERO (renal) and AML12 (hepatic). The cells were treated for 24 hours with each concentration. Subsequently using the IP fluorochrome (propidium iodide) by flow cytometry and with the ModFit computer program, the changes produced with respect to the control were detected, by the different concentrations, in each phase of the cell cycle. For both cell lines we observed that the concentrations of Cr, Se and the highest Cd (adults), produce an increase in the percentage of cells in S phase, causing their blockade in this phase and preventing cell division. In the case of lead, we find that the effect is similar for the highest concentration (EC50), that is, blockade in S phase; however, at lower concentrations, an increase in the percentage of cells in G2 / M phase is observed, and therefore, an increase in the percentage of cells in mitosis.
Metals Found in Penguins Produce Oxidative Stress in Renal and Hepatic Cells

Ana Meseguer¹, Silvia Jerez², Andrés Barbosa², Miguel Motas³ (motas@um.es)
¹University of Murcia, Murcia, Spain, ²Museo Nacional de Ciencias Naturales, CSIC, Madrid, Spain, ³Health Institute Carlos III, Environmental Toxicology, Madrid, Spain

Antarctica is one of the last virgin regions, however studies carried out by our group have shown an increase in the levels of certain elements, in three species of penguin: Papua - Pygoscelis papua, Barbijo - Pygoscelis antarctica and Adelia - Pygoscelis adelia. The mean concentrations of Cd, Pb, Cr and Se and EC50 (effective concentration 50) found in chick, juvenile and adult individuals from three penguin species of the Antarctic Peninsula and Associated Islands, were evaluated in renal and hepatic cells (cell lines VERO and AML12). The cells were treated for 24 hours with each concentration. Later, using the colorimetric probe DCFH-DA (dichloro-dihydro-fluorescein diacetate) and by means of flow cytometry, the changes produced by the concentrations of each element on oxidative stress were detected. In the VERO cell line, the results show a decrease in fluorescence proportional to the concentration and therefore a decrease in the reactive oxygen species (EROs). This is due to the fact that these concentrations modify the integrity of the cellular DNA, not allowing the cell to produce EROs. Therefore, the determination of ROS is more an indicator of mortality than of toxicity for said cell line. In the AML12 cell line, the highest concentration corresponding to the average concentration of adults causes an increase in the EROs; for the rest of the elements no significant differences appear or, as in VERO, a decrease in fluorescence occurs in a concentration-dependent manner.
Adélie Penguin Diet: Comparison of Stomach Flushing with Faecal DNA Analysis

Bruce Deagle1 (bruce.deagle@aad.gov.au), Julie McInnes1, Louise Emmerson1, Michael Dunn2, Stacey Adlard2, Andrea Polanowski1, Claire Waluda2

1Australian Antarctic Division, Kingston, Australia, 2British Antarctic Survey, Cambridge, United Kingdom

Adélie penguin diet is studied at colonies around Antarctica as part of CCAMLR's Ecosystem Monitoring Program (CEMP). The standard methodology involves stomach flushing of breeding birds to identify prey species and record diet composition by mass. Due to the invasive nature of sampling, genetic approaches using faecal samples are being investigated.

High-throughput sequencing of DNA barcoding markers recovered from faecal samples has become a common method for assessing diet in a wide range of animals. However, direct comparisons of DNA-based diet analysis with traditional methods are still limited.

We report on a study carried out at Signy Island (South Orkneys) comparing stomach lavage data (n= 60; collected in 2014/15 and 2015/16) with DNA data from concurrently collected faecal samples (n=450). For the DNA analysis a conserved marker (18S rRNA) was used to identify broad prey groups and mtDNA markers used to provide high resolution taxonomy of main prey groups.

Antarctic krill (Euphausia superba) and bony fish (Actinopterygii) made up >98% of the stomach content mass and also >99% of the prey DNA sequence reads. Both datasets also identified a switch from a krill dominated diet in 2014/15 to a nearly even split between krill and fish in 2015/16. We discuss the strengths and weaknesses of each approach, comparability of the datasets and the prospects for incorporating DNA diet analysis into long-term monitoring programs.
Defining the impact of anthropogenic stressors on Antarctic wildlife continues to be an active aim for investigators. Physiological conservation has emerged as a new research topic that aims to identify key physiological variables that can help ecologists to assess the impact of human activities in the environment. Recently, telomeres have been suggested as a promising molecular tool to investigate the fitness of wild vertebrates. Telomeres are well-conserved repeated sequences of non-coding DNA located at the terminal ends of chromosomes. They shorten with advancing age and this telomere attrition is accelerated by the occurrence of environmental stressors. Furthermore, telomere length appears to be a reliable predictor of longevity and survival in captive and wild vertebrates. In this study, we examined the relationship between telomere length and various degrees of long-term human exposure in Adélie penguin chicks (*Pygoscelis adeliae*) from Terre Adélie, East Antarctica. Thus, telomere length was quantified and compared between chicks from two sites with sustained and continuous human activity (Petrels Island) and two sites on neighboring islands with little or no human presence (Lamarck and Bernard Islands). Our results will provide a powerful insight into the long-term impacts on wildlife living in close proximity to human activity, as well as contribute to the growing body of research on the efficacy of telomere length as an eco-indicator.
Sea-ice concentration in the Arctic Ocean has decreased by 9 % per decade since 1978. As a consequence, more vessels are navigating the Arctic, increasing the risk of alien species introduction by ballast water (BW) discharge. The ships depend on BW for stability and structural integrity. Ballast water, however, also contain aquatic species, and in turn, these introduced species might survive and establish a reproductive population. A tracer for BW was implemented into a high-resolution North Atlantic/Arctic Ocean-Sea Ice Model (NAOSIM). The flow of the BW-tracer discharged in the Arctic and possible areas of accumulation were investigated. In total, 17,407 vessels navigated the Arctic waters in 2013, with an estimated amount of discharged BW of about 13 million m³. In the model, the BW-tracer is released along the shipping routes navigated in 2013. Results show that the seasonal cycle of the ocean mixing affects the BW-tracer distribution significantly. In winter, the BW-tracer reaches deeper waters, than in spring, when the sea-ice starts melting and stratifies the upper ocean. In spring and summer, the BW-tracer remains within the upper 20 m, where the availability of sun and nutrients lead to favorable living conditions for non-indigenous species. One area of BW-tracer accumulation is the vicinity of the Kara Gate in the Barents Sea. There, 10 % of the BW-tracer remains more than 20 days after its release. Lower percentages of the BW-tracer remain almost three months.
Trophic and Non-trophic Connections of Potter Cove Marine Ecosystem

Vanesa Anabella Salinas1,2 (vane.salinas79@gmail.com), Fernando Roberto Momo1,3
1Universidad Nacional de General Sarmiento, Instituto de Ciencias, Los Polvorines, Argentina, 2CONICET, CABA, Argentina, 3Universidad Nacional de Lujan, Biology, Lujan, Argentina

Organisms eating each other are only one of many types of well documented and important interactions among species. However, ecological interactions of coexisting species involve much more than just feeding. Within an ecosystem, species interact with each other in many different ways including predation, competition and facilitation. These interactions can be modelled as trophic and non-trophic networks which constitute a group of links that mediates ecological communities’ response to perturbations, such as exploitation and climate change. Here we expose the trophic and non-trophic interactions of the marine ecosystem of Potter Cove (62°14’S, 58°40’W, King George Island, Antarctica) expressed in four different networks depending on the type of interaction: trophic (+/-), commensalism (+/0) and amensalism (-/0), mutualism (+/+ and competition (-/-). Conducting a preliminary analysis, we argue the importance of incorporating both direct and indirect non-trophic and trophic interactions and their ecological context, suggesting that it is the key to predicting community dynamics, thus its stability.
Snow and ice surfaces host viable and diverse bacterial and fungal communities. These originate partly from wet and dry aerial deposition. However, the impact of short or long distance air transport, meteorological features, selective deposition and colonization processes remain unclear in their role with air and snow microbial diversity. Rapidly changing climate patterns in polar regions evoke a pressing need to investigate such air-snow community dynamics.

Eighteen air samples, comprising 56m³ of air, were taken at 15 sites along three transects in northern Iceland, covering distances of 50 to 120km with MD8 Air Port (Sartorius) and Coriolis µ (Bertin) air samplers. In two transects 11 snow sites were sampled. Airborne and snow-associated bacterial and fungal diversity, abundance and ice nucleation potential were investigated for temporal and spatial variation and correlated with multiple environmental factors.

Bacteria and fungi feature some ubiquitous core phyla, but show significant differences between air and snow on taxa level. Local aerosolisation sources, geographical and meteorological features impact on small scale spatial variability. Temporal site variation amongst the respective habitat was low.

Results hint towards a high contribution to snow microbial diversity from other than single cell deposition, suggesting snow inoculators originate from wet deposition, particle-associated microbe input or airborne, rare but highly successful colonizers.
The role of snow on underwater photosynthetically active radiation (UWPAR) in the McMurdo Dry Valleys (MDVs) has been understudied due to lack of a detailed snowfall record. Research has shown that a relationship between snow cover and UWPAR exists, but the extent has never been evaluated in great detail. Although annual snowfall values in the MDVs are low (3 to 50 mm water equivalent annually), trends of increasing snowfall on the continent under future warming conditions could lead to an increased role for snow in regulating UWPAR (and associated primary productivity). Here, we discuss evidence from the snowfall record, surface PAR, and UWPAR, of the influence of snowfall on UWPAR in the major lakes of Taylor Valley. A new, detailed record of snowfall over the last 10 years created from camera and satellite imagery, and ground-based instruments will be presented. Statistical analysis of snow events within the record reveals the nature of their role in governing UWPAR rebound at Lake Hoare. In one large snowfall event in November 2016, UWPAR took 41 days to recover to levels equivalent to before the snowfall at Lake Fryxell which is more proximal to the coast. At the more distal West Lobe Bonney the recovery time was only 9 days. We will also present progress on a spatial model of UWPAR which will aid in evaluating the annual light budget under the lake and provide insight on snow as an ecological disturbance and the implications for lacustrine primary productivity.
Polar regions are characterised by microclimates that are highly variable in space and time. Such high climate variability is expected to negatively impact biodiversity as it increases the probability that conditions will exceed species’ physiological limits or the thresholds to ecosystem resilience. Not all microhabitats are equally variable, but few studies have examined how spatial differences in variability can affect the distribution of biodiversity. We surveyed 60 quadrats of Antarctic mosses over 10 years to determine if the health or composition were affected by the mean or variability of available water. We found that higher climate variability was associated with more green, photosynthetically active moss and a greater proportion of the endemic species *Schistidium antarctici*, compared to the cosmopolitan species *Ceratodon purpureus*. The healthiest quadrats were those with the highest mean water availability, but variability in water availability also positively affected species composition, especially where the mean water availability was low. Antarctic mosses can dehydrate and become physiologically inactive during drier periods to prevent damage, so our results suggest that periodic flooding is more beneficial for moss health and endemic species than having moderate, stable conditions. These results are especially important as 21st century climates are expected to be more variable and this could therefore impact ecosystems regardless of changes in mean climate.
Ecologists widely acknowledge that a complex interplay of endogenous (density-dependent) and exogenous (density-independent) factors impact demographic processes and that individuals respond differentially according to their age, ultimately shaping the population dynamics of wild species. Here we provide an insight of the mechanisms affecting four vital rates (survival probability, probability of breeding, probability of a successful breeding with one, and with two chicks) of an apex Antarctic marine predator by combining longitudinal time series of know-age individuals, abundance data, climatic and prey abundance covariates. We found evidence for age-related changes in the four vital rates. Traits at younger ages were smaller and had larger temporal variance than those of older age-classes for all parameters. Results clearly evidenced an impact of extrinsic factors, with a direct influence of local climate (sea ice concentration) and of available prey resources (penguins), and of intrinsic factors with an influence of the size of the breeding population. More covariate effects were found on reproductive traits than on survival traits, and age classes responded differentially to these effects, the younger age classes being more sensitive than the older ones. Using a half a century dataset, we provide a compelling evidence to support the importance of considering multiple causal effects when studying demographic process in seabirds and the impact of environmental variability.
Multi-million Year Antarctic Presence within the Moss Genus *Schistidium*

Elisabeth M. Biersma\(^1\)\(^2\) (elibi@bas.ac.uk), Jennifer A. Jackson\(^2\), Michael Stech\(^3\)\(^4\), Howard Griffiths\(^2\), Katrin Linse\(^2\), Peter Convey\(^2\)

*Schistidium* is the most species-rich plant genus in the Antarctic, as well as containing most Antarctic endemic moss species. To assess the diversity, richness and relative age divergences within the genus in Antarctica we applied phylogenetic and molecular dating methods, using the nuclear Internal Transcribed Spacer, on all known Antarctic species with available samples. We additionally investigated the continent-wide genetic diversity within the common and widespread endemic species *Schistidium antarctici*. Most previously described Antarctic *Schistidium* species were genetically distinct, confirming their specific status. All species had separated from each other at least ~1 Mya. In particular, *S. antarctici* diverged from other Antarctic *Schistidium* species as early as the late Miocene, thereby being the oldest extant plant species currently known in Antarctica, and providing strong support for vegetation survival through multiple glacial periods. Genetic patterns within *S. antarctici* suggest the mountainous spine on the Antarctic Peninsula has formed a strong barrier to gene flow over time, while the increased genetic diversity in this species in the northern Maritime Antarctic indicates likely glacial refugia in this area. This study provides an important first step towards assessing the evolutionary history of the largest plant genus in the Antarctic, and provides an insight into their adaptive potential to climate change over both past and contemporary timescales.
Coccolithophores are an important component of the Earth system and represents an essential footing to the marine ecosystem. This study presents the results of 10 year observational investigations on coccolithophore ecology and morphology in the Southern Indian Ocean (SIO). Samples were collected during four SIO Expeditions and three Antarctic Expeditions (December-April). Our data evidently indicates a pronounced seasonality in coccolithophore biogeography and noticeable size variation in *E. huxleyi*. The *E. huxleyi* show highest production in the STF and SAF region during the early austral summer and is more prone to dissolution at South of the SAF regions despite of high pH saturation. Whereas, during mid-austral summer, *E. huxleyi* population expands southwards forming heavily calcified morphotypes despite of low pH saturation. The study indicates it is unlikely that the increase in PAR and probable shifts in carbonate chemistry could cause *E. huxleyi* shift in high latitudes. We documented over-calcification in *E. huxleyi* when conditions were most acidic contrary to the earlier predictions. However, the occurrence of large *E. huxleyi* cells with numerous coccoliths in mid austral summer period indicates slowed cell division to cope with low pH conditions. On the contrary rapid increase in heterotrophs and subsequent grazing on coccolithophores in the late austral summer period raises further questions about the fate of coccolithophores in the future high-CO2 world.
Understanding species distribution in the Southern Ocean is challenging in many aspects. Sampling in this region is logistically difficult because of its remoteness and extreme environmental conditions. Today, species distribution models (SDM) can be used to provide spatial projection of species distribution and quantify the relationship between species occurrence and their environment, and can fill knowledge gaps in data deficient areas. Based on the SDM approach, ecoregionalisation aims at defining ecoregions for conservation purposes that is, biogeographic entities that differ in their biotic and abiotic characteristics. In the context of rapid climate change, ecoregionalisation can provide a direct prediction of species assemblages that are linked to environmental features in under-sampled areas. In addition, projection of ecoregions in future environmental conditions can help identify regions that might be particularly at risk. In this framework, we proposed an ecoregionalisation of the Southern Ocean for echinoid species, which are common benthic organisms in the Southern ocean benthic communities. We first developed individual SDM for each species and then combined them using a Gaussian mixture model and a clustering approach using R to define ecoregions.
Robertson Bay lies to the west of Cape Adare at the North Western corner of the Ross Sea (71.5°S 170°E). It is 500 m deep at its deepest and open to the North. A temperature inversion in the summer months results from strong offshore winds, linked to cyclonic storms, drawing warmer deep water into the bay. In the winter and spring months, the winds are decoupled from the ocean by the formation of sea ice. At the surface, water circulates in a clockwise gyre, developing a South-North long-shore current along the Adare Peninsula of a few knots. Flora and fauna are strongly coupled to the marine environment. The shallow benthos is diverse with many ophiuroids, anenomes, and sponges, and common macroalgae (also observed at Cape Hallet but no further south). The water column is also rich with plankton. Within 5-km of Ridley Beach, at the tip of Cape Adare, diversity and density of benthos drops off due to the presence of the million strong Adelie penguin colony. The penguin colony also dominates the terrestrial flora and microbial signature. At Robertson Bay, rather than deep warm water incursion driving change in the environment, the strong South / South East cyclonic winds dominate and drive ocean circulation. This phenomenon has recently been reported further west in East Antarctica where the cyclonic winds also influence the extent of sea ice. But the extent of sea ice does not seem indicative of circulation at depth where warm water is being drawn onto the continental shelf.
The rapid environmental change occurring in the Antarctic Peninsula region has led to changes in the biota and community structure. Changes in top predator populations include shifts in distribution, abundance and the relative importance of top predators within the ecosystem. As ice-habitat in the Peninsula region has decreased, Leopard seals (*Hydrurga leptonyx*) have been dramatically increasing on land at Cape Shirreff, Livingston Island. Animals hauling out are primarily large females and juveniles. Remarkably, there is no published information on the social structure of leopard seals. Therefore, we set out to investigate the social structure of Leopard seals, via the estimation of genetic relatedness and parentage analyses. A preliminary assessment (17 samples; 10 microsatellite markers) revealed two pairs of mother-offspring, suggesting some level of individual association in hauling out behavior. However, genetic diversity was relatively low (heterozygosity, $H_e = 0.57$), so more genetic markers are needed to increase statistical power in our analyses. Despite this caveat, our results suggest that kinship associations are common and likely an important aspect of hauling out patterns in Leopard seals. We are currently expanding the scope of our study to add more samples, including animals from other areas, so we can better understand this species' behavior and population dynamics.
What’s in a Size? Phenotypic Variation across *Acutuncus antarcticus* Populations

Katherine Short¹ (katort80@bas.ac.uk), Sandra McInnes¹, Davide Pisani², Peter Convey¹

¹British Antarctic Survey, Cambridge, United Kingdom, ²University of Bristol, Biological Sciences, Bristol, United Kingdom

Tardigrades, are one of the most diverse and common groups of animals found throughout continental Antarctica and play an important role in biological processes in its challenging terrestrial ecosystems. *Acutuncus antarcticus* is currently thought of as a truly pan-Antarctic species which can survive in most terrestrial habitats in Antarctica, although it is most commonly found within algal mats. Previous studies into phenotypic variation between continental populations of this species showed little difference. Here we build on these studies by measuring phenotypic variation over a geographical area expanded to include the sub- and maritime Antarctic. Principal component analysis of morphological data obtained identified distinct regional variation and suggested two alternative explanations for the variation seen. Firstly, local adaptation to their environment in individual populations or second, the early stages of speciation across different geographical areas. These alternatives will be addressed with molecular phylogenetic analyses. Knowing the history and colonisation routes of these animals in Antarctica could contribute to predicting future changes to biodiversity associated with climate change.
Three Decades of Plant Succession at Rip Point, Nelson Island, Antarctica

Daniela Schmitz (danni_schmitz@hotmail.com), Jair Putzke, Carlos Ernesto Gonçalves Reynaud Schaefer

Federal University of Viçosa, Núcleo Terrantar, Department of Plants Biology, Viçosa, Brazil, Federal University of Pampa, Núcleo de Estudos da Vegetação Antártica, São Gabriel, Brazil, Federal University of Viçosa, Núcleo Terrantar, Department of Soils, Viçosa, Brazil

Long-term studies of plant succession are still negligible in Antarctica. Such evaluations allow correlations between plant development, climatic change and ecological consequences in specific areas of Antarctica. We compared the phytosociological data collection carried out in 1990 with recent data from 2017 Austral Summer at Rip Point, Nelson Island - Maritime Antarctica. Ten areas dominated by mosses selected in 2017, which out of 17 areas studied in 1990. The Braun-Blanquet square methodology was adapted to the Antarctic conditions, in which we compared vegetation differences through frequency and coverage data and analyzed the plant community succession in the area. The results indicate that varying water availability influences local vegetation, reducing cushion forming mosses and Warnstorfia spp. community, more dependent on waterlogging. This was attributed to lower snow cover, remaining in the area compared with data 1990, the general species composition revealed the appearance of Brachythecium sp. not observed in the earlier study. Sanionia spp. carpets area now increasing growing and vigour, except in areas under intense human impact, where the community is reducing. Even though the decreasing water availability with time, Polytrichum piliferum Hedw. is being completely overgrown by S. uncinata. Some areas showed the appearance or increasing growing of muscicolous lichens, indicating a process of plant succession at Rip Point.
Efficiency of the Antarctic Protected Areas Conserving the Terrestrial Diversity

Oscar Ramos¹ (ojramos@unisalle.edu.co), Maria Fernanda Lozano², Gelys Mestre¹, Mayerling Sanabria³
¹University of La Salle, Department of Basic Sciences, Bogota, Colombia, ²University of La Salle, La Salle Museum, Bogota, Colombia, ³University of La Salle, Faculty of Engineering, Bogota, Colombia

The Antarctic Specially Protected Areas and Managed Areas (ASPA/ASMA) are Antarctic zones defined to protect scientific, historic and environmental values, including the conservation of the fauna and flora. The delimitation of these areas is reviewed regularly during the workshops of the Antarctic Treaty Meetings. However, information of the geographic distribution of the Antarctic biodiversity has not been considered strictly to delimit these areas. Thus, to produce a baseline to support this kind of decisions, this study was focused to estimate how the terrestrial biodiversity is distributed within the protected areas and how it changes as the distance from their current limit increase. To achieve this, first, we estimated the geographic distribution of the terrestrial Antarctic biodiversity using stacked distribution models of 68 species. Each species distribution was obtained from a consensus model, combining MaxEnt, GARP, GAM and SVM models. After, we estimated how the biodiversity changes as the distance to the current ASPA/ASMA increased: evaluating dissimilarity due to species replacement and species loss in ring buffers located at different distances to the protected areas. Finally, we ranked all the ASPA/ASMA from the most efficient to the less one based on the replacement and loss of species. The maps of change in biodiversity and the efficiency ranking obtained constitute a key baseline to redefine the limits of the Antarctic protected and managed areas.
Closely Related Antarctic Octopus Show Different Spatial Genetic Structures

Jan Strugnell¹ (jan.strugnell@jcu.edu.au), Louise Allcock², Phillip Watts³
¹James Cook University, Townsville, Australia, ²National University of Ireland, Galway, Galway, Ireland, ³University of Oulu, Oulu, Finland

Determining whether comparable processes drive genetic divergence among marine species is relevant to molecular ecologists and managers alike. Sympatric species with similar life histories might be expected to show comparable patterns of genetic differentiation and a consistent influence of environmental factors in shaping divergence. We used microsatellites to quantify genetic differentiation across the Scotia Arc in three octopod species; Pareledone turqueti, P. charcoti, and Adelieledone polymorpha. The relative importance of environmental factors in shaping genetic structure was investigated. Isolated populations of P. turqueti and A. polymorpha at these species’ range margins were genetically different to samples close to mainland Antarctica; however, these species showed different genetic structures at a regional scale. Samples of P. turqueti from the Peninsula, Elephant and Signy Islands were genetically different, and this divergence was associated primarily with depth. By contrast, weak or nonsignificant spatial genetic structure was evident across the Peninsula, Elephant and Signy Island regions for A. polymorpha. P. charcoti exhibited no genetic differentiation between samples from a small region of the Scotia Arc. Thus, closely related species with similar life history strategies can display contrasting patterns of genetic differentiation depending on spatial scale; moreover, depth may drive genetic divergence in Southern Ocean benthos.
What Drives the Distribution of Antarctic Krill at the South Orkney Islands?

Sally Thorpe\textsuperscript{1}, Angelika Renner\textsuperscript{2} (angelika.renner@imr.no), Emma Young\textsuperscript{1}, Olav Rune Godø\textsuperscript{2}, Thor Klevjer\textsuperscript{2}, Eugene Murphy\textsuperscript{1}

\textsuperscript{1}British Antarctic Survey, Cambridge, United Kingdom, \textsuperscript{2}Institute of Marine Research, Tromsø, Norway

Antarctic krill is a key species in the marine ecosystem of the Southern Ocean and the target of a commercial fishery. Determining the physical and behavioural drivers for krill distribution, including the formation, maintenance and distribution of krill aggregations, is essential to understanding the ecosystem, its function, and sensitivity to climate change and human impacts. This is particularly important as the fishery for krill is increasingly geographically focussed on local krill hotspots.

Here we present modelling results from two related projects investigating the distribution of Antarctic krill at the South Orkney Islands (\textdegree 60\textdegree S, 45\textdegree W). One of the main fishing grounds for krill, this region is also critical for determining the overall availability of krill across the wider Scotia Sea. Modelling studies using state-of-the-art ocean-sea ice models at differing spatial resolutions allow us to understand temporal and spatial variability in krill flux into and out of the South Orkney region, and the relationship to sea ice conditions. Individual-based models incorporating key behavioural characteristics permit further investigation into the role of krill behaviour on retention and dispersal of krill in the region. Such insights and predictive tools are essential for a sound implementation of a feedback management system for Antarctic krill, which is currently being developed under the auspices of the Commission for the Conservation of Antarctic Living Resources (CCAMLR).
The Southern Ocean (SO) plays a crucial role in the global ocean and climate system. Its ecosystems affect global biogeochemical cycles, sustain globally important marine biodiversity and will be important in maintaining food security. Somewhat alarming therefore is the rapid rate of environmental change being experienced by the region with resultant impacts to ecosystems and food webs. Understanding the impacts of a changing physical environment on biological systems is a key question in marine ecology. However, linking ecosystem changes to physical ones remains difficult. Ecosystem models allow computational exploration of disruptions on ecosystems that would otherwise be impossible experimentally. However, much research to date has focused on species-specific research. Therefore a great emphasis has been placed on the need for the development of modelling strategies that span all levels of the biotic system, from end to end. While integrated whole ecosystem views of the SO from nutrients through primary producers and consumers to top predators are starting to emerge, models integrating physics and biology are lacking. Therefore we use physical oceanographic data to drive biological ecosystem models of the sub-Antarctic Prince Edward Islands. Physical oceanographic processes are of considerable importance to the marine ecosystem in the vicinity of these islands and therefore changes to these processes are predicted to have significant impacts on species and communities.
Integrating Niche Modelling to Assess Spatial Risks of an Invasive Midge

Luis R. Pertierra\(^1\) (luis.pertierra@gmail.com), Jesamine Bartlett\(^2\), Grant Duffy\(^3\), Greta C. Vega\(^1\), Kevin Hughes\(^4\), Scott Hayward\(^2\), Pete Convey\(^4\), Miguel Angel Olalla-Tarraga\(^1\), Pedro Aragón\(^5\)

\(^1\)Universidad Rey Juan Carlos, Mostoles, Spain, \(^2\)University of Birmingham, Birmingham, United Kingdom, \(^3\)University of Monash, Melbourne, Australia, \(^4\)British Antarctic Survey, Cambridge, United Kingdom, \(^5\)Museo Nacional de Ciencias Naturales, Madrid, Spain

**Eretmoptera murphyi**, a flightless midge endemic to the sub-Antarctic island of South Georgia, was inadvertently introduced to Signy Island (South Orkney Islands) in the 1960s, establishing an alien population that has since been expanding locally. In order to identify future expansion risks, different modelling techniques are explored here. Mahalanobis distances were calculated based on the species' current realized distribution, as an indication of environmental distances to the species niche centroid at different sites. In addition, ecophysiological experiments were performed on E. murphyi larvae to identify those temperatures most beneficial for survival to build into mechanistic models. Potential range distribution scenarios are generated for current and predicted future scenarios up to 2100. Increasing risk of invasion into Antarctic locations further south is predicted over time. Sites in synergy with high visitation at the South Shetland Islands and northern Antarctic Peninsula are likely to be at particularly high risk. How the endemic maritime Antarctic midge (*Belgica antarctica*) will be affected in the event of southwards range spreading and range overlap with *E. murphyi* remains to be assessed. Human activities in the this region should follow particularly strict biosecurity protocols if visiting Signy Island or South Georgia and then traveling to other maritime Antarctic locations, in order to minimize the risk of assisted dispersal to such highly vulnerable sites.
Polar Regions are experiencing multiple environmental stressors and the increasing contaminant influxes are likely becoming more severe. As filter-feeders, in Porifera ingestion becomes the primary route in the uptake and accumulation of particle-associated contaminants, which may accumulate in animal tissues. Porifera also provide an important habitat for aquatic prokaryotes that colonize outer surfaces and interstices of ostia and oscula, and may be particularly responsive against contaminants accumulated in the sponge tissues. Symbiotic microorganisms can adhere to the sponge surfaces by forming biofilm with complex 3D-structures, composed by microbial consortia encased in an extracellular polymeric substances. The exopolymeric substances possess high biotechnological potentialities with applications in biomedical, cosmetic, food and environmental fields. Despite Porifera are abundant invertebrates in Antarctica, the associated prokaryotic communities and their biotechnological potentialities were largely disregarded. Funded by the Italian PNRA, the P³ project "Antarctic Porifera: Hot-spots for Prokaryotic diversity and biotechnological Potentialities" (PNRA16_00020) will aim at linking the ecological traits (e.g., phyllogenetic diversity and metabolic activities) and biotechnological potential (e.g., biofilm production, pollutant degradation) of prokaryotes associated with Antarctic Porifera by applying a multidisciplinary approach.
Peracarids of the Larsen-C Shelf Area Compared with Non-ice Covered Regions

Angelika Brandt1 (angelika.brandt@senckenberg.de), Katrin Linse2, Huw Griffiths3

1Senckenberg Institute and Natural History Museum, Frankfurt, Germany, 2British Antarctic Survey, Cambridge, United Kingdom, 3British Antarctic Survey, Cambridge, United Kingdom

The Larsen-C PEARL Project (The influence of Larsen-C ice-cover on macrobenthic peracarid crustacean assemblages on the Antarctic shelf) compares and analyses the benthic peracarid distribution in ice covered (Larsen-C, calved iceberg A 68) and ice-free Southern Ocean areas. The project’s governing hypothesis is: H:

"Until the calving of the Larsen-C iceberg, A68, the benthic fauna on the seabed beneath ice shelf has likely comprised oligotrophic assemblages resembling deep-sea Weddell Sea assemblages. The calving of A68, and the exposure of the seabed to open-marine and sea-ice conditions will initiate a rapid colonisation by new species that will transform the benthic ecosystem significantly within a short timeframe." Larsen-C Pearl will focus on peracarid crustaceans and analyse biodiversity and assemblage structure of the epi- and suprabenthic peracarid crustaceans and compare the occurrence of species from the Larsen-C area with that of the deep sea of the Weddell Sea as well as the Filchner Trough and South Orkney area.
Presentation will be made on Social Networks of animals to understand animal behaviour, animal cognition and the dynamics of animal societies in extreme environments like Antarctica. And its role in the designing the instinctive layer of social systems.

Social structure of penguins—a group of primitive flightless birds living in the coastal regions of Antarctica continent will be explored. These primitive birds living in the earth for more than 60 million years by withstanding extreme evolutionary challenges. Various adaptive strategies in their daily life are examples of highest level of cooperative behaviour, and reasons for their survival for such a long time; while majority of animals of that period are now extinct and no longer exist in earth. All this made possible with a very primitive brain structure. Importance of multidisciplinary studies will be explored to understand the structure and dynamics of their social system; biological and mathematical characteristics responsible for developing into a well-structured organised society. Adaptive features of their anatomy, physiology and cognition will be presented. The studies into the social network of penguins will make it possible to understand instinctive nature and robustness of their social systems functioning with a primitive and simple brain, body and social structure. The role of biotic and abiotic factors in shaping up animal societies will also be discussed.
According to the recent biogeographical classification (Terauds et al. 2012, Terauds & Lee 2016), ice-free regions of Antarctica are divided into 16 Antarctic Conservation Biogeographic Regions (ACBRs), each of those with characteristic fauna including microscopic organisms (fungi, algae, microarthropods and other invertebrates). Various historical and contemporary drivers may underlay the observed biodiversity patterns, including population isolation during glacial maxima, physical and/or atmospheric connectivity barriers. Our research aims at discovering the patterns of isolation/long-distance dispersal in the populations of 5 species of Antarctic rotifers: (1)Adineta editae, (2)A. emsliei, (3)A. grandis, (4)Macrotrachela cf musculosa, (5)Philodina gregaria. Species were collected in 7 ACBRs of maritime (1,4) and continental Antarctica (1,2,3,5). Sequences of mtCOX1 partial gene were used for AMOVA, Mantel test and building TCS haplotype networks. The analysis has shown significant patterns of local isolation in the populations of all species, and long-distance dispersal for (4).
Under Sea-ice and under Protection: Low Impact Sampling of Antarctic Toothfish

Davide Di Blasi¹ (davide.dibiasi@ge.ismar.cnr.it), Simonepietro Canese², Erica Carlig¹, Laura Ghigliotti¹, Steven J. Parker³, Eva Pisano¹, Marino Vacchi¹

¹National Research Council, Institute of Marine Sciences (ISMAR), Genoa, Italy, ²Istituto Superiore per la Ricerca e la Protezione Ambientale (ISPRA), Rome, Italy, ³National Institute of Water and Atmospheric Research (NIWA), Nelson, New Zealand

The Antarctic toothfish (Dissostichus mawsoni) is the largest notothenioid fish inhabiting high Antarctic waters where it is a keystone species in the food web as apex predator, and commercially fished. The life cycle of the species is only partially known since large amount of data is available from open waters, where the toothfish resides as adult, whereas information from sea-ice covered areas is still poor. This leaves in the field of uncertainty a significant portion of the species life cycle, including the sub-adult phase. Where and how the sub-adults toothfish forage in the water column and to what extent they are able to perform vertical migration in sea-ice sheltered areas are among the issues that still remain uncovered.

In this frame, and taking into account the conservation goals of the recently established Ross Sea Region Marine Protected Area (RSRMPA), low environmental impact methodologies for the visual survey of Antarctic toothfish are being developed for collecting data from under sea-ice areas. The work, performed under the umbrella of the scientific scholarship 2017 of the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR), aims at contributing to refine the sustainable management of the Antarctic toothfish, and to develop a standardized protocol for non-invasive sampling to be used for monitoring in the RSRMPA.
Antarctic lichens are resistant to low temperatures and to deep dehydration. The understanding of that requires the knowledge on the formation of tightly and of loosely bound water fractions at different steps of hydration process.

The thalli of fruticose lichen *Cetraria aculeata* (Schreb.) Fr. were collected in maritime Antarctica. $^1$H-NMR spectra were collected on Bruker Avance III 300 spectrometer (Bruker Biospin). DSC scans were performed on Perkin Elmer DSC 8000 calorimeter.

$^1$H-NMR experiments allow us to distinguish besides the signal from lichenized fungus tissue also the signal from tightly bound (immobilized) water and the signal from loosely bound (more mobile) water fraction.

$^1$H-NMR spectra temperature dependence reveals two processes of bound water immobilization, *i.e.* coherent ice freezing and gradual non-coherent immobilization of water molecules. Besides these two mechanisms observed by us in other biological systems/living organisms, *e.g.* in wheat photosynthetic membranes, a novel effect was discovered using DSC, namely ice crystallites growth inside the Antarctic *Cetraria aculeata* thallus was retarded by diffusion of supercooled liquid water molecules. The retardation is probably correlated/induced by morphological diversity of the thallus, consisting of fungus and of isolated algal cells.

However, there is a question to what extent this phenomenon creates an evolutionary advantage of lichenized fungi.
Microbial biofilms play a key role in substrate colonization in aquatic environments, as hot spots of biodiversity and sources of secondary metabolites with biotechnological potential. In Terra Nova Bay (Ross Sea, Antarctica), microbial biofilm communities are under-explored in their structure and functions; particularly, their response to environmental and/or anthropogenic forcings remains to be elucidated yet. Funded by National Antarctic Research Program (XXXIII Italian expedition), the ANT-Biofilm project "Microbial colonization of benthic ANTarctic environments: response of microbial abundances, diversity, activities and larval settlement to natural or anthropogenic disturbances and search for secondary metabolites" (PNRA16_00105) includes short and long term (3-12 months) experiments in two bays (Road Bay and Tethys Bay) characterized by anthropogenic (i.e. sewage) and natural (i.e. low salinity) stressors, respectively. Total, viable and respiring prokaryotes, culturable bacteria, potential enzymatic activity rates, physiological community profiles, microalgae and macrobenthic community are studied. Selected biofilm samples will be sequenced and analyzed by hybridization (i.e. Card-FISH) and bacterial isolates screened for antibiotic resistance and metabolite production. This contribution reports the preliminary results obtained by the four Research Units during the short term experiments.
Environmental Drivers of Mesopelagic Community Structure on the Kerguelen Axis

Rowan Trebilco¹ (rowan.trebilco@utas.edu.au), Andrea Walters², Jess Melbourne-Thomas³, Sophie Bestley⁴, Martin Cox³, Sven Gasteur¹, Michael Sumner³, Andrew Constable³

¹Antarctic Climate & Ecosystems CRC, University of Tasmania, Hobart, Australia, ²Institute for Marine and Antarctic Studies, University of Tasmania, Hobart, Australia, ³Australian Antarctic Division and ACE CRC, Kingston, Australia, ⁴CSIRO Oceans & Atmosphere, Hobart, Australia

In January - March 2016, the Antarctic Climate and Ecosystems CRC led an integrated ecosystem survey voyage on the Southern Kerguelen Axis - a productive region spanning from Banzare Bank on the southern Kerguelen Plateau towards Prydz Bay in East Antarctica. The voyage track encompassed an 8850 km path including 9 transects, designed to encompass major environmental transitions that may drive ecosystem structure in the region. A primary goal was to characterize the pelagic foodweb structure and major energy pathways, with a strong focus on the mesopelagic community. The mesopelagic community was sampled at 36 stations, from the surface to 1000m in 200m depth strata, using an IYGPT net equipped with a multiple cod-end MIDOC device. Calibrated acoustic data were also collected throughout the voyage, using SIMRAD EK60 echosounders, operated at 38, 120 and 200 kHz. We present a summary of the mesopelagic community results from this voyage, including abundances key nekton groups, and analyses examining the relationship between catch composition, total acoustic backscatter, and key environmental drivers. This work provides new information on a poorly represented ecosystem component and pilots methodologies for future ecosystem observation and monitoring.
Assessment of Ground versus UAS Flight Surveys on Antarctic Predator Behavior

Douglas Krause¹ (douglas.krause@noaa.gov), Jefferson Hinke¹, Wayne Perryman², Michael Goebel¹, Donald LeRoi³
¹NOAA Fisheries/Southwest Fisheries Science Center, Antarctic Ecosystem Research Division, La Jolla, United States, ²NOAA Fisheries/Southwest Fisheries Science Center, Marine Mammal and Turtle Division, La Jolla, United States, ³Aerial Imaging Solutions LLC, Old Lyme, United States

Accurate population counts are fundamental to wildlife management. The recent proliferation of unmanned aerial systems (UAS) has provided new opportunities for collecting census and distribution data that are as, or more, accurate than traditional ground surveys. Reports on the effects of UAS on wildlife, however, vary widely. Wildlife response differs depending on many factors including species, type and size of UAS, method of operation, amplitude and frequency of noise, etc. We compared the effects of UAS flights to ground surveys by assessing the behavioral responses of chinstrap penguins (CP), Antarctic fur seals (AFS), and leopard seals (LS) to flights at specific altitudes. For CP & AFS we also controlled for differences in human exposure history and stage of reproduction. Flights were conducted Jan-Mar 2017. Observations for all three species were recorded by a UAS camera, a lateral camera with a sound meter and visual observers. We conducted 35 flights over CP (N=272), AFS (N=68) and LS (N=10). Lateral camera and visual observations were also made for ground surveys of CP (N=130) at the same location. During flights as low as 8 m < 1% of CP, 10% of LS, and < 15% of AFS responded to UAS. No animals moved their location. By comparison >85% of CP and 100% of LS left their location during ground surveys. Our studies indicate that a UAS, operated within guidelines appropriate to the situation, can have less impact on wildlife than traditional survey methods.
Leopard seals are a widespread and important predator in Antarctic coastal ecosystems. Previous studies have identified a broad range of prey items; however, due to anecdotal or otherwise limited information leopard seal diets remain largely unresolved by seal sex, inter-individual variability, age class, region, or season. As a result, leopard seals are commonly reported as generalist predators. Over three summer field seasons we collected visual, scat and stable isotope tissue (blood and plasma) data from nineteen adult female and two adult male leopard seals foraging near mesopredator breeding colonies at Cape Shirreff. We summarized a priori diet information and applied a three isotope (δ¹³C, δ¹⁵N and δ³⁴S), four source (fish, fur seal, krill, penguin) Bayesian mixing model to examine temporal variability in both prey sources and leopard seal tissues, and define their trophic position within the local food web. The distribution of the four prey groups in isospace appears to explain the entire leopard seal diet. Rather than a generalist diet pattern, posterior probabilities of prey proportions identified two distinct groups among female diets. One diet was dominated by Antarctic fur seal pups and krill, while the other was predominately penguin and demersal fish. The diet of the two males was mostly krill. Additionally, δ¹⁵N values were consistently enriched for plasma versus red blood cells implying a seasonal diet change for both female groups.
Ecological systems are being impacted by a wide variety of environmental stressors. Changes in the abiotic environment and resource extraction are two areas of particular concern in the Southern Ocean. Parsing the impacts of these stressors, however, has proven difficult. Not only is resource extraction in the region difficult to quantify, impacts of both abiotic and biotic stressors may result in similar ecological responses in metrics commonly measured by researchers. Using data on penguin demographics, krill catch, and abiotic environmental conditions such as sea ice dynamics, we assess the impact of these drivers on penguin reproductive performance. We combined data on *Pygoscelis* penguin reproductive success from a network of remote time-lapse cameras positioned across the Antarctic Peninsula and previously unanalyzed high-spatial and temporal resolution krill catch data obtained from Aker BioMarine. A hierarchical Bayesian state-space model was used to estimate penguin chick survivorship as a function of both abiotic environmental conditions and krill catch across both space and time. Through the integration of multiple sources of data over large spatial scales, we identify key drivers of penguin breeding success, which has important implications for management efforts and our understanding of the Southern Ocean marine ecosystem.
The Ross Sea region of the Southern Ocean is a significant focus of global research. Important unanswered questions remain on the drivers and extent of oceanographic change and on the response of marine ecosystems to a changing environment. Managing and mitigating the effects of human activities (especially fishing and tourism) against this backdrop of environmental change is challenging and has led to the establishment of the world’s largest Marine Protected Area in the Ross Sea region. Ongoing stewardship requires an understanding of environmental-ecosystem interactions and the development of an effective approach to monitoring.

This presentation outlines the first results from a New Zealand research voyage to the Ross Sea region in 2018. New information will be presented on the main science questions:

1. How has the export of Antarctic Bottom Water from the Ross Sea changed over the past two decades?
2. What are the key interactions between aerosols and cloud formation?
3. How do marine microbial planktonic communities vary across the Ross Sea region?
4. What is the structure, and key environmental drivers, of benthic and demersal habitats and faunal communities of the Pacific-Antarctic Ridge in the Ross Sea sector?
5. Is the Ross Sea region ecologically critical for key species of Antarctic whales?
6. How is the distribution, abundance and trophic ecology of mesopelagic fishes and zooplankton in the Ross Sea region related to the oceanographic environment?
Complementary eDNA and Micropaleontological Foraminiferal Record from Ross Sea

Ewa Demianiuk¹ (ejdemianiuk@gmail.com), Wojciech Majewski¹, Mateusz Baca², Danijela Popović², Lindsay Prothro³, Lauren Simkins³, John Anderson³

¹Institute of Paleobiology, Polish Academy of Sciences, Warsaw, Poland, ²University of Warsaw, Centre of New Technologies, Warsaw, Poland, ³Rice University, Department of Earth, Environmental & Planetary Sciences, Houston, United States

The seafloor morphology of the western Ross Sea has been shaped by glacial and post-glacial processes, including subglacial deposition, erosion of paleo-ice streams, and iceberg scouring. The similarities of repeatedly recycled sediments pose a problem with distinction between sedimentary facies. However, in most of these records, foraminiferal microfossils are present, carrying significant information.

During the NBP15-02A cruise, we collected samples from megascale glacial lineations (MSGls), Grounding Zone Wedge (GZW) topsets, foresets and slope deposits for micropaleontology and next-generation sequencing of environmental DNA (eDNA). In sediments from different geomorphological features, we found various assemblages of fossil foraminifera, which are complemented by information from foraminiferal DNA. Species detected by molecular methods were dominated by monothalamids, which are absent in the fossil record. Information derived from eDNA increases our knowledge of true foraminiferal diversities as well as supports the interpretation of in-situ character of investigated assemblages. The distribution of biogenic remains fits well with environmental interpretations based on sedimentology and geomorphology. It shows an absence of eDNA in sediments from GZW topsets and MSGls paired with low microfossil abundances. In contrast, in GZW foresets, eDNA is accompanied by numerous foraminiferal tests.
The West Antarctic Peninsula is one of the areas on Earth mostly affected by global warming which is inducing a temperature rise at an alarming rate. This makes the Antarctic Peninsula an open-air laboratory where the study of the genetic and molecular traits of the adaptation of living organisms to rapidly changing environmental conditions may allow the disclosure of molecular biomarkers for efficient climate change monitoring. The two plants species native to Antarctica, Deschampsia antarctica Desv. and Colobanthus quitensis (Kunth) Bartl., are exposed to high light and low temperature during their natural growing season which alter their photosynthetic yield and make them more susceptible to photooxidative damage.

In this work, we investigated the influence of the temperature rise on the C. quitensis photosynthetic performance. To this, we compared the expression level of key genes of the photosynthetic pathway in plants grown in natural conditions versus plants grown for one year inside small greenhouses open on the top (Open Top Chambers) which determine an increase of about 4 °C during midday, mimicking the effect of global warming.

Interestingly, we found that higher temperatures induce a general over-expression of the genes involved in the photosynthetic process, but plants seem to be less protected from high irradiation since the genes involved in the non-photochemical quenching appear to be down-regulated.
Assessment of Housekeeping Genes for qPCR Data Normalization in \textit{C. quitensis}

Laura Bertini\textsuperscript{1} (lbertini@unitus.it), Francesca Focaracci\textsuperscript{1}, Fabiana Canini\textsuperscript{1}, Silvia Proietti\textsuperscript{1}, Leon Bravo\textsuperscript{2}, Claudia Rabert\textsuperscript{2}, Carla Caruso\textsuperscript{1}

\textsuperscript{1}University of Tuscia, Ecological and Biological Sciences, Viterbo, Italy, \textsuperscript{2}University La Frontera, Ciencias Agronomicas y Recursos Naturales, Temuco, Chile

The areas along the Antarctic Peninsula are warming faster than any other part of the world hard testing the native organisms which often live at their physiological limits. This makes particularly interesting to study the genetic and molecular traits of the local plants to assess the molecular basis of adaptation to low temperatures and their ability to respond to climatic changes. The use of molecular tools, such as qPCR, to perform differential gene expression studies requires the identification of the most stable housekeeping genes (HKG) to normalize the data and obtain robust and consistent results.

In this work, we identify and validate new reference genes for qPCR data normalization in the Antarctic plant \textit{Colobanthus quitensis} (Kunth) Bartl. under various abiotic stresses (temperature, nitrogen and salinity). In particular, we selected a set of eight candidate HKG whose stability was evaluated using the freely available \textit{RefFinder} web tool that uses 4 different software (NormFinder, BestKeeper, \Delta Ct and geNorm) to calculate the geometric mean of weights for the comprehensive ranking order recommended and to determine the best reference gene or pair of genes.

In addition, to test the reliability of the selected reference genes, expression analysis of catalase was presented. Ultimately, our data provide a useful set of reference genes that can be used in qRT-PCR to analyze gene expression in \textit{C. quitensis} under different experimental procedures.
Sexual segregation in foraging habitat occurs in many marine predators and is usually attributed to intra-specific competition or habitat specialisation associated with sexual size dimorphism. We studied habitat use, diet and feeding ecology of female and male wandering albatrosses Diomedea exulans, fitted with GPS and stomach-temperature loggers during the chick-rearing period at South Georgia. During this period, when oceanographic conditions were unusual and prey availability was low in Antarctic waters, tracked wandering albatrosses showed high consistency in foraging areas at a large spatial scale. Despite consistency in overall habitat use, males and females showed different foraging behaviours in response to oceanographic conditions. Males appeared to be more opportunistic, exploiting oceanic and less productive waters mostly to scavenge for offal or non-target fish discarded by fishing vessels. In contrast, females commuted directly to natural productivity hotspots; most prey ingestions were on the outbound part of the trip, returning directly to the chick and fed on a wide variety of fish and cephalopods. The consistency in habitat use at a large scale, and sex differences in feeding ecology and behaviour at finer scale, indicate that males and females adopt different strategies in core foraging areas when prey availability is low. This leads to differences in diet composition between sexes in the absence of large-scale sexual segregation.
Discovering the environmental predictors of foraging locations can be challenging and is often the critical missing piece for interpreting the ecological significance of the observed movement patterns of marine predators. This is especially true in dynamic coastal marine systems, where food resources are diffuse and must be either physically or biologically concentrated to support top trophic levels. At Palmer Canyon, a known biological hotspot in the West Antarctic Peninsula, we deployed an integrated polar observatory consisting of high frequency radar, coordinated gliders, and moorings. Lagrangian coherent structures (LCS) derived from surface currents measured by high frequency radar were used to estimate the location of convergent ocean features relative to penguin foraging locations. Acoustic scattering measurements from an underwater glider suggest that krill may be more prevalent within convergent LCS, suggesting they are important for penguin foraging behavior. We found that shallower foraging (< 50 m) Adélie penguins selected for surface convergent features, while the deeper diving (< 100 m) gentoo penguins did not demonstrate the same preference, suggesting that these species are selecting for different dynamic habitats. Changes in the location of convergent LCS appear to explain historic patterns in Adélie penguin foraging behavior, suggesting that the frequency and location of surface convergent features are important ecological drivers in this region.
Facilitating Southern Ocean Population Genomics - A RADseq Pilot Experiment

Henrik Christiansen¹ (henrik.christiansen@kuleuven.be), Bruno Danis², Franz M. Heindler¹, Bart Hellemans¹, Quentin Jossart³, Marc Kochzius³, Frederik Leliaert⁴, Francesca Pasotti⁵, Tasnim Patel⁵, Henri Robert⁵, Anton P. Van de Putte¹,⁵, Ann Vanreusel⁴, Marie Verheye⁵, Filip A. M. Volckaert¹, Isa Schön⁵

¹KU Leuven, Laboratory of Biodiversity and Evolutionary Genomics, Leuven, Belgium, ²Université Libre de Bruxelles, Marine Biology Laboratory, Brussels, Belgium, ³Vrije Universiteit Brussel (VUB), Department of Marine Biology, Brussels, Belgium, ⁴Ghent University, Marine Biology Research Group, Ghent, Belgium, ⁵Royal Belgian Institute of Natural Sciences, OD Nature, Brussels, Belgium

The Southern Ocean (SO) is subject to (local) rapid environmental changes and increasing anthropogenic perturbation. Consequently, major efforts are under way to protect, manage and/or sustainably use the living marine resources. Such aspirations depend on knowledge of spatio-temporal distribution and diversity patterns of Antarctic organisms. Reduced representation sequencing such as RADseq enables cost-efficient characterization of genome-wide SNP markers in non-model species. Large numbers of SNPs facilitate population genomic studies to investigate intra- and interspecific genetic differentiation, as well as evolutionary adaptation potential. Obtaining useful amounts of SNPs at appropriate sequencing depth, requires carefully optimized experimental designs, particularly in species lacking genomic resources. Here, we present a pilot experiment to determine if and how RADseq approaches can be applied to a variety of SO taxa (Bivalvia, Amphipoda, Asteroidea, Perciformes and Aves). We perform computational in silico digestion of simulated genomes and genomes of related taxa with a variety of restriction enzymes and size selection combinations to determine the expected number of markers. Results are compared to empirical data from actual DNA digestions and promising combinations are used to prepare pilot sequencing libraries. We present this approach as it will likely be useful and applicable to other target organisms, ultimately advancing SO conservation efforts.
Ecological traits such as the dispersal ability will influence the biogeographical patterns of benthic organisms in a significant way over local to large scale in space and time. When biogeographical observations are based on morphological identification of specimens, conclusions assume morphology accurately reflects evolutionary processes. In order to test the fit of morphologically based biogeographic patterns recently identified in Antarctic sea stars with contrasting reproductive modes (here used as a proxy for dispersal ability), we re-examine the dataset with the addition of mitochondrial sequence data. We identified diversity and divergence patterns of 1500 specimens across five genera of Southern Ocean asteroids with contrasted dispersal abilities. Using a comparative phylogeographical approach we were able to test for shared historical processes as phylogeographic congruence among lineages. These outcomes were critically compared to the interpretation of the former study.
Accepted Taxonomy versus Real Specific Diversity in Southern Ocean Sea Stars

Camille Moreau¹ (mr.moreau.camille@gmail.com), Guillaume Achaz², Bruno Danis¹, Marc Eléaume², Christopher Mah³, Thomas Saucède⁴, Quentin Jossart⁵

¹Université Libre de Bruxelles, Biomar, Brussels, Belgium, ²Muséum National d'Histoire Naturelle, Paris, France, ³Smithsonian National Museum of Natural History, Washington, United States, ⁴Université de Bourgogne Franche Comté, Dijon, France, ⁵VUB, Bruxelles, Belgium

Studying and estimating species diversity of given taxonomic groups has been an ongoing process for centuries. First based on a morphological characterisation of specimens, the study of diversity is nowadays more powerful than ever with the democratisation of molecular tools such as the DNA barcoding. Correlatively with the enhancement of genetic analysis is observed a decrease of experimented systematists to fulfil the work of morphological characterisation of species.

We propose in this work via the analysis of asteroids barcode sequences a powerful tool to highlight the gap between the accepted taxonomy and the real specific diversity. COI sequences of over 2,500 specimens of sea stars collected in the Southern Ocean were analysed following a genus-by-genus approach. Procedures like the ABGD, GYMC or PTP could rapidly help taxonomists into pinpointing taxonomic groups to focus on. The Southern Ocean certainly is a particularly adapted laboratory for such a study as it is the theatre of various diversification processes leading to the presence of cryptic/unrecognized diversity.

This study is the perfect example of the interest of this kind of analyses as it demonstrates the large gap between what is described in books and what is observed at the molecular level.

Kerguelen Asteroid Fauna Diversity and Biogeography with the Southern Ocean

Camille Moreau¹ (mr.moreau.camille@gmail.com), Bruno Danis¹, Marc Eléaume², Charlène Guillaumot¹, Quentin Jossart¹, Thomas Saucède³
¹Université Libre de Bruxelles, Biomar, Brussels, Belgium, ²Muséum National d'Histoire Naturelle, Paris, France, ³Université de Bourgogne Franche Comté, Dijon, France

Marine fauna of the isolated archipelago of Kerguelen has been studied for decades as it might represent a crucial link for benthic biogeography of the Southern Ocean. Its pivotal position in the sub Antarctic (between South America - the Scotia Arc and the Macquaries) and the possible links with high Antarctic might play an important role in the global biogeography of the region.

Compiling data from three research projects (POKER, Proteker and ACE - ASCCC) we conducted diversity, phylogeographic as well as multivariate analyses to better characterize the Kerguelen Plateau in term of asteroids assemblages (Echinodermata).

Mitochondrial gene COI sequences of hundreds of specimens were used to understand the relationships of the Kerguelan Islands with the surrounding Southern Ocean. Gene sequences from the Kerguelan's specimens were compared with thousands from the whole Southern Ocean allowing a better understanding of the role of the Kerguelen Islands in the frame of the Southern Ocean.

This work brings new insight in term of the possible origin of the asteroid fauna on the Kerguelen Plateau but also in term of the role of this sub Antarctic area as a source for post-LGM recolonization.
Remote Characterization of Microbial Mats in Taylor Valley, Antarctica

J. E. Barrett¹ (jbarre@vt.edu), Eric Sokol², Lee Stanish², Mark Salvatore³

¹Virginia Tech, Department of Biological Sciences, Blacksburg, United States, ²Battelle Ecology, Inc., National Ecological Observatory Network (NEON), Boulder, United States, ³Northern Arizona University, Department of Physics & Astronomy, Flagstaff, United States

Microbial mat communities, consisting primarily of cyanobacteria, are the most abundant and widely distributed terrestrial phototrophs in the McMurdo Dry Valleys of Antarctica. Prior work has shed light on the niche preferences and eco-physiology of these communities, but the combination of low photosynthetic rates and patchy distribution has limited assessment of microbial mat dynamics to habitat-scale investigations. We present data using high-resolution multispectral remote sensing techniques linked with field sampling campaigns in Taylor Valley to examine the sensitivity of these microbial mat communities to environmental variation. Our work demonstrates that:

1. microbial mat communities can be identified from orbit;
2. satellite images can be captured throughout a season and can be synchronized with in-situ measurements; and
3. the temporal resolution is sufficient to discern temporal variation in microbial mat activity.

Our results highlight the opportunity for using remote sensing in coordination with field-based campaigns to systematically study the base of terrestrial Antarctic food webs, i.e., microbial mat communities, at scales relevant to quantify spatial distribution and detect the influence of hydroclimate variability on temporal dynamics of microbial communities.
A Synergistic Approach to Understand the Ecological Impacts of Climate Change

Rachel Cavanagh¹ (rcav@bas.ac.uk), Eugene Murphy¹, Nadine Johnston¹, Thomas Bracegirdle¹, Andrew Constable²,³, Stuart Corney², Susie Grant¹, John Turner¹, Claire M Waluda¹
¹British Antarctic Survey, Cambridge, United Kingdom, ²University of Tasmania, Institute for Marine and Antarctic Studies (IMAS), Antarctic Climate and Ecosystems Cooperative Research Centre (ACE CRC), Hobart, Australia, ³Australian Antarctic Division, Hobart, Australia

Understanding potential climate change impacts on Southern Ocean ecosystems requires the inclusion and interpretation of climate model projections. The use of global climate models in ecological studies is growing, but drawing meaningful conclusions is difficult. Issues of temporal and spatial scale are amongst the key challenges. For instance, these models do not sufficiently represent ecologically important features such as the marginal ice zone since it is relatively small in area and comprises a complex variety of sea ice types. Using Southern Ocean sea ice as an example, given its crucial role for the biology of the region, we initiated a joint study comprising ecologists, biogeochemists, climate modellers and fishery scientists, to explore the use of these models for ecological insights. With an emphasis on ecologically-relevant criteria (sea ice extent and seasonality) we selected a subset of available global climate models that reliably reproduce extant sea ice distributions. Whilst the mean of this subset is similar to the model ensemble, there is a marked reduction in the range. This improved the precision of projected future sea ice distributions by approximately one third, and means they are more amenable to ecological interpretation. Our study demonstrates how multidisciplinary evaluation of climate models can enhance their ecological application, and is a first step towards a set of community-agreed future scenarios for Southern Ocean ecosystems.
Local Rapid Expansion of the Antarctic Hair Grass in the Maritime Antarctic

Christina Braun¹ (chr.braun@uni-jena.de), Hans-Ulrich Peter²
¹University of Jena / Institute of Ecology and Evolution, Polar & Bird Ecology Group, Jena, Germany

During the past decades, the western and northern parts of the Antarctic Peninsula (Maritime Antarctic) have experienced the largest warming trend of atmospheric temperatures. This climatic change strongly affects biotic and abiotic components of Antarctic ecosystems on different levels. Fildes Peninsula and Ardley Island, King George Island, South Shetland Islands, represent one of the largest ice-free areas in the Maritime Antarctic and are characterized by a high biodiversity. The terrestrial ecosystem hosts a diverse range of breeding bird species, high numbers of seals and locally the best-developed and most extensive plant communities in the South Shetland Islands. The only vascular plant present in this area is the Antarctic hair-grass Deschampsia antarctica. Repeated assessments of its distribution have been carried out in 1984/85, 2000/01, 2007/08 2004-06, and recently in 2016-18. The data revealed a considerable expansion of the distribution of D. antarctica over the past three decades. The grass has spread at many known sites and has additionally colonised further suitable areas. The distribution is widely connected to associations with mosses and lichens, but also includes fresh moraine material in areas newly exposed by glacier retreat. Apparently, entry of nutrient by birds and seals have a strong impact on the growth of D. antarctica. Moreover, regional warming seems to be crucial for the considerable expansion for vascular plants in the Maritime Antarctic.
Latitudinal Consistency of Food Web Topology in Subtidal Rocky Bottoms

Luis Cardona¹, Elena Lloret¹, Conxita Avila¹ (conxita.avila@ub.edu)

¹University of Barcelona, Evolutionary Biology, Ecology and Environmental Science, Barcelona, Spain

The potential impact of latitude on the structure of the food web of shallow sublittoral rocky bottoms was assessed using stable isotopes of C and N. Samples were collected at five sites along a gradient from King George Island (South Shetland Islands; 62°11′04″S 58°54′14″W) to Adelaide Island (western Antarctic Peninsula; 67°34′06″S 68°07′33″W). Phytoplankton, encrusting red algae, brown macroalgae (Himantothallus grandifolius, Desmarestia menziesii and Desmarestia anceps), red algae (Palmaria decipiens), sponges (Dendrilla antarctica), snails (Margarella antarctica), limpets (Nacella concinna), holothurians, sea urchins (Sterechinus neumayeri), nemerteans (Parborlasia corrugatus) and starfishes (Odontaster validus and Diplasterias brucei) were collected at each site. Results revealed short food webs, supported by a diversity of carbon sources. Phytoplankton was the main source of C for holothurians, sea urchins relied primarily on macroalgae and encrusting red algae were the staple food of limpets. Sponges were more depleted in $^{13}$C than any other animal group, thus revealing a unique niche. The starfish Odontaster validus was usually the top predator of the ecosystem. No latitudinal differences in food web topology were observed, but sites differed in the stable isotope baseline and the diversity of C sources, thus highlighting that local processes are more relevant for benthic communities than any potential latitudinal gradient.
Polar Cod Population Structure: Connectivity in a Changing Ecosystem

Sarah Maes¹ (sarahmaeske@gmail.com), Henrik Christiansen², Felix C. Mark², Magnus Lucassen², Anton P. Van de Putte³, Filip A.M. Volckaert¹, Hauke Flores²
¹KU Leuven, Leuven, Belgium, ²Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, ³Royal Belgian Institute of Natural Sciences, Brussels, Belgium

Climate-induced changes put an increasing pressure on the Arctic ecosystem and its populations, including the most abundant circumpolar marine fish polar cod (Boreogadus saida). As a keystone species, changes in its abundance and distribution will impact the entire Arctic food web. Despite polar cod’s significance, its population structure is largely undescribed. The genetic diversity and population connectivity of polar cod living in fjords of West-Spitsbergen and the Eurasian Basin were investigated using eight microsatellite loci. On a local scale, polar cod from Arctic (Billefjorden, Hornsund) and Atlantic (Kongsfjorden) influenced fjords were compared, and on a larger scale also specimens from the Amundsen and Nansen Basin were included. Results revealed significant population structuring on both local and large scale, suggesting reduced gene flow between these areas. Juvenile polar cod track sea ice drift and consequently, the under-ice distribution depends on coastal populations where sea ice originates (David et al., 2015). Hypothetically, polar cod hatched in the Kara and Laptev Sea drift into the Nansen and Amundsen Basin, respectively, and join populations in downstream areas by following the Transpolar Drift System. Understanding polar cod’s population spatial and temporal dynamics, population diversity and adaptive divergence is critical for making predictions about its future distribution and for protecting this key species in the Arctic.
Hierarchical Bayesian Modeling of Continental-scale Pygoscelid Penguin Abundance

Christian Che-Castaldo¹ (cccweb@icloud.com), Casey Youngflesh¹, Stephanie Jenouvrier², Mathew R. Schwaller³, Heather J. Lynch¹

¹Stony Brook University, Ecology and Evolution, Stony Brook, United States, ²Woods Hole Oceanographic Institution, Woods Hole, United States, ³NASA/Goddard Space Science Center, Greenbelt, United States

We present a hierarchical Bayesian model of pygoscelid penguin abundance and distribution at all 509 known pygoscelid colonies. This model incorporates both presence-absence data and abundance estimates, collected from all known publically accessible data on pygoscelid penguin abundance and distribution, including nest and chick data derived from ground counts, aerial surveys, satellite imagery, and citizen science efforts. Our model provides abundance estimates for each population in each year since the 1979/80 season, including years for which no data are available, and allows us to both estimate species-specific trends at each penguin breeding site and understand how sites co-vary in their interannual dynamics. We investigate whether Allee effects, stemming from skua predation on penguin chicks and eggs, were mitigated for small Adélie or chinstrap populations embedded in larger gentoo colonies. Our model provides the best global-scale model for pygoscelid penguin population dynamics, and provides a means by which to assess the impact of climate change and other hypothesized drivers of population change.
Dive Behavior and Stable Isotopes: Index of Foraging Specialization in Seals

Daniel Costa¹ (costa@ucsc.edu), Luis Huckstat¹, Kimberly Goetz¹, Michelle Shero², Jennifer Burns²
¹University of California Santa Cruz, Ecology & Evolutionary Biology, Santa Cruz, United States, ²University of Alaska Anchorage, Biology, Anchorage, United States

Understanding the response of marine organisms to climate change requires a set of indices that can be obtained on a routine cost effective basis. While electronic tagging provides considerable insight into the foraging behavior ecology of marine vertebrates, it can be expensive and is applicable to those species where instruments can be deployed and recovered. Stable isotope analysis (SIA) can be carried out from tissues obtained by remote biopsy methods, from carcasses, from preserved or ancient material. However, alone at best SIA can provide an estimate of diet, but no information on the foraging behavior of the animal sampled. Here we determine the efficacy of using SIA data to infer the foraging behavior of the Weddell seals in the Ross Sea. Over a three year period (2010-2012) the foraging behavior and movement patterns of 63 Weddell seals was examined by instrumenting them with Satellite Relay Data loggers near Ross Island Antarctica. At capture tissues samples (hair, blood and whiskers) were collected and later analyzed for Carbon and Nitrogen isotope levels. The SIA data provided information on distinct differences between individuals and their diet that correlated with the individual specific diving behavior. This approach suggest that with sufficient validation SIA analysis can provide information not only on diet, but also on individual specific foraging patterns.
Myctophid (Gymnoscopelus nicholsi) Population Dynamics from Otoliths

Angela Klemmedson¹ (aklemmedson@sandiego.edu), Christian Reiss², Ronald Kaufmann¹, Michael Goebel², Emmanis Dorval³
¹University of San Diego, Environmental and Ocean Sciences, San Diego, United States, ²NOAA Fisheries/Southwest Fisheries Science Center, Antarctic Ecosystem Research Division, San Diego, United States, ³NOAA Fisheries/Southwest Fisheries Science Center, Fisheries Resources Division, San Diego, United States

Myctophids are ecologically important in the Southern Ocean, where they constitute an important energy resource to higher predators and serve as an alternative to krill in trophic pathways. Given the changes predicted for Southern Ocean ecosystems owing to climate change and the recovery of top predators, understanding the population dynamics of key prey species like myctophids is critical for ecosystem-based management. Due to challenges associated with sampling mesopelagic fishes, there is a lack of information on their life histories and population dynamics. Using biological samplers, such as piscivorous mammals, may provide large amounts of information about myctophid demographics. Here we reconstruct age, growth and length of Gymnoscopelus nicholsi using sagittal otoliths recovered from scats of Antarctic fur seals (Arctocephalus gazella) at Cape Shirreff (Livingston Island). We derived a 16-year time series (2000-2015) and found that G. nicholsi in the diets of fur seals ranged from 2 to 6 years of age. Additionally, we found that G. nicholsi mean age declined significantly during this time frame. This study demonstrates the utility of biological samplers to assessing population dynamics of mesopelagic fishes. The results presented here show that myctophids in waters off the South Shetland Islands exhibit dynamics that have yet to be understood, especially given the environmental changes and ecosystem regime shifts occurring in this region.
Animals that feed in a dynamic environment should adopt strategies that will optimise energy acquisition. The use of top predators as a bio-samplers is a complementary approach to understand how physical changes in the environment may influence their foraging success. The thermal structure of the water column is a key physical feature in pelagic waters that likely affect the vertical distribution of micronekton (fish, crustacean), and ultimately the foraging efficiency of their predators. Here, for the first time, we examine how this information links predator foraging behaviour with access to their pelagic prey. During the MYCTO-3D-Map campaign performed off the eastern side of Kerguelen (Southern Indian ocean), in situ conductivity-temperature-depth (CTD) profiles, acoustics, and net sampling of micronektonic organisms (prey) have been combined with bio-logging tracks of seabirds and marine mammals (predators). This information is then exploited for identifying potential foraging hotspots in outputs of ocean models (MERCATOR). Our aim is to determine the threshold of each species based on their access to prey along the horizontal and vertical axes. A better understanding of the links between ocean physics and the trophic food web has strong implications for predicted environmental shifts in the face of future climate change.
Antarctic glacier retreat is expected to have an important impact on the microbial communities embedded in perennial ice. In this context, our study focused on investigating the bacterial diversity from glacier ice and subglacial streams of King George Island, NW Antarctica, in relation with the spatial distribution and substrate geochemistry.

Samples were collected from Barton, Weaver and Potter Cove areas. Physicochemical measurements indicated a low mineral content and slightly alkaline pH in glacier ice relative to subglacier water. All ice samples showed a reduced organic carbon content and a homogenous Na-HCO₃ type chemistry, while stream water was more heterogeneous, belonging to Na-Ca-HCO₃ and Na-Cl types, with a high Al, Fe and Sr content. Illumina MiSeq sequencing of 16S rRNA gene highlighted variations of bacterial diversity with the type of habitat, locations and geochemical characteristics. Phyla distribution in the two types of habitats showed the dominance of Proteobacteria followed by Bacteroidetes, with spatial variations of other phyla representation between the peninsulas. High content of Proteobacteria characterized both the ice and stream microbial communities, with a major presence of Acinetobacter mainly in glaciers.

Analysis of the distribution pattern of bacterial communities in ice and subglacial streams, in relation with the habitat geochemistry, contributes to unravel the impact of melting glaciers on the resilience of the embedded microbiome.
Levels of Heavy Metals in Rocky Bottom Organisms along the Antarctic Peninsula

Luis Cardona¹, Paula de Castro¹, Conxita Avila² (conxita.avila@ub.edu)
¹University of Barcelona, Evolutionary Biology, Ecology and Environmental Science, Barcelona, Spain

Previous research has revealed the existence of a latitudinal gradient in the levels of several heavy metals in pelagic predators foraging along the Antarctic Peninsula. To assess the generality of that pattern, samples of benthic organisms were collected at five sites along a latitudinal gradient from King George Island (South Shetland Islands; 62°11′04″S 58°54′14″W) to Adelaide Island (western Antarctic Peninsula; 67°34′06″S 68°07′33″W). Phytoplankton, brown algae (Desmarestia menziesii and Desmarestia anceps), red algae (Palmaria decipiens), limpets (Nacella concinna) and starfishes (Diplasterias brucei and Odontaster validus) were collected at each site. Levels of Cr, Pb and Hg were assessed in each organism. Results revealed much higher levels of heavy metals in macroalgae than in phytoplankton or any animal organism considered, thus suggesting a minor role of Desmarestia antarctica, Desmarestia anceps and Palmaria decipiens as sources of organic matter for limpets and starfishes. On the other hand, levels of Hg increased from Nacella concinna to both starfish specie, thus suggesting biomagnification. Levels of Cr, Pb and Hg differed among sites, but no latitudinal gradient existed. This suggests that local processes are more important that regional patterns in determining the levels of heavy metals on benthic organisms and that the existence of permanent scientific research stations might be a relevant factor.
Genetic Identification and the Southern Ocean CPR Survey: A Useful Combination?

Bruce Deagle¹, Laurence Clarke¹,² (laurence.clarke@aad.gov.au), John Kitchener¹, Andrea Polanowski², Andrew Davidson¹

¹Australian Antarctic Division, Kingston, Australia, ²Antarctic Climate & Ecosystems Cooperative Research Centre, University of Tasmania, Hobart, Australia

Plankton surveys using the continuous plankton recorder (CPR) have characterised biodiversity along open ocean transects covering thousands of kilometres in Polar Regions. We investigated the potential to use DNA metabarcoding (species identification using high-throughput DNA sequencing) in the Southern Ocean CPR survey. Samples (n= 53) were collected in two transects and metazoans identified using standard microscopic methods and by sequencing a mitochondrial COI marker. DNA increased the number of metazoan species identified and provided high resolution taxonomy of groups problematic in conventional surveys (e.g. larval echinoderms and hydrozoans). Metabarcoding also generally produced more detections than microscopy, but this sensitivity may make cross-contamination during sampling a problem. In some samples, the prevalence of DNA from large plankton such as krill masked the presence of smaller species. Overall, the genetic data represents a substantial shift in perspective, making direct integration into current long-term time-series challenging. We discuss a number of hurdles that exist for progressing DNA metabarcoding from the current snapshot studies to the requirements of a long-term monitoring program. Given the power and continually increasing efficiency of DNA metabarcoding, it is almost certain this approach will play an important role in characterising polar marine ecosystems.
Spring Bloom of *Corethron* in Coastal Waters of the Western Antarctic Peninsula

Deneb Karentz¹ (karentzd@usfca.edu), Joe Grzymski²

¹University of San Francisco, Departments of Biology and Environmental Science, San Francisco, United States, ²Desert Research Institute, Division of Earth and Ecosystem Sciences, Reno, United States

*Corethron* is a cosmopolitan taxon and one of the most abundant diatom genera in the world ocean (Malviya et al. 2016). *C. pennatum* is often a dominant species in polar plankton communities with historical bloom events preserved in sediments (Leventer et al. 2002). During austral late winter/early spring 2011, observations of phytoplankton species succession in coastal waters of the Antarctic Peninsula documented the inception and development of a *C. pennatum* bloom. Cell densities increased from 100 (Sept) to 11,000 (Nov) cells/L, representing 25-100% of the net phytoplankton. Eighty-three phytoplankton taxa (including several abundant picoplankton species) were recorded, and *C. pennatum* comprised the bulk of the phytoplankton biomass during the study period. Cell diameters of *C. pennatum* ranged from 6-74 µm. From early Sept to mid-Oct mean cell diameter decreased from 29±9 to 19±8 µm. Doublets ranged from 9-32% of cells, with the maximum proportion of cells dividing in mid-Oct coinciding with sexual reproduction and auxospore formation. Up to 4% of cells observed at this time were male gametangia or auxospores. Enlargement of cells after auxosporulation resulted in a mean cell diameter of 33±11 µm by mid-Nov. Sequencing of the transcriptome indicates correlation between the occurrence of doublets and proteins involved in DNA replication (e.g., helicases), providing additional insights on the physiological state of *C. pennatum* during bloom formation.
Ross Island Adélie Penguin Population Responses to Variability in Sea Ice Extent

Fiona Shanhun1 (f.shanhun@antarcticanz.govt.nz), Natalie Robinson2, Kerry Barton3, Phil Lyver4, Rebecca McLeod1
1Antarctica New Zealand, Christchurch, New Zealand, 2National Institute for Water and Atmospheric Research, Wellington, New Zealand, 3BartonK Solutions, Nelson, New Zealand, 4Landcare Research, Lincoln, New Zealand

Adélie penguins (*Pygoscelis adeliae*) are an indicator species used to detect and monitor the effects of environmental change on Antarctic marine ecosystems. Since the early 1980s, New Zealand has conducted an annual census of Adélie penguins in the Ross Sea region, with data submitted to the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) Ecosystem Monitoring Programme (CEMP). Changes in the number of breeding pairs are considered in relation to environmental factors, allowing hypotheses about population responses due to natural versus anthropogenic changes to be tested.

Sea ice conditions in McMurdo Sound in November 2016 and 2017 were significantly different. Extensive and persistent sea ice cover in McMurdo Sound in 2016 led to many abandoned Adélie penguin nests at colonies on Ross Island. The number of breeding pairs at Cape Royds, Cape Bird and Cape Crozier decreased by 44%, 23% and 8%, respectively, compared to 2015 numbers. The early breakout of sea ice in the 2017 austral summer provides a complete contrast. This inter-annual variability is considered in terms of the short-term impact on Adélie penguin populations on Ross Island, with a view to predicting longer-term effects of changing environmental conditions on Adélie penguin populations in the Ross Sea.
Alpha Amylase from Geomyces sp. Isolated from Antarctic and Arctic

Abiramy Krishnan¹² (abiramy.krishnan@gmail.com), Peter Convey³, Zazali Alias², Marcelo Gonzalez Aravena⁴, Siti Aisyah Alias¹⁵
¹University of Malaya, National Antarctic Research Centre, Kuala Lumpur, Malaysia, ²University of Malaya, Institute of Biological Science, Kuala Lumpur, Malaysia, ³British Antarctic Survey, Cambridge, United Kingdom, ⁴Instituto Antártico Chileno, Punta Arenas, Chile, ⁵University of Malaya, Institute of Ocean and Earth Science, Kuala Lumpur, Malaysia

Geomyces sp., a soil microfungi deserve a very special place in the polar ecosystem. This species is reported to be positive for various hydrolase enzymes which makes it a successful decomposer in the polar region. Objective of this study is to compare alpha-amylase from Geomyces sp. from Arctic and Antarctic. Soil samples were collected from King George Island, Antarctic during 2007 Austral summer and Svalbard, Arctic during boreal summer in 2006 and 2010. Soil microfungi were screened for amylase activity. One strain with highest relative enzyme activity from each region were chosen for further enzyme activity analysis. Alpha amylases were purified using forced affinity chromatography column. The purified enzymes were run on SDS PAGE to confirm the molecular weight. Twenty five of 33 Antarctic and 4 of 4 Arctic Geomyces sp. showed significant relative amylase activity in the preliminary screening. From this, one best amylase producer from each region were chosen for enzyme activity assessment. Purified alpha amylase of both isolates showed optimum temperature for enzyme activity at 10°C and the optimum pH was 6.6. SDS PAGE showed both alpha amylase had molecular weight around 70kDa. Alpha amylase from Antarctic Geomyces showed higher enzyme activity in comparison with Arctic Geomyces. This is probably because, relatively harsher environment of Antarctic prepared these fungi to perform maximally when the optimum temperature provided.
Polyphasic Characterization of Terrestrial *Leptolyngbya* on Signy Island

Ranina Alya Mohamad Radzi¹ (raninaalya@gmail.com), Faradina Merican¹, Paul Broady², Peter Convey³

¹University Sains Malaysia, School of Biological Sciences, Penang, Malaysia, ²University of Canterbury, School of Biological Sciences, Canterbury, New Zealand, ³British Antarctic Survey, Cambridge, United Kingdom

Studies of members of the genus *Leptolyngbya* are mostly reported from tropical and temperate regions. Although the genus often dominate microbial communities in Antarctic soils, their diversity and ecological significance are not well understood. We have investigated four *Leptolyngbya* strains obtained from soil collected from Signy Island, South Orkney Islands, and maritime Antarctic. Morphologically, all four strains in culture showed diacritical characteristics consistent with the genus *Leptolyngbya*. However, 16S rDNA analysis showed that three of the strains were closely related to the genus *Wilmottia* while one was a close relative of the new cyanobacterial genus *Nodosilinea*. At present, only two *Wilmottia* species, *Wilmottia murrayi* and *Wilmottia sp.*, have been characterized from Antarctica. Under the most recent classification system, *Wilmottia* is recognised as a special genus (*Wilmottia* gen. nov.) because of its similarities with *Leptolyngbya* and *Phormidium* while *Nodosilinea* includes members with unique ability to form nodules along the length of the filament and has mostly been recorded from environmentally extreme locations. Polyphasic characterization is now being used to evaluate the taxonomic positions of these four strains. Moist plate enrichment culture of the soil, transmission electron microscopy (TEM) and physiological studies such as pigment tests and salinity tolerance assessment are being used to aid in species identification.
Marine Ecosystem Assessment of the Southern Ocean: Outcomes of MEASO2018

Andrew Constable\(^1\) (andrew.constable@aad.gov.au), Jessica Melbourne-Thomas\(^1\), Rowan Trebilco\(^2\), Michael Sumner\(^2\), Philip Boyd\(^3\), So Kawaguchi\(^1\), Klaus Meiners\(^3\), Kerrie Swadling\(^3\)

\(^1\)Australian Antarctic Division and ACE CRC, Kingston, Australia, \(^2\)Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia, \(^3\)University of Tasmania / Institute for Marine and Antarctic Studies, Hobart, Australia

Status and trends of Southern Ocean ecosystems are being assessed to update the SCAR Antarctic Climate Change and Environment Report and to provide inputs to the Sixth Assessment Review of the IPCC. These assessments are also intended to provide scientific inputs on marine ecosystems important to the Committee on Environmental Protection under the Antarctic Treaty and to the Commission for the Conservation of Antarctic Marine Living Resources. Interpretable measures of change in habitats, species and food webs are being synthesised for four sectors of the Southern Ocean (East and West Pacific, Atlantic and Indian), and divided into assessments for coastal/sub-polar and subantarctic areas. Results from the recent Marine Ecosystem Assessment for the Southern Ocean (MEASO) conference in Hobart in April 2018 will be presented on behalf of many scientists from ICED, SCAR Life Sciences, AnT-ERA, AntEco and SOOS. We summarise the conclusions and gaps in the assessments for each sector and highlight directions for the next MEASO.
Snow packs are important interfaces with global climate and biogeochemistry (Wadham et al., 2013) and form a biologically productive microbial habitat (Hodson et al., 2008). However, far less attention has been paid to supraglacial snow packs compared with snow covers on top of soil and aquatic ecosystems (Jones 1991). In addition, snow packs are getting wetter and less persistent globally in response to warming air temperatures. More importantly, supraglacial snow packs are well-connected to marine and terrestrial systems, therefore any changes will result in ecological implications downstream. Therefore, in order to understand the variation in space and time of microbial diversity and biogeochemistry of a supraglacial snow pack, samples were collected monthly for four months on seven areas of a High Arctic ice cap (Foxfonna, Svalbard). This work will therefore establish the changing ecology of snow with the evolution in the snowpack’s physical condition during melt and hence present the systematic change expected in resident microbial communities and nutrient dynamics through the summer, both spatially and temporally. In summary, this work will present a seasonal ‘album’ for ecology of glacial snow packs.
Changing Light Regimes in Polar Deserts: A Metatranscriptome Analysis

Kathryn Coyne¹ (kcoyne@udel.edu), Jill Sohm², Andrew Kalmbach³, Troy Gunderson², Christopher R. Main¹, Doug Capone², Edward Carpenter³, Craig Cary¹,⁴

¹University of Delaware, Lewes, United States, ²University of Southern California, Los Angeles, United States, ³Romberg Tiburon Center for Environmental Studies, Tiburon, United States, ⁴University of Waikato, Hamilton, New Zealand

Microbial communities in Antarctic Dry Valleys are dominated by cyanobacteria that provide the heterotrophic community with photosynthetic carbon as well as nitrogen through diazatrophic activities. Diazatrophic heterotrophs also contribute to nitrogen input, but are a carbon sink rather than a source. Little is known about the seasonal effects of changing light intensity on the dynamics of these two groups of microbes. The objectives of this study were to investigate the transcriptional response of the microbial community to changes in light regime. Plots along a stream in Taylor Valley were shaded to reduce light by 10%, 50% and 100% and samples were collected at the initial time point and after 11 days. The transcriptomes were paired-end sequenced and assembled, producing approximately 55,000 transcripts with an N50 of 2,098. Reads from each treatment were mapped to the assembled transcripts for differential expression analysis. Analysis is ongoing, but shows that metatranscriptomes generated from samples collected on day 11 were significantly different from the initial time point, and also that samples collected from the 50% and 100% reduced light treatments on day 11 were significantly different from the 10% treatment. Here, we will present an analysis of transcriptional changes affecting carbon and nitrogen cycling. Results of this research will contribute to our understanding of microbial dynamics and community responses to changing light regimes in polar deserts.
Phylum Tardigrada is a minute, hydrophilous animal group with a five segmented body which consists of a head and four trunk segments. This phylum is famous for the ability to survive the severe conditions such as cold, dry, or high radiation environments. The limno-terrestrial tardigrades are one of the dominant animal groups in the terrestrial ecosystem of Antarctica. However, due to their limited morphological characteristics and restricted access to the habitats, taxonomic study on Antarctic tardigrades is difficult to carry out. KOPRI ecology team collected several species of tardigrades from King George Island, Antarctica during 2014-2015 season expedition. Among the collected tardigrades, one species shows a bucco-pharyngeal apparatus with 10 peribuccal papillae reminiscent of *Macrobiotus*-type and the cuticular connection between claws, which are characteristics of the genus *Dactylobiotus*. This species is large in size (600-700 µm) with smooth cuticle and no conical papillae between 3rd and 4th limbs. Key morphological characters of bucco-pharyngeal apparatus and claws are being measured, and \( pt \) ratio (the ratio of the length of a given structure to the length of the buccal tube) are compared to that of other *Dactylobiotus* species to see whether the species is a previously reported *Dactylobiotus* species documented in other regions around the world, or a new species.
We have deployed, for the first time, a close-distance remote sensing system to study leaf level physiological processes of Blechnum penna-marina at fine time scales (minute x minute) on Marion Island, over an annual cycle. Combined with this, standard leaf gas exchange approaches were also employed. We placed the remote sensing stations at a range of elevations, and these collected micrometeorological data, as well as an index which indicates levels of plant stress. Experiments using a LICOR 6400xt gas exchange system were performed on low altitude plants, which were acclimated for 3 days at different treatment temperatures. Field data suggested that plants experienced stress above 11°C, and leaf gas exchange information allowed us to explore this relationship in more detail. We used structural equation modelling, to identify the major meteorological factors that influence plant stress response. Machine learning was used to characterize the archetypical diurnal conditions, which in turn allowed us to further understand how plant physiology reacts to the abiotic environment. We argue that this mix of techniques allows the exploration of crucial aspects of how the abiotic environment affects plant function. In conclusion, a multi-tiered approach using both remote sensing and gas exchange will be valuable in future to understand the complex interaction climate has with organisms.
Phototrophic Picoeukaryotes and their Antarctic Winter Niche

Carla Gimpel\textsuperscript{1} (cgimpel@hawaii.edu), Christian S. Reiss\textsuperscript{2}, Elliot L. Weiss\textsuperscript{3}, B. Greg Mitchell\textsuperscript{3}, Alison E. Murray\textsuperscript{4}

\textsuperscript{1}University of Hawai`i at Manoa, Daniel K. Inouye Center for Microbial Oceanography: Research and Education, Honolulu, United States, \textsuperscript{2}Southwest Fisheries Science Center, Antarctic Ecosystem Research Division, La Jolla, United States, \textsuperscript{3}Scripps Institution of Oceanography, University of California, San Diego, La Jolla, United States, \textsuperscript{4}Desert Research Institute, Division of Earth and Ecosystem Sciences, Reno, United States

Reduced photoperiod, absence of picocyanobacteria, low surface temperatures and a highly variable sea ice ecosystem shape the polar winter, which has become increasingly warmer and shorter. A survey was conducted off the South Shetland Islands (SSI) during three consecutive late winter seasons. The expected low chlorophyll a concentrations in the system correlated with phototrophic picoeukaryote (PPE) abundances in the upper mixed layer (UML), characterized by Winter Water and varying sea ice types. To further address the ecological significance of Antarctic PPE, we also quantified contemporaneous bacterioplankton populations. The highest microbial abundances where detected north of the SSI and PPE counts correlated with chlorophyll a concentrations stronger than with prokaryotes in the UML. High throughput amplicons of the hypervariable V4 region of the 16S and 18S rRNA marker gene were used to better comprehend the diversity and potential functional networks of the microbial community, revealing a strong presence of Bathycoccus in open waters. Multivariate statistical analyses were used to test the significance of the influence of inherent physical properties of the ocean on the diversity and plasticity of Antarctic picoplanktonic assemblages. The interannual nature of this study contributes to revealing the ecosystem biological baseline and explores its resilience given the current changes in the ecosystem.
Elevated Salinity Alters Biotic Interactions in McMurdo Dry Valley Soils

E. Ashley Shaw¹ (elizabeth.shaw@colostate.edu), Diana H. Wall¹
¹Colorado State University, Department of Biology, Fort Collins, United States

The McMurdo Dry Valleys (MDV), Antarctica are relatively simple soil ecosystems compared to temperate soils. Soil microbes and a few species of nematodes, rotifers, tardigrades, and micro-arthropods occur in the MDV; however, soil food web structure varies landscape-wide. Nearly 95% of the area is dry soil (< 3% gravimetric moisture) dominated by an endemic microbivore nematode, Scottnema lindsayae. Wet soil habitat is generally limited to lake and stream margins and contains greater invertebrate biodiversity. Climate change is predicted to alter hydrological connectivity across the MDV, shifting soil salts and solutes and changing dry and wet soil habitat distribution. It is unknown how this will affect the distribution, abundance, and interactions of soil biodiversity.

MDV Long Term Ecological Research data show nematode populations are negatively associated with soil salinity, but responses to soil moisture are species-dependent. We tested the effect of increased salinity and moisture on four different soil communities in a laboratory microcosm experiment (full factorial: 2 salinity x 2 moisture x 4 biota treatments). Elevated moisture significantly reduced adult S. lindsayae abundance, while elevated salinity significantly reduced the total S. lindsayae population. In the presence of S. lindsayae, total microbial abundance was significantly lower, but this effect was diminished under the high salinity treatment, possibly due to a release of predation pressure.
The need for information about population structure is most acute for ecologically key species like salps because they play a key role in the marine ecosystem, and are likely to be heavily influenced by climate change. This impact is believed to be positive in the Antarctic waters, with pronounced expansion of pelagic tunicates under favorable environmental conditions. This study as one of the first shows a different approach to research on Antarctic salps population and possible could fulfill the gap in knowledge about their evolution and expansion in the Southern Ocean.

Oozoids caught off South Georgia, the Antarctic Peninsula and Polar Front area generated barcodes consisting of a few different DNA sequences and reveal some signals of inter and intra-population variation. Analysis of the prominent barcode sequence data yielded high haplotype (h: 0.7198-0.9346) and low nucleotide (p: 0.0099) diversities, and reveal statistically significant evidence for genetic structure between studied population (Fst= 0.37748 with P value= 0.0000) as assessed using analysis of molecular variance. Negative Tajima’s D and Fu and Li’s D statistics indicates excess of new mutation as a result of evolutionary forces, such as selective sweeps or population grow. It could be as well an evidence for heteroplasmy arising from a dynamic mitochondrial genome.
Morphometric Analysis of Antarctic Foliose Lichens Using 3-D Digital Microscopy

Alla Orekhova¹ (asp.sniish@mail.ru), Miloš Barták¹, Romana Gašparová¹
¹Masaryk University, Faculty of Science, Department of Experimental Biology, Brno, Czech Republic

Recently, digital microscopy is an emerging technique that combines the tools of classic light microscopy with a computerized imaging system. Here we present application of the method in morphometric analysis of Antarctic lichen thalli. The main goal of the study was to evaluate changes in 3-D structure of thalli as dependent on hydration status, and interspecific differences as well. Another goal was to provide quantitative biometrical data on size and shape of morphological structures such as fruiting bodies. Lichen thalli collected from several sites on deglaciated northern part of James Ross Island were analysed using a digital VHX-900F microscope (Keyence, Japan) with a maximum resolution of 19.5 megapixels. The microscope with built-in LEDs allowed accurate measurements of lichen surface structures viewed in real time depth composition at the magnification ranging from 20 to 200. Data forming a 3-D view of the upper cortex were used to analyze the size of lobes, outgrowths, and fruiting bodies, respectively. Using a VHX software, we applied processing tools: 1) height profile along a selected line placed across a thallus, 2) DFP method (Depth From Defocus) which compiles different focal planes. We studied Placopsis contortuplicata, Dermatocarpon polyphilizum, Rhizoplaca melaophthalma and other species. Gained results on a 3-D structure are discussed: interspecific, hydration-, and developmental stage-dependent differences. Thank to support from CzechPolar, ECOPOLARIS.
Relating Antarctic Krill Lipids and Fatty Acids to Environmental Parameters

Nicole Hellessey1,2,3 (nicoleh3@utas.edu.au), Jessica Ericson1,2,3, Peter D Nichols2, Robert Johnson4, Stephen Nicol1, So Kawaguchi3,5, Nils Hoem6, Patti Virtue1,2,3
1Institute for Marine and Antarctic Studies, Hobart, Australia, 2Commonwealth Science for Industry Research Organisation, Oceans and Atmosphere, Hobart, Australia, 3Antarctic Climate & Ecosystems Cooperative Research Centre, Ecology, Hobart, Australia, 4Australian Bureau of Meteorology, Hobart, Australia, 5Australian Antarctic Division, Kingston, Australia, 6Aker BioMarine, Oslo, Norway

Antarctic krill are at the centre of the Antarctic ecosystem, linking phytoplankton and higher organisms. Knowledge of their lipid (oil) biochemistry can assist in understanding and predicting potential ecological changes and can also inform the fishery on sustainable practices, optimising krill harvest. Knowing how krill will respond to environmental changes is difficult to predict or explore at large scales through typical experimentation. The use of satellite imagery can help look at krill production by using their lipids and fatty acids as a proxy for their health and ability to reproduce.

This study examined how the lipid and fatty acid content and composition of Antarctic krill was linked to large scale environmental parameters determined through satellite imagery. Lipids were analysed from krill collected by a commercial krill fishery over 3 years, allowing for long-term environmental and seasonal shifts to be seen, as well as from the K-Axis and ACE voyages, allowing for regional differences to be seen. The fluorescence levels, chlorophyll a, irradiance, sea surface height and temperature from the same collection dates and locations was used to compare krill lipids and fatty acids to their environment. Whilst this link has been studied on small scales and with few samples, this study describes differences seen temporally (over 3 years in the Scotia Sea) and spatially (in 3 ocean basins) in krill lipids with their relationship to environmental conditions.
As the primary producers in Antarctic terrestrial and fluviol ecosystems in the McMurdo Dry Valleys (MDV), the distribution and areal extent of microbial mats is hypothesized to reflect changes to water and nutrient availability. Therefore, observations of "sentinel" microorganisms such as Nostoc, Phormidium, and other Cyanobacteria can be used as a proxy for environmental change. In order to utilize such biological proxies, it is necessary to produce a baseline census of mat distributions and compositions to compare to future change. Here we report on observations collected in 2016-2017 of microbial mat occurrences in Wright Valley that link ground-based hyperspectral and molecular measurements with a UAS-enabled hyperspectral airborne survey (600-1000 nm with 4 nm band spacing). We compare these observations to near-concurrently collected, satellite-based Worldview-2 imagery in order to identify diagnostic microbial mat absorptions that can be mapped using multispectral data. Initial observations suggest that the targeted mats are low-reflectivity at visible wavelengths and bright in the near-IR portion of their reflectance spectra, consistent with reflectance from photosynthetic pigments. NIR-bright mats can be detected in ground-based and airborne (UAS) hyperspectral observations. Space-based mat detection is hampered by the need to generate scene-specific atmospheric corrections due to large polar phase angles and subpixel mixing of mat, sediment, and rock spectra.
Historically, large-scale monitoring (both spatially and temporally) of Antarctic and sub-Antarctic penguin colonies has been impracticable, owing to technological restraints and the remote locations involved. A remote camera network, comprising ~100 time-lapse devices positioned across the Falkland Islands, South Georgia and the Antarctic continent, aims to fill this data gap. However, with each camera capturing ~8000 images per year, we are presented with another issue - how to efficiently process the photographs and automatically extract meaningful phenological data. Here we discuss Penguin Watch, an online citizen science project (part of the Zooniverse platform) which asks volunteers to ‘tag’ penguins in time-lapse images. To date, over six million images have been classified by nearly 48,000 registered volunteers. Annotations are clustered and filtered (to allow removal of erroneous classifications), and used to create time-series data, which in turn can be used to extract phenological information such as date of adult arrival and date of chick hatching.
King Penguin Population Monitoring through Remote Sensing

Catherine Foley¹ (catherine.foley@stonybrook.edu), Tom Hart², Heather Lynch¹
¹Stony Brook University, Department of Ecology & Evolution, Stony Brook, United States, ²Oxford University, Department of Zoology, Oxford, United Kingdom

Over the past century, king penguin colonies have been increasing in number and spatial area across the island of South Georgia. Monitoring these populations has proven difficult due to limited access and the large numbers of individuals within the major breeding colonies. Additionally, the unique multi-year breeding cycle of the king penguin complicates survey efforts, since there is no single point at which the number of individuals engaged in breeding can be directly assessed. Remote sensing methods have been used for other species of seabirds and marine mammals that colonize regions with limited access for on-the-ground censusing. To monitor populations of king penguins, we used high-resolution (sub-meter) satellite imagery to estimate the distribution and abundance of king penguins in South Georgia. To accommodate for the complex phenological challenges of translating counted individuals into an estimate of the breeding population, we developed an individual-based simulation model that allows us to correct for availability bias in direct or remotely-derived counts completed throughout the austral summer. These methods, which were used to estimate the total number of king penguins currently breeding in South Georgia, represent a first step in a more-regular monitoring scheme tracking the total abundance of king penguins in South Georgia and identifying changes in abundance that are relevant to their conservation.
Weddell Seal Count: Citizen Science for the Ross Sea Region MPA

Stuart Grayson¹ (stuart.l.grayson@gmail.com), Regina Eisert²
¹University of Canterbury, Gateway Antarctica, Christchurch, New Zealand

Weddell seals (Leptonychotes weddellii) are a focal species for research & monitoring in the new Ross Sea region Marine Protected Area. Weddell seals have a pronounced diel or quasi-diel haul-out cycle that affects their availability for counting. We investigated two potential drivers of haul-out behaviour, solar altitude and ocean tides, as a basis for effective monitoring of Weddell seals in the Ross Sea region by remote sensing. Using two autonomous survey cameras activated at 10-minute intervals, we collected ca. 10,000 static images of the Turtle Rock seal colony, McMurdo Sound (77°44’38.22”S, 166°46’33.42”E), from Nov 2014-Jan 2015. Turtle Rock is surrounded by sea ice and seals access the water through tidal cracks. Seals in images were counted by two methods: (a) citizen science ('Zooniverse'); (b) automated image processing using machine learning. We compared both methods for efficacy and for accuracy relative to images counted by the authors. Preliminary results indicate that during a 20-day period from 28 Nov 2014, the activity pattern of Weddell seals appeared to be correlated both with solar altitude and with the tides, with peak haul-out at low tide/solar noon. Given the unusual tide cycle in McMurdo Sound (low tides largely coincide with solar noon during summer), further research at different latitudes and/or times of the year may be required to disentangle the relative importance of solar altitude and tides as zeitgebers for Weddell seal haul-out behaviour.
Multi-modal Survey Reveals the Danger Islands as a Seabird Hotspot

Heather Lynch¹ (heather.lynch@stonybrook.edu), Alex Borowicz¹, Philip McDowall¹, Casey Youngflesh¹, Thomas Sayre-McCord², Gemma Clucas³, Rachael Herman¹, Steven Forrest⁴, Melissa Rider⁴, Mathew Schwaller¹, Tom Hart⁵, Stephanie Jenouvrier², Michael Polito⁶, Hanumant Singh⁷

¹Stony Brook University, Ecology & Evolution, Stony Brook, United States, ²Woods Hole Oceanographic Institution (WHOI), Woods Hole, United States, ³University of New Hampshire, Durham, United States, ⁴Antarctic Resource, Inc., Denver, United States, ⁵Oxford University, Oxford, United Kingdom, ⁶Louisiana State University, Baton Rouge, United States, ⁷Northeastern University, Boston, United States

Despite concerted international effort to track and interpret shifts in the abundance and distribution of Adélie penguins, ecologically significant populations of Adélie penguins continue to be identified. Here we report on a major hotspot of Adélie penguin abundance discovered in the Danger Islands off the northern tip of the Antarctic Peninsula (AP). We present the first complete census of Pygoscelis spp. penguins in the Danger Islands, estimated from a multi-modal survey consisting of satellite imagery, direct ground counts, and computer-automated counts of unmanned aerial vehicle (UAV) imagery. Our survey reveals that the Danger Islands host 751,527 pairs of Adélie penguins, more than the rest of AP region combined, and include the third and fourth largest Adélie penguin colonies in the world. Our results validate the use of Landsat medium-resolution satellite imagery for the detection of new or unknown penguin colonies and highlight the utility of combining satellite imagery with ground and UAV surveys. The Danger Islands appear to have avoided recent declines documented on the Western AP and, because they are likely to remain an important hotspot for avian abundance under projected climate change, deserve special consideration in the negotiation and design of Marine Protected Areas in the region.
Is the Antarctic Petrel Breeding Colony on Mt. Biscoe the Largest in the World?

Heather Lynch¹ (heather.lynch@stonybrook.edu), Mathew Schwaller², Arnaud Tarroux³, Brandon Prehn⁴
¹Stony Brook University, Stony Brook, United States, ²Stony Brook University, Ecology & Evolution, Stony Brook, United States, ³Norwegian Polar Institute, Fram Centre, Tromso, Norway, ⁴University of British Columbia, Vancouver, Canada

We recently developed an algorithm to retrieve Antarctic petrel (Thalassoica antarctica) colonies from Landsat-8 Operational Line Imager data, and applied the algorithm in a continent-wide search for new and existing breeding locations. One of the results of this survey suggests that the breeding population at Mt. Biscoe (66°13’S 51°21’E), currently reported to be in the 1000s, may actually be on the order of 400,000 breeding pairs. If verified, this colony would be the largest known Antarctic petrel breeding community in the world, and a colony of this size would nearly double the known breeding population of this species. Our results also suggest other testable hypotheses: we provide geographic coordinates of a previously suspected but undetected breeding colony on Mt. Provender, and we make predictions on how the diet of the Antarctic petrel (and therefore the chemistry of its guano) may affect the detection of colonies in satellite remote sensing. We lay out a way forward for verifying the results of our survey, for algorithm improvement, and for employing such improvements in a successively more precise understanding of the distribution and abundance of the Antarctic petrel with remote sensing techniques.
To understand habitat use by Weddell seals, it is imperative to know where and when they are present around the continent. The necessary data to date have been impossible to gather across such a large geographic area. We established our project, Satellites Over Seals (SOS), in late 2016 as a crowd-sourced method of gaining information about presence and abundance of Weddell seals on fast ice around Antarctica. To engage citizen scientists, we used a novel technology: the online platform at Tomnod to select and host high-resolution satellite imagery (VHR) for “the crowd” to search, using VHR from November 2010 and 2011, covering the Ross, Amundsen, Bellingshausen and Weddell Sea regions. More than 318,000 citizen scientists searched 550 images covering 105,124 km² of fast ice to determine locations of seals. Seal presence ranged from 0.5% - 2% on all maps (n = 778,447) searched. When detecting presence/absence of seals on a map (i.e., not seal abundance) rate of false negative detections was 0%, though false positive rates were high (80%); this highlights the importance of training for image interpretation to ensure differentiation among seals and landscape features. We provide recommendations on image resolution, quality, training and outreach for future implementation of citizen science methods to learn about Southern Ocean ecology.
Combining Satellite Datasets to Track Changes in the Vegetation of Kerguelen

Damien Fourcy¹ (damien.fourcy@inra.fr), Jean-Louis Chapuis², Marc Lebouvier³, Marc Robin⁴
¹INRA, UMR 985 ESE, Rennes, France, ²MNHN, UMR 7204 CESCO, Paris, France, ³CNRS, UMR 6553 Ecobio, Rennes, France, ⁴Université de Nantes, UMR 6554 LETG, Nantes, France

The Kerguelen Islands (49°30’ S, 69°30’ E) are among the most isolated islands in the world, located in the sub-Antarctic region 2000 km from Antarctica and 3800 km from Africa. The vegetation of these uninhabited islands is very little diversified (only 22 native phanerogams) and undergoes changes that increase since the last two decades. The structure and the composition of the plant communities are strongly affected by the combined effects of climate change and the introduction of animal and plant species.

In order to track changes in plant communities over large spatial and temporal scales, we have developed a mapping method based on satellite images from different sources. High resolution SPOT images were used to characterize the evolution of vegetation cover from 1995 to 2016, i.e. since the observation of the first significant changes in plant communities. In addition to SPOT, Sentinel-2 imagery, thanks to its easy access, allowed to expand temporally and spatially this general monitoring. For the most recent years, very high resolution Pléiades images allowed a mapping of all the different plant communities. Moreover, fine data on the evolution of floristic composition of the communities were recorded from field surveys carried out since 1995.

This mapping approach, based on multi-source satellite data and combined with field data, provides a better understanding of the current dynamics and is a valuable tool for managing these fragile ecosystems.
Camera Derived Phenology of Pygoscelid Penguins in Relation to Fishing

Tom Hart¹ (tom.hart@zoo.ox.ac.uk), Fiona Jones¹, Beccy Wilebore¹, Grant Humphreys⁵, Caitlin Black³, Heather Lynch⁴, Byron du Preez¹, Ron Naveen⁵
¹University of Oxford, Oxford, United Kingdom, ²Black Bawks Data Science, Edinburgh, United Kingdom, ³University of Cambridge, Zoology, Cambridge, United Kingdom, ⁴Stony Brook University, Stony Brook, United Kingdom, ⁵Oceanites, Inc., Washington, United States

On the Antarctic Peninsula, chinstrap and Adélie penguins are in decline while gentoo populations are expanding in size and range. Potential drivers of these changes include climate change, winter sea ice extent, ocean productivity, tourism, fishing and prey competition with other predators. However these drivers are usually confounded in space and time, presenting a challenge that cannot be answered by conventional remote monitoring. Here we show that a combination of time-lapse cameras, citizen science and machine learning allows us to elucidate the timing of breeding and nest-based reproductive success. We show differences in the timing of breeding, reproductive success and crèching behaviour across the breeding range of these penguin species. We also report remotely monitored Automatic Identification System (AIS) derived spatio-temporal patterns of fishing, their overlap with foraging ranges during the penguin breeding season, and the potential impact on penguin reproductive success. A proposal for an Antarctic Peninsula Marine Protected Area (MPA) is already being discussed in CCAMLR and, once extant catch limits expire after the 2020/21 fishing season, it is expected that there will be pressure to increase krill fishing quotas in the region. We consider our paper a first step towards a more sophisticated analysis to investigate the influences of fishing pressure on krill predator reproductive success and to disentangle the confounding stressors in the region.
The opportunistic fungi (OF) were studied in the soils contaminated by the industrial plants emissions, as well as their virulence was estimated on the basis of protease, phospholipase activity, and the growth capability at a temperature of 37°C. 51 species of the fungi belonging to the OF group, were isolated in the soils of the Kola Peninsula. The share of the OF increases to 15-20%, compared to the background soil, under the anthropogenic impact (oil products, the aluminum and copper-nickel plant emissions).

The most dangerous for a human being are considered to be 7 fungi strains from the checked 75 ones: Amorphotheca resinae st.1, Aspergillus fumigatus st.1, A. niger, Paecilomyces variotii st.1, Penicillium commune, P. purpurogenum, Trichoderma viride. 55% of the investigated fungi strains isolated from the soils contaminated by the aluminum plant emissions had the pathogenicity properties, compared to the strains of the same species isolated from the clean soil (25%). A. fumigatus, Paec. variotii, P. aurantiogriseum showed both protease and phospholipase activity. A. resinae, Cephalotrichum stemonitis, Cladosporium herbarum revealed protease activity and the growth capability at a temperature of 37°C. The fungi isolated from the soil can constitute a danger to the human being’s health, as most of them reveal the pathogenicity properties, to a greater or lesser extent. The regular monitoring research should be fulfilled to determine potentially-dangerous fungi species.
Does Arctic Warming Affect Lichen- and Bryophyte Microbiota and their Functions?

Ingeborg Klarenberg1,2 (ingeborg@unak.is), Oddur Vilhemsson1,3
1University of Akureyri, Faculty of Natural Resource Sciences, Akureyri, Iceland, 2University of Iceland, Faculty of Life and Environmental Sciences, Reykjavík, Iceland, 3University of Iceland, Biomedical Center, Reykjavík, Iceland

Lichens and bryophytes are an essential part of the vegetation in Arctic ecosystems. In addition to the mutualistic association of a fungus and an alga and/or a cyanobacterium, lichens are also known to harbour species-specific bacterial communities, typically dominated by Proteobacteria. Similarly, bryophytes possess their own microbiome. Among the potential functional roles of these bacteria are inorganic phosphate mobilization and nitrogen fixation. In the light of climate change and the effect on Arctic ecosystems, the question rises what the effect will be on lichen and bryophyte associated microbiomes and their functions. The main aim of this study is to characterise and compare the composition of lichen- and bryophyte-associated bacterial communities differentially impacted by a long-term warming experiment. Active and resident bacterial communities are assessed by taxonomic analysis of MiSeq libraries of 16S-rDNA and -rRNA targeted amplicons. Also, expression of different genes involved in N-fixation are measured by RT-qPCR. The lichen and bryophyte-associated microbiota are strongly dominated by Proteobacteria, with members of Rhizobiales, Sphingomonadaceae and Burkholderiales particularly prominent. Changes in abundance of individual taxa are expected to reflect the different living conditions expected in the warming Arctic. In addition, some microbial functions might emerge, others disappear, with consequences for the biogeochemical cycles in Arctic ecosystems.
What is the Best Practice for Microbial C and N Assessment in Subarctic Soils?

Mikhail Maslov1 (maslov.m.n@yandex.ru), Olga Maslova1
1Lomonosov Moscow State University, Moscow, Russian Federation

The aim of our work were to assess the comparability of the results of determining microbial carbon (C) and nitrogen (N) in organogenic Subarctic soils by different methods under maximally standardized conditions. Four methods of microbial C and N pools assessment were considered to subarctic soils in the European part of Russia: fumigation-extraction (FE), fumigation-incubation (FI), rehydration-extraction (RE) and rehydration-incubation (RI). We studied organogenic horizons of soils under 4 types of vegetation in the mountain tundra, 2 vegetation types in the lowland tundra, soils of birch and spruce forests, and swamps. FI and RI methods require a substantial amount of time and little use for subarctic soils (including due to low pH and predominance of fresh litter). FE and RE methods are more rapid and gives good reproducible results, but FE method usually gives higher values of microbial biomass C and N in comparison with the RE method. The microbial C:N ratio, determined by these methods in almost all soil is the same. The greatest differences are characteristic of the horizon containing fresh litter. Obviously, fumigation with chloroform leads to greater mobilization of carbon and nitrogen of plant residues compared with the drying. Concentration of microbial C and N (determinate by FE and RE methods) more comparable for horizons with a lower content of fresh litter. The study was supported by the Russian Science Foundation (grant No. 17-76-10020).
Biological soil crusts (BSCs) are biological communities inhabiting the uppermost layer of soil. They are frequently formed in polar regions, where the severe environmental conditions limit the growth of higher plants. The intact BSCs represent complex communities of cyanobacteria, algae, fungi, lichens, bryophytes, bacteria and even small invertebrates. Generally, BSCs show high resistance to stress factors common in Antarctica, i.e. low and freezing temperatures, desiccation, high UV-B doses in austral spring, high global radiation in austral summer and no radiation in winter. In this study, the tolerance to these stress factors was tested in single-species cultures of cyanobacteria isolated from the BSCs collected during Czech Antarctic expeditions to James Ross Island, Antarctica (2016, 2017). We tested Leptolyngbya sp. and Nostoc sp. cultivated on agar plates to evaluate their physiological activity under a variety of temperature and irradiance treatments. The species showed temperature- and radiation-dependent changes in chlorophyll fluorescence parameters derived from slow Kautsky kinetics and quenching analysis (Fv/Fm, Quantum Yield, NPQ). We concluded that the isolated cyanobacterial species showed different sensitivity of their photosynthesis to temperature and irradiance. The results present activity limits of cyanobacterial component of the Antarctic BSCs.

Dust particles on the glacier surface melts into the ice and forms nutrient rich melt water holes called cryoconite holes that provide refuge for diverse and active microbes. We show here that cryoconite holes from Antarctica and a Himalayan glacier (Sutri Dhaka) harbour genes responsible for carbon fixation (Betaproteobacteria, Basidiomycota), nitrogen fixation (Actinobacteria, Betaproteobacteria), ammonia oxidation (Betaproteobacteria, Basidiomycota), nitrate reduction (Actinobacteria, Alphaproteobacteria, Betaproteobacteria), denitrification (Alphaproteobacteria, Actinobacteria, Betaproteobacteria, Basidiomycota), dissimilatory nitrate reduction (Actinobacteria, Betaproteobacteria) and anaerobic ammonium oxidation (Actinobacteria), indicating that they have good potential for cycling C and N in these ecosystems. Microcosm experiments show that resident microbes are able to degrade carboxylic acids, such as lactate, acetate, formate, propionate and oxalate found within the cryoconite hole environment. In addition, microbial communities are also capable of metabolizing a diverse array of compounds, such as, proteins, lipids, carbohydrates, cellulose and lignin that are documented to be present within cryoconite holes, thereby influencing the chemistry of these environments. It is proposed that, in the event of glacier melting, these microbes can act as important colonizers that can influence biogeochemical processes in downstream ecosystems.
Are High-alpine Microbial Communities Able to Deal with Temperature Extremes?

Petra Lulakova¹ (petrica@centrum.cz), Carla Perez-Mon², Joel Ruethi², Beat Frey²
¹University of South Bohemia, Faculty of Science, Ceske Budejovice, Czech Republic, ²Swiss Federal Research Institute WSL, Birmensdorf, Switzerland

The response of microbial communities to the predicted rising temperatures in the alpine regions may be an important part of the ecosystem ability to deal with climate change. Soil microbial diversity, community structure and activity might be significantly affected by higher temperatures which influence the ecosystem functioning of high-alpine soils. To evaluate the potential of the permafrost microbiome to adapt to temperature extremes we set up an incubation experiment with permafrost soils (collected at a soil depth of 160 cm) and an active soil layer from a high-alpine mountain ridge of Schafberg, Switzerland. Soils were incubated to increasing temperatures (4 - 40 °C) for two weeks as a pre-treatment before exposing them to a heat shock of 40 °C for 5 days. All the samples were then evaluated for the changes of the bacterial and fungal communities and their functional abilities by measuring respiration, enzyme activities and carbon utilization patterns. Results revealed a different ability of the microbial communities to withstand and regenerate after the heat shock according to the origin of the soils and also partly due to the pre-treatment. The adaptability of the permafrost microbiome to the temperature rise and the heat shock will be discussed.
Polar ocean plankton communities are extremely important for global biogeochemical processes. However, recent efforts to survey marine eukaryote diversity focussed on tropical and temperate plankton communities, with limited sampling of the polar oceans. We sequenced 18S ribosomal DNA to characterise eukaryotic diversity in 284 size-fractionated plankton samples collected across 52 sites south of the Kerguelen plateau, one of the most productive regions in the Indian Sector of the Southern Ocean.

We show that a single parasitic Marine Alveolate group I (MALV I) operational taxonomic unit comprised more than half the reads in samples from several locations near the sea ice edge. Although an identical MALV 18S sequence was previously found to be associated with a Northern Hemisphere radiolarian, we find the sea-ice associated cercozoan, *Cryothecomonas* sp., is the likely host in the Southern Ocean samples. Parasitic MALV are also known to be abundant in marine and sea ice ecosystems in the Arctic and Western Antarctic Peninsula. Parasites divert energy and nutrients from the phytoplankton - krill - marine predator food chain to the microbial loop but are rarely included in marine ecosystem models. Our findings indicate MALV parasites have the potential to influence the abundance of a key sea-ice organism, influencing biological and geochemical processes in polar marine and sea ice ecosystems.
Freshwater terrestrial water ponds and small basins are important aquatic habitats for autotrophs in deglaciated Antarctic areas. Since 2011, we have been monitoring physical properties (temperature regimes, continuous data, supplementary conductivity, pH, photosynthetic active radiation-PAR, dissolved oxygen concentration-DOC courses during summer period) in two selected water ponds in the northern part of James Ross Island. The two ponds differ in size, morphology, and origin. First one is located in a depression of sedimentary rock (10 m a.s.l.), the other one on stony glacier surface (220 m a.s.l.). In both of them, *Nostoc* and *Leptolyngbya* are dominant autotroph species in microbiological mats forming a bottom cover. The ponds freeze during winter, temperature decreases to -15 to -20°C. In austral summer, a long ice-free period (5-10 weeks) occurs. Daily courses of DOC recorded in summer showed frequent supersaturation. However, a strong variability in DOC was found. DOC changes within a day and season were dependent on PAR, pH, and lake area to depth ratio (positive correlations). Water temperature and electrical conductivity were negatively correlated. These parameters, supplemented with chlorophyll concentration, serve as inputs for a multiple regression model. An analysis of the dynamics of the ecosystem and prediction of autotrophs activity are done using the model.

**Acknowledgements:** The study was supported by the CzechPolar infrastructure and the ECOPOLARIS project.
Lake Cadagno, an alpine meromictic lake originated around 10,000 years ago. It has a persistent oxic and anoxic layers separated by a bacterial biofilm and are known to inhabit ancestral microorganisms. Although photosynthetic and heterotrophic bacteria have been studied extensively, however, nothing is known about viruses in this Lake. To fulfill this gap, we have collected samples at different depths of the lake to isolate 'Bacteriophages' (viruses that infect bacteria) and to investigate their relations with host microbial communities. Virus/host abundance was investigated using Flow Cytometry and metagenomics analyses were employed to characterize the viral diversity in the lake, which may probe the presence of 'ancient' virus-host models. Also, results will be put in relationship with chemical gradients as well as bacterial and phytoplankton biodiversity and productivity. Our study is the first step towards an exploration of the role of viruses in the ecological functioning of Lake Cadagno.
Heat Shock Response of Glacier Microbiome

Glacier ice occupies a significant area of the planet and is currently experiencing one of the most rapid and severe melting rate, associated with possible changes of microbiome composition due to exposure to temperature variations when passing to adjacent soil. Our study investigated the thermal response of total and active ice-contained microbiome from a Svalbard glacier ice core and using a psychrophilic model bacterium, in order to identify an enzymatic biomarker. Glacier melted ice samples were submitted to a 7-day heat/freeze cycling experiment, and the total DNA and RNA was extracted and analyzed. Changes in the total and active microbiome composition after heat shock treatment are currently investigated by Shotgun metagenomics and metatranscriptomics. Quantitation by qPCR of the aspartate transcarbamoylase (ATC) expression, a key enzyme of pyrimidine nucleotides biosynthesis, revealed associated changes in the microbiome DNA synthesis. Thermal response of pyrimidine gene expression was investigated in a parallel bacterial model experiment using psychrophilic Glaciibacter superstes. Analysis of the ATCase gene expression pattern in the psychrophilic bacterium and ice microbial community is currently carried out in order to propose an enzymatic biomarker for ice microbiome response to temperature variations when changing habitats due to glaciers melting.

Microbes from extreme environments represent untapped sources of novel, bioactive metabolites with unique molecular frameworks, as they have evolved genes, many of which are cryptic or silent under standard fermentation conditions, required for survival in unusual environments. Only recently have microbiological samples been obtained from cold, dark isolated ecosystems in Antarctica. Blood Falls, one of the better-characterized subglacial environments in Antarctica, is a cold (-7 °C), iron-rich (~3.4 mM) subglacial brine (8% NaCl) that leaks out from below the Taylor Glacier. A moderately halophilic, heterotrophic psychrophile was recently isolated from the Blood Falls brine that clusters within the *Marinobacter* genus. Bioinformatic analysis of this strain's genome indicated the presence of at least four gene clusters involved in secondary metabolism with low sequence identity (~30%) to other known genes in GenBank. These gene clusters are most similar to those that produce aryl polyenes and terpenes, which function as pigments/antioxidants, protecting bacteria from reactive oxygen species. To identify uncharacterized, cryptic secondary metabolites with potential bioactivity, we used culture-dependent and -independent methods to induce the expression of cryptic biosynthetic gene clusters. Our data provide insight into the *Marinobacter* metabolome and its role in cold environments, such as those found in Antarctica.
The biological productivity of McMurdo Dry Valley ecosystems is composed primarily of microbial processes, which are limited by the availability of liquid water and extreme weather conditions. Climate models predict an increase in temperature for the next decade, which will likely impact the hydrology and consequently the biodiversity and functionality of the ecosystem. Facing a regime of change, it is critical to understand to what extent microbial communities are able to retain their functions, thereby maintaining ecosystem services and the status quo. Using a “space-for-time” approach to approximate resilience, four wetness transects were sampled from the edges of Lake Brownworth and Lake Vanda, Wright Valley. We hypothesize that systems without historical hydrological changes (Lake Brownworth) harbor microbiomes well adapted to the permanently wet/dry conditions and that these microbiomes are structurally and functionally different to systems subjected to annual hydrological changes (Lake Vanda) where the microbiomes are more functionally heterogeneous and potentially more resilient to hydrological changes. Using a combination of metagenomics and metatranscriptomics, the levels of functional redundancy present in communities from both stable and dynamic systems will be examined, and the capacity of current microbiomes to engage with future environmental change will be discussed. Work of this type will help us to understand the fragility and resilience of polar ecosystems.
Melt-water streams in McMurdo Dry Valleys (MDV) harbor a diverse assemblage of mat-forming cyanobacteria that play a key role in nitrogen cycling due to their diazatrophic activity. Prior research showed that heterotrophic diazatrophs may also contribute over 50% of nitrogen fixation in some mats. Our goals were to survey heterotrophic diazatrophs across the MDV to identify factors that regulate distributions. We collected samples from wetted, adjacent hyporheic, and dry regions at 23 sites, with and without visible mat. 16S rRNA genes were sequenced from 69 samples and \textit{nifH} was sequenced from samples with positive amplification. Results show that the heterotrophic and cyanobacteria community structures were significantly correlated. Assemblages from several mat-free sites were more closely correlated with those from dry sites, regardless of the presence of water, suggesting that mats play an important role in structuring bacterial communities. \textit{NifH} sequence analysis also showed that diazatrophs were highly and significantly correlated to the bacterial community as a whole. In addition, \textit{nifH} genes were not amplified from samples collected in mat-free areas, suggesting a metabolic coupling between phototrophic and heterotrophic diazatrophs. This work contributes to our understanding of key drivers of bacteria community structure in polar deserts and informs future efforts to investigate the contribution of nitrogen fixation to community diversity and resilience in the MDV.
As permafrost thaws across the Arctic, more of the organic carbon stored in permafrost soils is becoming available for transport to aquatic ecosystems. The response of arctic stream microbial communities to the effects of permafrost thaw will help determine how much added carbon is taken up or released, but this is a poorly characterized part of the Arctic carbon cycle. Deeper water movement through the thawing soil profile and thermokarst formation will increase terrestrial resource subsidies to aquatic microbial communities, and it may also alter the inoculation of soil microbes to streams, impacting community composition and function. To assess the effects of thaw depth on stream microbial communities, we sampled streams during the early and late growing season throughout three watersheds on Alaska’s North Slope: the Kuparuk, a tundra stream; the Oksrukuyik, a lake-influenced tundra stream; and Trevor Creek, a mountain stream. To investigate how nutrient additions alter community composition and rates of dissolved organic matter decomposition, we also incubated a subset of streamwater samples with combinations of N, P, and C amendments. We characterized in-stream and incubation bacterial communities via a target metagenomic approach. We hypothesized that increased thaw depth will create greater soil-stream community connectivity, with diversity decreasing downstream, and that concurrent carbon and nutrient additions will most affect incubated stream communities.
Microbial Communities along Consecutively Connected Habitats in East Antarctica

Klemens Weisleitner¹ (klemens.weisleitner@uibk.ac.at), Alexandra Perras², Christine Moissl-Eichinger², Dale T. Andersen³, Birgit Sattler¹
¹University of Innsbruck, Institute of Ecology, Innsbruck, Austria, ²Medical University of Graz, Department of Internal Medicine, Graz, Austria, ³Carl Sagan Center, SETI Institute, Mountain View, United States

The ultraoligotrophic Lake Untersee is the largest and deepest surface lake of Central Queen Maud Land in East Antarctica. It is located in a cirque-like valley which is dammed by the Anuchin glacier at its northern tip which provides the only known water source for the lake. Water-loss only occurs through ablation and sublimation of the perennially lake ice cover. Lake Untersee pelagic and benthic microbial communities are relatively well studied. However, the Anuchin glacier is still unexplored even though its potential role as major contributor of nutrients and biota to the lake ecosystem.

Based on 16s rRNA gene targeted PCR and subsequent Illumina tagged sequencing, we show that aerial deposition of biota on the glacier leads to distinct microbial communities in glacier ice and cryoconite holes. These communities ultimately become part of the lake Untersee ecosystem. Significant differences in microbial diversity were also recorded between supraglacial habitats and the lake ice cover, suggesting a shift in glacier microbial communities once they melt into the lake. The highest relative abundant phyla in lake, glacier and aerosol samples belong to Actinobacteria, Cyanobacteria, Bacteriodetes, Firmicutes, and Proteobacteria.

The glacier can be considered as a vector for the colonization of Lake Untersee and hence shapes the lake Untersee ecosystem. The microbial input from deeper depths of the glacier to the lake is unknown and requires further investigation.
Due to organic matter accumulation and anaerobic microbial processes, wetland ecosystems are known to contribute greatly to global warming through methane emissions. Polar wetlands are more strongly affected by climate change, resulting in expected modifications of microbial community structure and methanogenesis activity rate, leading to a positive feedback on regional methane budget and global warming. Yet, the outcome of temperature increase on methanogenic communities and processes in Sub-Antarctic wetlands in comparison with their Sub-Arctic counterparts has not been investigated to date.

In this study, the screening of methane production rate in lake sediments and peatlands from 10 Sub-Antarctic ecosystems (Patagonia to Cape Horn, Chile) and 15 (sub)Arctic ecosystems (Denali to Toolik, AK, US) collected in austral summer, highlighted the heterogeneity of methanogenic activities between the considered ecosystems, with regional specificities and higher potential in lake sediments. In controlled microcosm incubations, methane production pathway was mainly acetoclastic and increased temperature (5-10-15-20°C) resulted in enhanced methane production rate. The most temperature-sensitive samples were identified by comparison of modeled energy activation. The quantification of functional genes involved in methanogenesis in in-situ and microcosm samples and microbial diversity evaluated by sequencing will be investigated.
What Determines the Microbial Succession on the Glacier Foreland?

Binu Tripathi¹, Hye-Ryeon Gyeong¹, Mincheol Kim¹, Ji Young Jung¹, Yoo Kyung Lee¹ (yklee@kopri.re.kr)
¹Korea Polar Research Institute, Incheon, Korea, Republic of

Glacier forelands are ideal places to study the ecological succession but microbial succession is relatively poorly understood. We conducted a meta-analysis of bacterial communities using six different successional soils datasets, scattered across different regions, with different pH conditions in early and late successional soils. We found that extreme acidic or alkaline pH conditions lead to the assembly of phylogenetically more clustered bacterial communities through deterministic processes, whereas pH conditions close to neutral lead to phylogenetically less clustered bacterial communities with more stochasticity. We suggest that the influence of pH, rather than successional age, is the main driving force in producing trends in the phylogenetic assembly of bacteria. We also investigated the microbial succession along the chronosequences in front of two different glaciers (Austre Lovénbreen & Blomstrandbreen) in Svalbard. Ordination analysis revealed that all microbial communities shifted from early to the later successional stage following deglaciation in both glacier forelands. The main factor of the bacterial succession was soil pH, whereas fungal communities differed more by vegetation type and coverage. The successional age since glacier retreat is not a single driver of community convergence at the later stage of succession, but alternate factors such as geochemistry and geomorphology could also lead to distinct convergence pattern of microbial communities.
Functiona Metagenomic of Microbial Communities Associated to Antarctic Sponges

Nicole Trefault¹ (nicole.trefault@umayor.cl), Mario Moreno-Pino¹, Mariela Guajardo¹
¹Universidad Mayor, GEMA Center for Genomics, Ecology and Environment, Santiago, Chile

Marine sponges harbor diverse and abundant microbial communities, that perform fundamental processes related to biogeochemical cycling and nutritional coupling with the host, forming what is called the sponge holobiont. Most studies about sponge holobionts have focused on the bacterial component and come from temperate and tropical environments, and functional roles of sponge symbionts from Polar Regions remain largely unknown. Here, we use a combination of metagenomic and culture-based approaches, with the aim to explore the functional potential from microbial communities associated to Antarctic sponges. Our analyses indicate that Antarctic sponge holobionts display a particular taxonomic signature, with the absence of Cyanobacteria and Poribacteria, two common phyla in temperate and tropical sponges. Functional potential analysis shows genes involved in nitrogen, carbon, sulfur and phosphorus cycles. Protein-coding genes related to vitamin synthesis and host-microbe interactions are enriched inside the sponges compared to planktonic communities. Genomic features of bacterial strains isolated from Antarctic sponges showed several genomic signatures related to symbiotic lifestyle. To our best knowledge, this work is the first insight into the functional potential of sponge-associated microbial communities from the Antarctic environment and reveals that fundamental biogeochemical, defense and nutritional processes are transversal across sponge-holobionts.
Impact of Increased Snow Melt on the Development of Cryospheric Communities

Birgit Sattler¹ (birgit.sattler@uibk.ac.at), Klemens Weisleitner¹, James Bradley², Arwyn Edwards³
¹University of Innsbruck, Institute of Ecology, Austrian Polar Research Institute, Innsbruck, Austria, ²University of Southern California, Department of Earth Sciences, Los Angeles, United States, ³Aberystwyth University, Centre for Glaciology, Aberystwyth, United Kingdom

The vast snow covers of the cryosphere are covering up 35% of the Earth’s surface and exert substantial impact on the biosphere. Hence, it has been addressed merely as a physical component that, due to hostile conditions has long been regarded as devoid of life. However, snow and ice microbial communities have gained increasing interest due to their potential to contribute to the labile carbon which is available after snow melt. Nowadays, the general picture of snow merely being a repository for wind-transported and snow-trapped microorganisms has changed dramatically even to breeding chambers for microbial life once liquid water is available. Here we show a study from Svalbard, where the impact of the snow pack has been investigated over glacier ice, lake ice and soil, respectively, during the period of snow melt. All three habitats show distinct responses to the input of ions, biological particles and nutrients which causes an enhancing effect for microbial productivity during these few weeks. With ongoing increase in temperature which implies more liquid water, snow melt is a crucial process for the adjacent habitats in terms of increased productivity, activity and metabolism. Hence, with global warming the periods of dormancy are reduced leading to higher carbon turnover rates over large areas potentially altering the carbon budget of high altitude and high latitude regions.
Glacier Monitoring in Bhagirathi River Basin using Remote Sensing

Har Amrit Singh Sandhu1 (haramritsingh.pec@gmail.com), H.S Gusain2, Manoj Kumar Arora3
1PEC University of Technology, Civil Engineering Department, Chandigarh, India, 2Snow Avalanche and Study Establishment, Chandigarh, India, 3PEC University of Technology, Chandigarh, India

The Bhagirathi river basin is an important basin of central Himalaya and is a source of the river Ganges, which feed water to most of the northern Indian states. Here, glaciers of this basin are monitored using remote sensing for more than a decade and status of the glaciers are presented. The area has been divided into six sub-basins i.e. Bhagirathi, Bhilangna, Pilang, Jahnvi, Jalandhri and Kaldi. The glaciers were selected from all the sub-basins with different area, altitude, orientation etc. to make representation of the basin. In the present study, Landsat satellite images from the year 2000 to 2015 were used to monitor 20 glaciers. The snout elevation varies approx. from 3800m m.s.l to 5200m m.s.l. ASTER GDEM V2 has been used for extraction of glacier terrain features e.g. elevation, slope, area, orientation etc. It is observed that Bhagirathi sub-basin has maximum glacierised area about 35% followed by Jalandhri, Jahnvi, Bhilangna, and Pilang with 13%, 9%, 4.5% and 3.2% respectively. Kaldi is the only sub-basin having no glacier. It is also observed that 4 glaciers has more than 70% area towards North, while 10 glaciers has area in the range of 50%-70% towards North, while 06 glaciers shows having area less than 50% North. 17 glaciers have shown retreat, while 3 glaciers have shown advancement during last 15 years. The recession has been observed from 62m to 913m, while three glaciers have shown advancement of 3m to 239m.
An Overview of Deep Ice Core Drilling Project at Dome A in Recent Two Seasons

Zhengyi Hu¹ (hu Zhengyi@pric.org.cn), Guitao Shi¹, Yuansheng Li¹
¹Polar Research Institute of China, Shanghai, China

Recently, the news that 2.7-million-year-old ice core drilled in Antarctic had been detected, which causes the human attention. Although the ice age exceeds 1.9 million years than the previous record-holder, the record is not continuous and difficult to explain climate change. Dome A is the place, where more than one million years of continuous ice most likely to be found. Therefore the process of deep ice core drilling at Dome A received a high degree of attention in many countries.

During the Antarctic field season of 2015/2016 and 2016/2017, 9 scientific research team members from 4 different organizations had been dispatched to Antarctic by Polar Research Institute of China (PRIC), to perform “Deep Ice Core Drilling Project at Dome A”, near to which China’s Antarctic Kunlun Station sits. After two expedition seasons, a total of 117+93 drilling roundtrip was implemented, 6400+3600 liters drilling fluid was injected, 18+12 drums ice chips was collected within 12 days. What’s more, 353.3+145.86 meters ice core has been extracted, 351.5+146.21 meters borehole has been penetrated by these nine drill crews with the deep ice coring drill. So far the total depth of the bore hole has been drilled to 800.93 meters, which is the first time to drill through shallow ice layer and this depth is also the deepest glacier drilling depth in China.
Subglacial Conditions of Antarctic Ice Sheet between Zhongshan Station to Dome A

Xueyuan Tang\textsuperscript{1} (tangxueyuan@pric.org.cn), Bo Sun\textsuperscript{1}
\textsuperscript{1}Polar Research Institute of China, Shanghai, China

A radar dataset was collected by using a ground-based radar system, along a 1083 km traverse line from Zhongshan station to DT401, in 2004/2005. The internal layering structure and subglacial conditions were revealed along the radar profile. The continuous internal layers, disturbed layers and Echo Free Zones (EFZ) along the profile were identified and classified, and its spatial distribution was presented. Basing on the recent surface ice velocity, we found that the internal layers at depth 200-300 m in the upper ice sheet are continuous and smooth, and nearly parallel to the ice surface topography. The thick band of the continuous layers changes little with increasing latitude. Below the depth of 300 m, the geometric structure of the internal layers and the vertical width of the EFZ band were influenced by the surface ice velocity and the bed topography. The relatively high disturbance, discontinuity of the layers and the larger width of the EFZ band correspond directly to higher surface ice velocity and sharper bed topography. In particular, two areas are identified as that, Zone 1: at km 60-70, there exists a concave zone with a 200 m depth of surface depression; Zone 2: at km 650-950, the Lambert Glacier Rift at the Gamburtsev Mountains with faster ice flow, where the radar system failed to obtain the echo signal from its bed, the revealed internal layers are disturbed or broken, and the maximal vertical width of the EFZ band is likely more than 2000 m.
Reconstruction of the past dynamics of the Antarctic ice sheets by studying records from their margin is essential to evaluate their stability and their contribution to future sea level rise. Recently, the first direct evidence for a paleo-subglacial lake on the Antarctic continental shelf was reported from a sediment core from a small bedrock basin in Pine Island Bay (PIB), West Antarctica. Here we report further evidence for this paleo-subglacial lake based on down-core changes in Be-10 concentrations in the sediments. Very low Be-10 concentration in the lower part of the core indicate limited input of meteoric Be-10, suggesting deposition of the corresponding sediments in isolation from the open ocean. The Be-10 concentration shows a drop within a sand, silt and mud interval in the middle part of the core that was interpreted to result from deposition during the transition from the subglacial lake to a sub-ice shelf cavern caused by grounding line retreat in PIB around 11 kyrs B.P.. The Be-10 concentration increases significantly toward the top of the core, indicating the establishment of an open marine setting later during the Holocene. In addition, we report new Be-10 data from marine sediment cores in other parts of PIB. Our results demonstrate that Be-10 concentration changes in marine sediments from glaciated margins are a valuable recorder of ice sheet - ice shelf transitions.
The ability to include ocean cavities below ice shelves is a new feature of the U.S. Department of Energy’s Energy Exascale Earth System Model (E3SM). This capability is critical for projecting Antarctica’s potential future contributions to global sea level, which is one of E3SM’s primary science drivers. In part I of this talk we describe the model configuration and tuning, while part II describes analysis and comparison to observations. E3SM is a coupled climate model with variable-resolution components, which allows global simulations to include enhanced-resolution regions below ice shelves. The ocean, sea ice, and land ice components use the Model for Prediction Across Scales (MPAS) framework for unstructured horizontal meshes based on Voronoi Tessellations.

In order to gain confidence in our implementation of ice shelf cavities, we have performed a series of standard, idealized test cases as well as comparisons of global simulations with and without ice shelf cavities. Validation uses observed sub-marine melt rates and other relevant oceanographic features, and the identification and minimization of coupled model biases. Here we present the results from a large number of global simulations at modest resolution (30 to 60 km grid cells), most of which include static ice-shelf cavities. Based on these simulations, we attain a tuned moderate resolution state that we use as a control configuration for a smaller number of sensitivity experiments at higher resolution.
A complex crevasse field forms offshore of Minna Bluff, along the western coast of the Ross Ice Shelf. Tracking the crevasses downstream is equivalent to tracking propagation history in time and thus provides a unique opportunity to investigate the evolution of secondary features around a system that is analogous to strike-slip faults in Earth’s crust. A primary population of mode II (shear) fractures propagate into the shelf and arrest at the edge of a relict flow boundary. A subset of these open into through-cutting rifts and continue to propagate as mode I (opening) fractures until they also arrest at a relict flow boundary. We characterise relationships between the primary rifts and associated secondary crevasses, and compare these to other strike-slip systems. Secondary crevasses form on both the extensional and compressional sides of the primary rifts but unlike elsewhere, the largest splays form in the compressional regime. Also unlike other settings, splay faulting appears to be initiated mainly by a change in fracture toughness of the ice rather than misalignment of the propagating tip with respect to far-field principal stresses. Correct understanding of these features will provide important insight into the role of ice properties in mediating crevasse and rift formation.
Early Warnings of Further Disintegration of Pine Island Glacier’s Ice Shelves

Stef Lhermitte (s.lhermitte@tudelft.nl), Christopher Shuman, Bert Wouters

1Delft University of Technology, Department of Geoscience & Remote Sensing, Delft, Netherlands, 2UMBC Joint Center for Earth Systems Technology, Greenbelt, United States, 3Utrecht University, Institute for Marine and Atmospheric Research (IMAU), Utrecht, Netherlands

Pine Island Glacier (PIG) is among the fastest changing outlet glaciers of West Antarctica, with strong changes in acceleration, retreat, and thinning in recent decades. If these changes continue, PIG is expected to have an even larger impact on accelerated future retreat and contribute to increasing mass losses from West Antarctica. Therefore, understanding evolving PIG behavior is crucial for improved future sea level rise estimations.

In this study we highlight some early warning signs of further weakening of PIG’s floating ice tongue and adjacent ice shelves by combining multi-source satellite data (optical, altimeter and SAR radar) and analysing derived acceleration, retreat, and thinning time series.

The early warnings of further PIG disintegration include changes in calving patterns and rifting dynamics. For example, over the last decade calving frequency has increased and the calved icebergs have disintegrated more rapidly as a result of changes in the rifting patterns likely caused by warm waters in Pine Island Bay. The rifting patterns have shifted from rifting in the shear zone near the northern ice shelf to internal rifting once this zone retreated. Satellite imagery since 2016 shows that a new rift zone is developing in the southern shear zone which may be related to changes in glacier velocity. This rifting may be part of a positive feedback loop which could result in a further decoupling from the southern ice shelf and which may initiate further disintegration.
Pine Island Glacier (PIG) is one of the fastest changing ice streams of the West Antarctic Ice Sheet. Its ice shelf underwent major calving events throughout recent years. The main factor for the considerable mass loss of PIG is sub-ice shelf melting caused by the advection of warm deep water into Pine Island Bay on the shelf of the southeastern Amundsen Sea Embayment (ASE). Unique ice conditions during expedition PS104 with RV "Polarstern" to the ASE in February-March 2017 allowed to recover a 7.59 m-gravity core in an area that had been covered by the PIG ice shelf until 2015. The sediment core PS104_008-2 was taken at a water depth of 698 m near the eastern margin of the ice shelf. The new sedimentological data from the core will provide insights into sub-ice shelf environmental conditions and the Holocene history of meltwater plume deposition and oceanic ice-shelf melting. We will present results of our new multi-proxy study, including down-core lithological changes, grain size distribution and excess 210Pb data. Occasional occurrence of calcareous benthic foraminifera shells in the lower part of the core will allow the application of radiocarbon dating. Coupled with the excess 210Pb data, the AMS 14C ages will provide constraints on sub-ice shelf sediment accumulation rates and the discharge rates of subglacial meltwater plumes.
The Larsen C Ice Shelf is the largest ice shelf on the Antarctic Peninsula. Radar and satellite data show that the ice shelf has been thinning from above and below which has been driven by a combination of decreased snowfall/warmer atmospheric temperatures together with basal melting/ice flow divergence, respectively. Continued thinning and retreat of the ice shelf front could push the ice shelf beyond a critical threshold, leading to rapid retreat and this subsequent discharge of continental ice. Ice shelves, however, can respond over a range of timescales from decades to millennia so it is critical to disentangle short-term variability from long-term trends. Collapse of Larsen B Ice Shelf in 2002 for example, was at least partly related to ocean-driven thinning over many thousands of years (Domack et al., 2005). This highlighted the need to understand the long-term history of ice shelves. Here we present new insight into the Holocene (past 11,500 years) history of Larsen C Ice Shelf based on the analyses of sediment cores recovered from beneath the ice shelf. This is combined with new dating constraints on cores recovered from the continental shelf, seaward of the current calving front, to reconstruct the timing of grounding line retreat and subsequent development of an ocean cavity. We conclude by placing our findings in the context of modern ice shelf retreat.
Tidal Grounding Line Migration at the Darwin Glacier

Oliver J. Marsh\textsuperscript{1} (oliver.marsh@canterbury.ac.nz), Dana Floricioiu\textsuperscript{2}, Christian T. Wild\textsuperscript{1}

\textsuperscript{1}University of Canterbury, Gateway Antarctica, Christchurch, New Zealand, \textsuperscript{2}German Aerospace Center (DLR), Wessling, Germany

The Darwin Glacier is a small outlet glacier draining the East Antarctic Ice Sheet through the Transantarctic Mountains. Its motion is affected by ocean tides yet largely shielded from climate-driven variability, allowing observations of short-term grounding line (GL) behaviour without the added complexity of contemporary mass-imbalance. We conducted a detailed study of the glacier grounding zone in the 16/17 field season, mapping surface and internal flexure, GL migration, sub-daily velocity fluctuation and ice thickness. This high-resolution data is used to re-interpret a sequence of twelve TerraSAR-X interferograms. Double-difference tidal flexure fringes are heavily modified by migration of the GL across a two-kilometre `ice-plain` at the glacier’s upstream margin, despite relatively steep basal topography.

The asymmetric vertical displacement is re-interpreted by separating the four-image interferograms using flexural modelling with a migrating GL and homogeneous rheology. In the flexure zone, a neutral bending layer is found in the upper third of the ice column suggesting stiffer or cooler ice near the surface. We show that GL migration is proportional to the bed slope in the migration zone, but that it does not equal the rate expected from a simple flotation criterion. This simultaneous analysis of multiple interferograms reveals new information on GL and ice properties that can help predict future GL retreat associated with glacier thinning or sea level rise.
Mass loss of ice shelf is of great significance to a better understanding of the ice sheet dynamics and a more precise prediction of global sea levels. However, the melting processes and ocean currents beneath the ice shelf remain poorly understood. The hot water drill, a highly efficient drill technique, provides an opportunity to investigate the physical and chemical processes beneath the ice shelf. With the financial support from the Ministry of Science and Technology of China, a hot water drill system has been successfully developed. Drilling test results show that the average drilling speed is >30 m h⁻¹, and the diameter of the obtained borehole is >35 cm. The length of the main hose is 2200 m. In the following five years (2018-2023), the hot water drill will be employed on Amery Ice Shelf to penetrate the ice at 9 sites with thickness varying from ~600 m to 1800 m (near the grounding line). Through the borehole, seawater and sediment beneath the ice shelf will be sampled. The ice core will be recovered from three layers of the ice shelf (i.e., the upper, middle and lower layers). In addition, CTD and ADCP will be installed beneath the ice shelf. Besides, the automatic weather station, surface mass balance observation system and the GPS will be set up near the drilling site. The data logging to a local disk will be performed, and the disk will be replaced annually.
Sea Ice Loss and Ocean Swell as a Trigger for Antarctic Ice Shelf Disintegration

Rob Massom¹ (r.massom@utas.edu.au), Ted Scambos², Luke Bennetts³, Phillip Reid⁴, Vernon Squire⁵, Sharon Stammerjohn⁶

¹Australian Antarctic Division and ACE CRC, Hobart, Australia, ²University of Colorado Boulder, National Snow and Ice Data Center, Boulder, United States, ³University of Adelaide, School of Mathematical Sciences, Adelaide, Australia, ⁴Australian Bureau of Meteorology, Hobart, Australia, ⁵University of Otago, Dunedin, New Zealand, ⁶University of Colorado Boulder, INSTAAR, Boulder, United States

Understanding the causes of catastrophic disintegration of ice shelves on the Antarctic Peninsula over the past few decades is crucial to: i) the improved representation of complex ice sheet-ocean-atmosphere interaction processes in Earth system models; ii) determining the impact on sea level rise; and iii) assessing the vulnerability of remaining shelves to environmental change. While progress has been made towards understanding melt-related and glaciological processes that precondition and weaken ice shelves, the mechanisms responsible for triggering their disintegration remain largely unknown. In this work, we combine satellite observations, wave hindcast data from WAVEWATCH III and ice shelf-sea ice-wave modeling to show possible linkages between regional decrease in sea ice coverage (both pack and fast ice), resultant enhanced impingement of ocean swells, and the disintegration events of the Larsen A and B and Wilkins ice shelves since 1995. In so doing, we highlight the potential role of regional sea ice loss in both i) contributing to preconditioning the shelves for collapse; and ii) determining the nature and timing of eventual disintegration of shelves weakened by multiple factors. The new results underline the need to consider sea ice (change) as a factor affecting ice-shelf stability, depending on the ice shelf.
Chinese Dome A Deep Ice Core Project: The Main Progress and Perspectives

Yuansheng Li1 (liyuansheng@pric.org.cn), Guitao Shi1, Chunlei An1, Zhengyi Hu1, Nan Zhang2, Xiaopeng Fan2, Pavel Talalay2
1Polar Research Institute of China, Shanghai, China, 2Polar Research Center, Jilin University, Changchun, China

Dome A deep ice core project was started in 2009-2010, when the main drill trench was constructed. In 2010-2011 season, the drilling slot construction was finished, then a 121 m deep pilot hole was drilled in 2011-2012. In 2012-2013 season, the deep ice core drill, i.e., the modified version of Japanese deep electromechanical drill, was installed. After surface and borehole testing the drilling fluid (n-butyl acetate) was dumped into the hole, and three runs were done from the depth of 112.3 m to 122.75 m with average core length of 3.66 m. During the season 2014-2015, the deep ice core drilling was continued, reached the depth of 304 m. In the season of 2015-2016, 354 m ice core was obtained, with the borehole depth extended to 654 m. Then, another 146 m ice core was recovered in 2016-2017, and the depth reached 801 m. The main scientific objectives of this project were to extend available climate records from ice cores, to investigate the main mechanisms of climate change, and to investigate the subglacial processes. In order to achieve the objectives, the deep ice core, with the diameter of 95 mm, will be divided into 6 parts, for the measurements of physical properties, gas concentrations and isotopes, major ions and nitrate isotopes, water isotopic compositions and biological signature. In general, an international cooperation on analysis of the deep ice core is essential, and the groups abroad are welcome to join and contribute to Dome A deep ice core project.
Drilling into marine sediments and their subsequent basement provides sound constraints on the geological history of a region. Although marine sediments have been successfully cored globally, the most valuable information about the paleo ice sheet evolution of East Antarctica is hidden in the inaccessible sub ice shelf deposits in our research area. Drilling of the presumably Cretaceous-Cenozoic sediments and the underlying basaltic basement is planned at the Ekstroem Ice Shelf. Thus, in the austral summer season 2016/17 an over-ice seismic presite survey was conducted to gain information on the sediment and basement structures. In this context, a precise depth estimate of the target horizons/basement is of critical importance for selecting the best drill sites. To achieve this, we installed seismic recording stations along several seismic reflection lines to record the refracted seismic energy at long offsets. In total, we setup 14 stations along 8 profiles. The number of stations per profile varied between 1 and 5 with a spacing of 7 to 13 km. Each station was equipped with a Reftek 130 recorder and 9 geophone chains consisting of six 4 Hz vertical components. The source was a 9-ton EnviroVibe vibrator with a maximum pressure of 57 kPa emitting a 10 s linear sweep within a frequency range of 10 to 220 Hz. The shotpoint distance was 120m. Here we present technical details and challenges of the experiment, the data processing and the first preliminary results.
This research examines the interactions between the Totten Glacier and the Southern Ocean during the Late Quaternary using a 350kyr sediment archive on the Sabrina Coast continental margin. Stable isotope and trace metal analyses were conducted on planktonic foraminifera *Neogloboquadrina pachyderma* (s) to reconstruct hydrographic changes in this region. Lithological and assemblage observations, sediment physical properties and ice rafted debris mass accumulation rates were combined to develop a conceptual model of climate induced depositional changes.

The Sabrina Coast record exhibits a muted oxygen isotope (d18O) signal across the MIS 5/6 transition where the observed isotopic shift is ~20% of the expected 1.0 per mil shift from global ice volume. Mg/Ca ratios suggest that Antarctic surface waters cooled by 2.4 ± 0.8°C between the Holocene and MIS 3, which indicates that changes in d18Ocal are primarily influenced by d18Osw. Other Late Quaternary d18O records from the Antarctic Margin appear to exhibit similar trends. We discuss possible mechanisms buffering the d18Osw ice volume signal including changes in deep water upwelling and increased [CO3²⁻] concentrations under permanent sea ice. Peak ice rafted debris is associated with glacial stages and deglacial transitions. The last glacial period is punctuated by a series of IRD spikes which could indicate millennial scale variability in the Totten.
Ice flow velocity is an important parameter for estimating mass changes in glaciers. Long-time observations on the surface velocity are of great significance for assessing the relationship between Antarctic ice sheet and global climate change. Existing research on Antarctica ice velocity based on modern satellite remote sensing dated back to 1970s, the early film-based ARGON satellite photographs extended the timeline back to 1960s. This research presents a rigorous geometric processing method for estimating Antarctica ice flow velocity fields by using ARGON/Landsat satellite images. In view of various image configurations in Antarctica, two different methods are developed and implemented. The first method proposes a novel parallax decomposition technique that separates the effect of the terrain relief from the ice flow motion is proposed for the ARGON stereo image pairs. The second method deals with images with longer time baselines and ortho-rectifies the images and then calculate ice flow velocity based on the feature matching technique. The above methods for estimating ice flow velocity are applied in mapping the major glaciers of East Antarctica (Totten, Amery, Rayner, etc.) from 1960s-1980s for the first time. Comparison with recent Antarctic ice velocity products from 2000-2010 shows different change patterns in different glaciers. The initial results and a discussion of the speed change and the associated cryosphere environment are introduced.
Improving our knowledge of the variability of the Antarctic surface mass balance (SMB; i.e. the difference between the incoming and outgoing mass at the surface of the ice sheet) is crucial to reduce the uncertainties of past, present and future Antarctic contribution to sea level rise. Here, we present an evaluation of the SMB simulated by those global climate models that have a last millennium simulation available. In the first phase, we focus on the last four decades, for which we present a detailed comparison with in-situ observations, atmospheric reanalysis, and regional atmospheric climate models. The goal is to estimate the ability of the models to reproduce the spatial distribution of the SMB, its temporal (seasonal and inter-annual) variations and the potential links with standard modes of large-scale climate variability such as Southern Annular Mode.

In a second step, we analyse the SMB over the last millennium as simulated by the GCMs following the PMIP3 (Paleoclimate Modelling Intercomparison Project Phase 3) protocol and compare it to ice core records synthesised in the framework of the Antarctica2K working group. In this exercise, we focus particularly the spatial structure, the main drivers of the SMB variability and the analysis of the natural climate variability role in SMB changes.
Using Damage Mechanics to Model Calving from Tidewater Outlet Glaciers

Rémy Mercenier¹ (remy.mercenier@geo.uzh.ch), Martin P. Lüthi¹, Christoph Rohner¹, Andreas Vieli¹
¹University of Zurich, Department of Geography, Zurich, Switzerland

Many ocean terminating glaciers in the Arctic are undergoing rapid retreat, thinning and strong acceleration in flow. The calving process plays a crucial role for the dynamical mass losses and occurs when the stresses at the calving front exceed the fracture strength of ice, leading to the detachment of blocks from the glacier front. However, the understanding of the processes involved in calving as well as the capability of flow models to represent this mechanism remain limited.

We use a transient 2d finite-element flow model coupled to a damage model to model break-off at the front of tidewater glaciers. The flow model computes velocities and the resulting stresses, which are in turn used to calculate the evolution of the glacier geometry and damage. The damage variable is defined by a change of rheological properties with increasing material degradation. Elements are removed once damage reaches a critical threshold. We use observations from glaciers in the Arctic to constrain the material properties. We further assess the sensitivity of the glacier evolution to external forcings such as submarine frontal melting or surface mass balance changes.

The coupled ice flow/damage model allows for reproduction of calving front geometries typically observed for different tidewater glaciers in the Arctic. The proposed approach should be applicable to model calving on any glacier, and thus be used to analyse the evolution of tidewater glacier variations from the past to the future.
Glaciological Characteristics of Ice Rises at Nivlisen Ice Shelf East Antarctica

Katrin Lindbäck¹ (katrin.lindback@npolar.no), Kenichi Matsuoka², Geir Moholdt¹, Bhanu Pratap², Thamban Meloth²

¹Norwegian Polar Institute, Tromsø, Norway, ²National Centre for Antarctic and Ocean Research (ESSO-NCAOR), Goa, India

The coastal region of the East Antarctic Ice Sheet has numerous ice shelves and ice rises, consisting of locally grounded ice that controls ice dynamics and mass balance of the region. An Indo-Norwegian joint project, called MADICE, is investigating dynamics and evolution of the Nivlisen Ice Shelf and adjacent promontory-type ice rises by means of geophysical field surveys, satellite remote sensing, ice-flow models and ice cores. We have conducted two field seasons in 2016-17 and 2017-18. Two ice rises, Djupranen and Leningradkollen, have dome shaped summits with elevations of 325 m and 170 m above sea level, respectively. Low-frequency radar data show relatively flat subglacial beds below the summits, with subglacial elevations of 100 and 150 m below sea level, respectively. Well-developed Raymond arches indicate that the summits have been stable the last hundred years, except for one ridge where the arches have migrated landward (south) in the shallower ice. Farther south from the ice domes towards the ice sheet, the subglacial topography drops 500 m at a 2 to 3 km narrow through aligned in the east-west direction, comprising a distinct margin between smooth beds in the north (seaward) and rougher subglacial terrains in the south (landward).
Going against the Flow: Small-scale Pinning Points within the Ross Ice Shelf

Holly Still¹ (holly.still@otago.ac.nz), Christina Hulbe¹, Adam Campbell¹
¹University of Otago, School of Surveying, Dunedin, New Zealand

The flow of the Ross Ice Shelf (RIS) is limited by regions of localised grounding termed pinning points. While pinning points are common features within the RIS and are generally assumed to have a stabilising effect, the mechanics of these features have not been studied in detail. This study focuses on a collection of small pinning points (and overlying ice rumples) located downstream from the outlets of the MacAyeal and Bindschadler Ice Streams within the eastern sector of the RIS.

Here we use high spatial resolution ice velocity derived from Landsat 8 imagery and thickness inferred from satellite laser altimetry to investigate the momentum balance and mass flux in the region. Drag forces exerted by the pinning points on the surrounding ice shelf are computed using a force budget approach and are compared to the forces expected for a similar ice shelf with no pinning points. The pinning points have contrasting effects on the surrounding flow field. Upstream, compressive stresses act to resist ice flow from the MacAyeal Ice Stream, supporting thicker ice than would otherwise exist. As the ice flows over and around the pinning points, its speed decreases and mass flux declines, creating a wake of thinner ice downstream. At the ice rumple boundaries, lateral shearing creates bands of heavily crevassed ice that advect downstream, further modifying the flow field. This analysis improves understanding of how small-scale pinning points regulate the flow of the RIS.
Theresa Maud Land

Current Status and past Evolution of Blåskimen Island, Dronning Maud Land

Vikram Goel1,2 (vikram.goel@outlook.com), Joel Brown1,3, Carlos Martin4, Kenichi Matsuoka1
1Norwegian Polar Institute, Tromsø, Norway, 2National Center for Antarctic and Ocean Research, Goa, India, 3Aesir Consulting LLC, Missoula, United States, 4British Antarctic Survey, Cambridge, United Kingdom

The ice-shelf-fringed coast of Dronning Maud Land in East Antarctica contains numerous ice rises that influence the dynamics and mass balance of the region. However, only a few of these ice rises have been investigated in detail. We present glaciological settings and late Holocene evolution of Blåskimen Island, an isle-type ice rise adjacent to Fimbul Ice Shelf. This ice rise is largely dome-shaped, with a pronounced ridge extending to the southwest from its summit (410 m a.s.l.). Its bed is mostly flat and about 100 m below the current sea level. Shallow radar-detected isochrones dated with a firn core reveal that the surface mass balance is higher on the southeastern (upwind) slope than the northwestern (downwind) slope by ~37%, and this pattern has persisted for at least the past decade. The mass balance estimated using the Input-Output method show that this ice rise has thickened by 0.12-0.37 m ice equivalent per year over the past decade. To investigate longer-term evolution, we applied a thermo-mechanically-coupled Elmer/ICE model to a profile going across the summit and along flowlines on either side. Constraining the model results with present-day flow speeds and englacial stratigraphy, it is likely that the ice rise is thickening with a rate of 0.4 m i.e. per year for at least a century. Also, we found a larger-than-present north-south imbalance in the surface mass balance sustained over several centuries in the past.
Predicting the Oldest Ice Optical Signal using a Marine Dust Record

Jessica Ng¹ (jyn002@ucsd.edu), Jeffrey Severinghaus¹, Ryan Bay²
¹University of California, Scripps Institution of Oceanography, San Diego, United States, ²University of California, Physics, Berkeley, United States

The marine sediment record shows that glacial-interglacial cycles transitioned from regular ~41,000 year cycles to irregular ~100,000 year cycles approximately 1 million years ago, an event known as the Mid-Pleistocene Transition. However, the ice core record only extends 800,000 years into the past, severely limiting our understanding of this major change in the climate system and thus of fundamental climate forcings and feedbacks. A primary goal of the International Partnership in Ice Core Sciences is therefore to retrieve a 1.5 million year old continuous ice core, yet complex glacial processes, limited bedrock data, and surprisingly young basal ice in previous cores necessitate careful reconnaissance studies before extracting a full core. Ice borehole optical logging reflects ice dust content and may be used to date ice quickly and inexpensively. Here I develop a transfer function between the 800,000 year optical dust log of the EPICA Dome C ice core and a 4 million year marine dust flux record from a sediment core in the subantarctic zone of the South Atlantic, which lies along the path of dust sources to Antarctic ice. I then use the transfer function to predict the optical signal in 0.8-1.5 million year old ice from the marine dust record. In future field seasons, I will extract the optical log at potential old ice sites using the newly developed Rapid Access Ice Drill (RAID) and apply the transfer function to evaluate these sites for 1.5 million year old ice.
A Minimal Model of Tidewater Glacier Evolution

Martin Luethi\textsuperscript{1} (martin.luethi@geo.uzh.ch), Andreas Vieli\textsuperscript{1}, Remy Mercenier\textsuperscript{1}
\textsuperscript{1}University of Zurich, Dept. of Geography, Zürich, Switzerland

The iceberg calving process influences the geometry of a tidewater glacier, and is in turn controlled by the terminus geometry through the stress field which controls damage and fracture of the ice. We analyze the feedbacks in this intricately coupled process with an explicitly formulated model, consisting of evolution equations for three state variables representing glacier geometry. The simplicity of the model allows for formal investigation of stability of glacier states on different basal geometries during advance and retreat. This model, complemented with a simple parametrization of glacier calving rates, can also be used to understand tidewater glacier change rates. Model runs on realistic bathymetries yield evolution histories which compare favorably with recorded tidewater glacier histories.
Pine Island Glacier (PIG) currently experiences the largest negative mass balance in comparison to other outlet glaciers in Antarctica and hence is the largest contributor to modern sea-level rise. Due to the glacier’s topographic setting, a bed that deepens beyond the grounding line to the deep interior basin of the West Antarctic Ice Sheet (WAIS), it has been suggested that this increased ice loss may be a precursor of WAIS collapse. Despite the increased mass loss, however, the calving front of PIG remained more or less stable since the earliest observations in the mid-20th century. Large icebergs where calved at intervals of a few years but subsequently the calving front re-advanced close to or even beyond its former position. This pattern changed in 2015 when a calving event resulted in a reoriented (45°-25° clockwise compared to previous calving lines) and most retreated calving line position ever observed. This new calving geometry was confirmed by a calving event in September 2017. In February 2017 we were able to access the formerly ice-shelf covered area during RV Polarstern expedition PS104. Bathymetric data from this area revealed a bathymetric ridge that has acted as a pinning point of PIG in the past. We use these bathymetric data in combination with satellite data from the last decades to investigate the correlation of bathymetric features to the calving dynamics of Pine Island Glacier.
Present ENSO Modulation of Summer Surface Melting of Amundsen Sea Ice Shelves

Enhanced surface melting over Antarctic ice shelves is known as an important precursor of ice-shelf break-up. Although the marked ice-shelf thinning along the Amundsen Sea (AS) coast observed in recent years has been mainly attributed to ocean-related sub-ice shelf melting, future climate model projections point toward increased summer surface melting in this area in the coming decades. A better understanding of atmospheric conditions promoting ice-shelf surface melting in the present-day climate can provide insight into the future of West Antarctic ice shelves. Here, we present the results of a 15-km resolution simulation of West Antarctic summer climate spanning 1979-2015 carried out with the polar-optimized version of the Weather Research and Forecasting model (Polar WRF) and complemented with melt data derived from satellite passive microwave observations. Consistent with previous studies, we find that a westward shift of the Amundsen Sea Low (toward the Ross Sea) favors warmer conditions and enhanced melting along the AS coast. The impact of the El Niño-Southern Oscillation (ENSO) is significant only when focusing on strong ENSO events, with surface melting being significantly enhanced during strong El Niños compared to strong La Niñas. In this context, the increase in the frequency and intensity of El Niño events projected for the twenty-first century could expose the AS coast to enhanced surface melting and thus to an enhanced risk of ice-shelf disintegration.
Under favourable conditions, the sediments within Antarctic subglacial lakes provide unique records of ice sheet history and microbial life. Subglacial Lake CECs, in West Antarctica, has the potential to host such an environment. However, key to record preservation are the lake volume and depositional environment. The lake lies beneath 2650 m of ice in a topographically-steep subglacial region to the west of the Ellsworth Mountains. The lateral extent of the lake has been delimited by surface radar measurements. However, no constraints have been placed on the bathymetry or bed conditions within the lake. In December 2016, a series of seismic reflection profiles was acquired across the lake to determine the water column thickness and bed properties. Profiles indicate a maximum water column thickness of 300 m at the widest part of the lake. The relative reflection strength from the ice-base and lake-bed have been used to investigate the bed material. The lake-bed is likely formed of fine-grained silts or clays, consistent with a low-energy sedimentary environment. The volume of water and low-energy depositional environment indicate that Lake CECs is a suitable candidate for deep exploration.
Recent Research Advances on Subglacial Lake CECs in West Antarctica

Andres Rivera1,2 (arivera@cecs.cl), Rodrigo Zamora3, Jose Andres Uribe1, Andy Smith3, Margit Schwikowski4, Pablo Paredes1, Jonathan Oberreuter1, Felipe Napoleoni1, Jorge Hernandez1, Alex Brisbourne3, Francisca Bown1

1Centro de Estudios Científicos, Glaciology, Valdivia, Chile, 2Universidad de Chile, Geography, Santiago, Chile, 3British Antarctic Survey, Cambridge, United Kingdom, 4Paul Scherrer Institute, Villigen, Switzerland

Subglacial Lake CECs (79°15’S / 87°34’W) is a near 20 km² fresh water body located underneath 2650 m of ice in West Antarctica. Recently collected seismic, radar and GPS data have allowed a more detailed delineation of the lake and the surrounding subglacial topography, including the pathways of water flow potentially coming in and out the lake. The repeat survey of 30 metal poles deployed in 2014 indicates a mean ice surface velocity of 83 cm per year and a surface snow accumulation of 23 cm water equivalent per year. This surface snow accumulation value is very close to the mean accumulation between 1986 and 2014 obtained by glaciochemical and stable isotope analyses of 2 shallow firn cores retrieved from the area. An automatic weather station (AWS) installed on the ice sheet surface at 2057 meters above sea level, close to the centre of the lake, has discontinuously recorded data since 2014. Thanks to power improvements carried out in December 2016, the station was able to measure and transmit data in real time during the entire Antarctic winter when an absolute minimum air temperature of -59°C was reached. Data collected at a permanent GPS station installed next to the AWS showed vertical movement commensurate with the surface mass balance, without any indication of elevation changes resulting from possible water volume changes within the lake. All these new insights confirm the advantages of this subglacial lake as a target for a deep exploration program.
The piling up of surface meltwater on ice shelves can lead to hydrofracturing, a process that severely damages the structural integrity of an ice shelf and could possibly lead to its collapse. Thorough analysis of the Surface Energy Balance and its individual components can provide insight in their separate contributions to surface melt.

In this presentation, we will present the results from running an Energy Balance model forced by 25 years of meteorological observations from Neumayer Station, located on the Ekström ice shelf in Dronning Maud Land, Antarctica. The model calculates the turbulent fluxes for sensible and latent heat, as well as subsurface processes such as meltwater percolation and densification of snow and firn. The melt season at Neumayer is limited to December and January in most years, with melt occurring on approximately 20 days on average. We will also comment on limitations due to measurement and modelling uncertainties.

In addition, we have forced the model by meteorological data from two additional automatic weather stations on Antarctic ice shelves (one on the Riiser-Larsen ice shelf and one on the King Baudouin ice shelf) in order to assess the spatial variability of the melt season. Furthermore, these results could be used to evaluate the ability of regional climate models to calculate the Surface Energy Balance.
Challenge in Determining the Impact of Warming Limited to 1.5/2°C for Antarctica

Christian Rodehacke¹² (christian.rodehacke@awi.de), Tido Semmler¹, Madlene Pfeiffer¹, Özgür Gurses¹, Thomas Kleiner¹
¹Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, ²Danish Meteorological Institute, Copenhagen, Denmark

To assess the impact of various future climate scenarios (1.5°C, 2°C, RCP4.5, RCP8.5) on the Antarctic ice sheet and its contribution to the global sea level, we exploit a large ensemble of ice sheet simulations. It covers the period from 1850 to 5000 to determine short-term and long-term implications of different future climate paths. To sample the uncertainty range, we use atmospheric and oceanic output of 3 CMIP5 models, two initial ice sheet states, and different ways in applying the climate forcing. Two major challenges are detected: First, the oceanic and atmospheric conditions of global climate models are too warm for pre-industrial and present-day climates. Hence the forcing cannot be applied directly, while our simulations driven by the widely established method of anomaly forcing are generally more realistic. Second, we detect a very large uncertainty of near future projections up to 2100 and more so for the far future projections. This uncertainty makes conclusions on the impact of global climate warming limitation difficult to impossible. Some ensemble members lose the West Antarctic Ice Sheet or even parts in the east, while others do not. Ultimately, realizations with instabilities project sea level rises significantly larger than CMIP5 estimates. On the other hand, some of the realizations even show a negative sea level contribution due to mass accumulation in the interior of the Antarctic.
The Antarctic Peninsula (AP) is the warmest region of the Antarctic continent. This work studies the paraglacial response in this region. Past glacial retreat since the LGM has reshaped the configuration of the AP, favouring the emergence of new lands and the exposure of formerly glaciated environments. The shrinking and spatial retreat of the glaciers has favoured glacio-isostatic uplift, which has redefined the coastlines, with the development of new islands, peninsulas, etc. These changes occurred during the paraglacial stage promoting changes in the distribution of wildlife and flora, mainly distributed along the coastal fringes. Glacial retreat has also conditioned environmental dynamics, which has been more or less intense according to topography, geomorphological setting and permafrost existence/absence. The pronounced warming trend recorded during the second half of the 20th century has accelerated some of these processes. The abundance and variety of records (glacial, periglacial, permafrost, alluvial, coastal) as well as observations on ecological processes, has shown evidence of the rapid paraglacial readjustment of AP environments in the transition from glacial to ice-free conditions. High uplift rates have continued to reshape coastlines, permafrost degradation in newly exposed areas is accelerating mass wasting, sediment redistribution and changing hydrological processes, and wildlife and flora are rapidly fitting within the new environmental setting.
During the last seasons and ongoing, pre-site seismic surveys have taken place in the Ekströmisen region of Dronning Maud Land, with the primary of building a stratigraphic age framework of the under-ice-shelf sediments. These sediments are overlying the Explora Wedge, a syn- or post-rift volcanic deposit. Expected ages range from Late Mesozoic to Quaternary. From new vibroseismic profiles we will select sites for short core seafloor sampling through Hot Water Drill (HWD) holes of the oldest and of the youngest sediment sequences to confine their age time span. There is further potential for drilling deeper sediment cores with the support of international partner. Deep drilling should recover the sediments overlying the Explora Escarpment, in order to discover the nature of the Explora Wedge. We expect the overlying sediment sequences to reveal the history of polar amplification and climate changes in this part of Antarctica, the build-up of the East Antarctic Ice Sheet during past warmer climates, and its Cenozoic and future variability.

Having HWD holes through the shelf ice and sampling the sea floor will provide the unique opportunity for further piggy back experiments consisting of multi-disciplinary nature. Experiments and measuring setup for oceangraphy, sea and ice shelf physics, geophysics, geology, hydrography, biogeochemistry could be planned to characterize the ocean-ice-sediment interactions, processes and ecosystem observations.
Seasonal Control on Totten Ice Shelf Dynamics by Sea Ice Buttressing

Chad A. Greene¹ (chad@chadagreene.com), Duncan A. Young¹, David E. Gwyther², Benjamin K. Galton-Fenzi³, Jamin S. Greenbaum¹, Donald D. Blankenship¹
¹University of Texas Institute for Geophysics, Austin, United States, ²Institute for Marine and Antarctic Studies, University of Tasmania, Hobart, Australia, ³Australian Antarctic Division, Hobart, Australia, ⁴Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia

Previous studies of Totten Ice Shelf have relied upon surface velocity measurements to investigate its mass balance and sensitivities to interannual climate forcing. However, short-term displacement measurements cannot be used to characterize long-term flow rates where ice velocity fluctuates with the seasons. Quantifying annual mass budgets or analyzing interannual changes in ice velocity requires knowing when, whether, and where observations of glacier velocity may be aliased by short-term variability. Here, we analyze 16 years of velocity data for Totten Ice Shelf, which we generate at sub-annual resolution by applying feature tracking algorithms to several hundred MODIS satellite image pairs. We find the ice shelf is characterized by a seasonal cycle of spring to autumn speedup of more than 100 m/yr close to the ice front. The amplitude of the seasonal cycle diminishes with distance from the open ocean, suggesting the presence of a resistive backstress at the ice front that reaches a maximum in winter. Springtime acceleration precedes summer surface melt and is not attributable to thinning from basal melt. We find that the ice shelf accelerates each spring in response to lost buttressing from the breakup of seasonal landfast sea ice.
Ice sheet model outputs require inputs from uncertain initial and boundary conditions, and other parameters. We show how one particular ice sheet model, SICOPOLIS (Simulation COde for POLythermal Ice Sheets), depends on these inputs through comprehensive adjoint-based sensitivity analyses. SICOPOLIS discretizes the shallow-ice and shallow-shelf approximations for ice flow, and is well-suited for paleo studies of Antarctica. The adjoint model of SICOPOLIS was developed via algorithmic differentiation, facilitated by the source transformation tool OpenAD. While model sensitivity to various inputs can be computed by costly methods involving input perturbation simulations, the time-dependent adjoint model of SICOPOLIS delivers model sensitivities to initial and boundary conditions throughout time at lower cost.

Here, we explore the sensitivity of the Antarctic Ice Sheet's entire and regional volumes to: initial ice thickness, precipitation, basal sliding, and geothermal flux over the Holocene epoch. The West Antarctic Ice Sheet (WAIS), in particular, is well known to be sensitive to changes in basal melting, and we use the SICOPOLIS adjoint model to make quantifiable the WAIS' sensitivity to these controls. Sensitivity studies such as described here are now accessible to the modeling community, based on the latest version of SICOPOLIS that has been adapted for OpenAD to generate correct and efficient adjoint code.
Bedrock Roughness in Antarctica: Connections to Subglacial Water and Basal Slip

Over the last twenty five years, extensive ice penetrating radar (IPR) coverage of Antarctica has been obtained, at lines spacings down to 1 km in some cases. However, many glacial processes occur at finer scales, so inferring likely landscape parameters is required for a useful interpolation between lines.

Here we present a compilation of IPR-derived profile roughness data covering three great basins of Antarctica: the Byrd Subglacial Basin in West Antarctica, and the Wilkes Subglacial Basin and Aurora Subglacial Basins in East Antarctica; and treat these data using root mean squared deviation (RMSD). Coverage is provided by a range of IPR systems with varying vintages with differing instrument and processing parameters; we present approaches to account for the differences between these systems. We use RMSD to investigate the self-affine behaviour of the bed at kilometer scales and extract fractal parameters from the data to predict roughness and uncertainties in ice thickness measurement, and compare to simulations from subaerial topography.

We further compare these data to inferences of subglacial hydrology from specularity content, lithology from airborne gravity, and inferences from basal slip and find a good match between a distinct quantifiable roughness parameter and subglacial "canal" systems, low density anomalies, and regions of high basal slip. This map can be used as a tool in modeling ice sheets.
Thinning and fracture of Antarctic ice shelves reduces their ability to restrain discharge of grounded ice into the ocean. Implementing these weakening processes in models of ice sheet-ice shelf systems could improve projections of ice sheet evolution and sea level rise. However, current models at this scale cannot accurately represent fracture-induced weakening despite attempts with damage mechanics. These damage models fail because they often lack a strong physical basis and they encounter numerical diffusion when damage is advected with the ice flow. Here, we overcome these issues by developing a modeling framework that incorporates a thermodynamically consistent and anisotropic damage model and is based on an implicit material point method (MPM) to ensure error-free advection of damage. In MPM, a set of Lagrangian particles discretize the ice domain, carry all variables, and advect with the flow. Similar to the finite element method, model equations are solved on an Eulerian grid, but the particles serve as moving integration points. We test our methods with a shallow shelf model of the Larsen C ice sheet-ice shelf system. We initialize the model using high resolution Cryosat-2 data for ice geometry and by conducting a dual inversion for the basal friction and damage parameters that minimize mismatch between modeled and Landsat-derived velocities. We simulate potential triggers of ice shelf collapse and discuss the resultant implications for stability of the ice shelf.
Surface melting is an important precursor for Antarctic ice shelf collapse owing to its ability to deplete firm air content and generate complex surface hydrological features including meltwater lakes. Recent ice sheet-climate modeling suggests intensified surface melting may initiate rapid change in the ice sheet system over this century. Accurate prediction of future melt evolution, and thus sea-level rise estimates, requires a robust observational baseline for melt owing to important nonlinearities in the melt response to a warming atmosphere. Here, we present new investigations of Antarctic ice sheet surface melt using satellite radar remote sensing and field observations. We focus on extending a legacy 10-year melt intensity record from the QuikSCAT satellite with more recent scatterometer missions. Next, we assess the capabilities of high spatial resolution satellite synthetic aperture radars in recording variability in ice shelf surface melt. Satellite data are evaluated against in-situ estimates of meltwater production derived from observations of the surface energy balance. We further evaluate satellite observations against field observations of refrozen melt stratigraphy resulting from a widespread 2016 West Antarctic melt event. Our resulting observations provide important insights into the coupling between the atmosphere, meltwater production, firm conditions, and ice sheet surface hydrology, all processes critical to quantify for improved sea-level projections.

Morphology and Mass Balance of Land-terminating Ice Cliffs in North Greenland

Rainer Prinz1,2 (rainer.prinz@uni-graz.at), Jakob Steiner3, Jakob Abermann4
1University of Graz, Graz, Austria, 2Austrian Polar Research Institute, Vienna, Austria, 3University of Utrecht, Utrecht, Netherlands, 4Asiaq Greenland Survey, Nuuk, Greenland

Wide parts of the ice sheet in North Greenland terminate as cliffs on land. However, the characteristics of this feature and its response to a changing climate have so far received little attention. While land-terminating ice cliffs are studied in other regions, detailed investigations in Greenland were carried out only more than six decades ago in the Thule area (Red Rock, Northwest Greenland). These studies showed a continuous advance at one location over multiple years, despite the local mass balance was reported negative. The purpose of our study is twofold. First, we extend the morphological analysis to the complete Northern ice margin employing high resolution digital terrain models (Arctic DEM). We focus on main characteristics of the land-terminating ice margin in Northern Greenland, its slope and aspect distribution and comparison to spatial datasets of flow velocity and mass balance. Results show that the advance at Red Rock is long-term, continuing unabated today at rates of up to several meters per year. Similar magnitudes were found for large other stretches along the ice margin. Second, we investigate processes and drivers of the ice cliff evolution. With data from our recent field experiment we show that under the same atmospheric forcing the mass balance response of the cliff front is different to the horizontal glacier surface above the cliff. Hence, the cliff morphology determines different energy balance regimes with specific sensitivities to climate.
Model parameters control the sensitivity of ice sheets to external forcings, and introduce uncertainty to model output due to poor understanding of their optimum, or true values. The complexity of model physics means few studies have explored parameter interactions. This study aims to
1. Quantify the influence of model parameters, and their interactions on GrIS evolution, and
2. Determine parameter ranges that reproduce a GrIS target state assumed to represent the its extent at the Medieval Warm Period (MWP) onset.
A parameter sensitivity analysis, using principal component data reduction and Bayesian approaches is performed using the Parallel Ice Sheet Model (PISM). For a suite of parameter settings, the GrIS is spun up from 125 to 1ka using grid sequencing to gradually increase spatial resolution from 40 to 5km. Modelled output at 1ka is compared with target model E-W ice thickness transects across the GrIS to
1. quantify sensitivity of ice sheet profile to parameter set-up and
2. to identify parameter values that best allow the GrIS to evolve into an assumed MWP extent.
3. Produce a posterior probability distribution of each influential parameter
4. Determine if posterior probability distributions of parameters are spatially variable
Identifying influential parameters and a probability distribution of their values allows for the development of a parameter scheme that closely reproduces target ice sheet extents and simultaneously quantifies their interactions.
Morphodynamical Changes and Predictions of Amery Ice Shelf, Eastern Antarctica

Avinash Kumar¹ (avinash@ncaor.gov.in), Babula Jena¹, Rahul Mohan¹, M Ravichandran¹
¹ESSO - National Centre for Antarctic & Ocean Research, Ministry of Earth Science (Govt. of India), Vasco, India

The Amery ice shelf (AIS) plays a critical role in Earth’s climate system and its morphology is controlled by the physical forcing and global human interventions. The coastline changes of AIS are investigated for about 460 km into three different sectors and each-sector into a number of transects at uniform intervals between 2001 and 2016 using multi-dated MODIS satellite images. Further, past coastline positions were constructed and future positions are estimated for 5- and 10- years. The rate of change in AIS coastline positions were estimated using the statistical methods—end point rate, average of rates and linear regression—and cross-validated with correlation coefficient and root-mean-square error (RMSE) methods. About 51% of transects exhibit ±200 m RMSE values, indicating better agreement between the estimated and satellite-based ice-shelf positions, and the transects closer to the sectors boundaries exhibit 47% uncertainties in coastline change rate estimations. Based on correlation coefficient and RMSE, the influence of physical/natural processes and global anthropogenic activities on coastline changes has been calculated. The AIS ice sheet are gaining mass (5.4 ± 3.1 Gt/yr) due to increased accumulation of snow in this region. Significant morphological changes in AIS have been recorded at every 5-years and attempted to link with the ice mass change and climate indices, such as El-Niño Southern Oscillation (ENSO) and Southern Annular Mode (SAM) at different sectors.
Finnish Geospatial Research Institute (FGI) has a long history in studying the Fennoscandian glacial isostatic adjustment (GIA) in Finland through modelling and different kinds of measurements. Absolute gravimetry (AG) has been done in Finland since 1980’s, first through international collaboration and then with our own gravimeters. FGI has also participated in seven Finnish Antarctic Research Program expeditions since 1989. The main research theme has been the study of the Antarctic glacial isostatic adjustment utilizing AG and constant GPS measurements. Absolute gravity measurements have been carried out at five research stations located in Dronning Maud Land, Antarctica. Repeated absolute gravity measurements can bring multiple benefits to geodynamical work, when used together with vertical rates or even in standalone mode. At individual stations, gravity rates can be used to control observed vertical rates and predictions from GIA models. In a regional approach, plotting gravity rates versus vertical rates at a number of stations provides a slope that gives information on the mechanism behind the vertical rates (e.g., GIA) and an intercept that can be used to control the reference frame of the vertical rates. Along with the above mentioned geodynamics studies, absolute-gravity stations are an important part of the global geodetic infrastructure. We review the FGI absolute gravity research in Fennoscandia and in Antarctica and present latest results.
Thanks to the complete lack of anthropic noise, Antarctica can be considered a perfect natural laboratory to investigate seismic signals generated by atmosphere-cryosphere-hydrosphere interaction. In the framework of the ICE-VOLC project (www.icevolc-project.com) funded by the Italian PNRA, Antarctic ice-quakes and microseisms were studied.

In particular, by a temporary installation of two seismic stations in Tethys Bay close to Mario Zucchelli Station in 2016, three icequakes were detected, with dominant low frequencies (below 2 Hz), located in the David Glacier area with local magnitude of 2.4-2.6. These events were likely to be generated at the rock-ice interface under the glacier.

As for microseism study, we quantitatively investigated the relationship between microseisms recorded on the coasts of the Ross Sea, sea ice concentration in the Ross Sea and significant wave height in the southern hemisphere. We show how, according to the different seismic station and frequency band, the areas characterised by the strongest anti-correlation between microseism amplitude and sea ice concentration are distinct. Accordingly, we present an algorithm to infer the sea ice distribution on the basis of the microseismic amplitudes. Finally, we note how the oceanic areas, whose wave activity mostly affects the microseisms recorded in the Ross Sea, are the Antarctic coasts close to Ross Sea and the Drake passage.
Antarctic GIA Estimated by Combining GRACE, ICESat and GPS

Zemin Wang1, Baojun Zhang1 (bjzhang@whu.edu.cn), Hong Geng2, Jiachun An1
1Wuhan University, Chinese Antarctic Center of Surveying and Mapping, Wuhan, China, 2Wuhan University, School of Resource and Environmental Sciences, Wuhan, China

Based on the significant difference between ice/snow density and lithospheric density, a new iterative method is proposed to simultaneously estimate the present-day glacial isostatic adjustment (GIA), ice/snow mass change and corresponding elastic vertical crustal deformation over the AIS by combining GRACE, ICESat and GPS datasets. The influence of active subglacial lakes on GIA estimates, which is up to 1.5 mm/yr with all datasets applying a 400 km Gaussian smoothing filter, are mitigated for the first time through additional processing of ICESat data. The inferred GIA shows that the strongest uplift is found in the Amundsen Sea sector and subsidence mostly occurs in Adelie Terre and the East Antarctica inland. The total GIA related mass change estimates for the entire AIS, West Antarctica Ice Sheet, East Antarctica Ice Sheet, and Antarctic Peninsula Ice Sheet are 43 ± 38, 53 ± 24, −23 ± 29 and 13 ± 6 Gt/a, respectively. The most significant ice mass loss and most significant elastic vertical crustal deformations are concentrated in the ASE and northern Antarctic Peninsula. Ice/snow mass loss rate in the northern Antarctic Peninsula and Amundsen Sea sector is more than 10 cm/a EWH. For the corresponding elastic vertical crustal deformation rates, in the Amundsen Sea sector is more than 4.5 mm/a and the Northern Antarctic Peninsula is about 2 mm/yr.
How to Give Accurate Surface Mass Balance Projections for the 21st Century?

Vincent Favier¹ (vincent.favier@univ-grenoble-alpes.fr), Gerhard Krinner¹, Charles Amory², Julien Beaumet¹, Hubert Gallée¹, Cecile Agosta²
¹IGE, Grenoble, France, ²ULg, Liège, Belgium

Climate models still fail to accurately reproduce the temporal Surface Mass Balance (SMB) trends at a regional scale, mainly because complex processes are still insufficiently considered, such as:

1) atmospheric circulation changes related to complex ocean/ice/atmosphere interactions,
2) specific polar atmospheric features (cloud microphysics, wind scouring and impact on stable surface boundary layers),
3) surface firn physics involved in surface drag variations, or in firn air depletion and albedo feedbacks.

We propose an approach based on 1) bias corrections of future sea surface conditions coming from AOGCM scenarios. These corrections are then used as boundary conditions for a modeling with a stretched grid atmospheric GCM (LMDZ4), whose systematic errors in atmospheric circulation are corrected using tendency errors from nudged simulations. These outputs are then used to force the regional atmospheric model (MAR) to assess future regional scale SMB variations in Antarctica. The MAR is adapted to account for interactions between drifting snow and surface drag over sastrugi fields by introducing a specific formulation for the roughness length. This formulation accounts for the relationship existing between snow-surface temperature and microrelief erodibility caused by the sintering of surface crystals. This adaptation is necessary to reproduce the seasonal variations in drifting snow frequency and horizontal snow mass transport as evidenced from observations.
GIA-induced Crustal Deformation around Syowa Station, East Antarctica

Jun'ichi Okuno1,2 (okuno@nipr.ac.jp), Koichiro Doi1,2, Yuichi Aoyama1,2, Takeshi Ishiwa3, Akihisa Hattori2
1National Institute of Polar Research, Tachiakawa, Japan, 2Graduate University for Advanced Studies, Department of Polar Science, Tachiakawa, Japan

Geodetic and geomorphological surveys in Soya Coast area, East Antarctica have been conducted by Japanese Antarctic Research Expedition (JARE) in order to evaluate the crustal deformation induced by Glacial Isostatic Adjustment (GIA) in various time scales. In particular, several geodetic observations (e.g., Global Navigation Satellite Systems: GNSS and continuous gravity observations) have been carried out on outcrop rocks in this area since the 1990s to monitor recent crustal movements. These observations include the components of the GIA induced by last deglaciation and elastic deformation due to recent surface mass balance. Therefore, it is important for the separation of the components of viscous and elastic signals to compare these observations with numerical predictions using GIA model. In this presentation, we will show the geodetic signals calculated by GIA model based on the previously published deglaciation histories, and the results of geodetic observations obtained by JARE for about 20 years. We intend to discuss the separation of the components between recent ice mass change and last deglaciation, and estimate influences of recent Antarctic ice sheet mass changes on the geodetic measurements in Soya Coast area.
Quantifying the contribution from ice sheets and glaciers to past sea level change is of great value for understanding sea level projections into the 21st century. However, quantifying and understanding past changes are equally important, in particular understanding the impact in the near-field where the signal is largest.

We assess the impact of 20th century mass balance of the Greenland Ice Sheet on land motion using results from Kjeldsen et al, 2015. These results suggest that the ice sheet on average lost a minimum of 75 Gt/yr, but also show that the mass balance was highly spatial- and temporal variable, and moreover that on a centennial time scale changes were driven by a decreasing surface mass balance.

Here we present and discuss land motion during the 20th century due to mass balance-, surface mass balance-, and ice dynamics changes.

Kjeldsen, K. K. et al. (2015), Spatial and temporal distribution of mass loss from the Greenland Ice Sheet since AD 1900, Nature, 396, 528, doi:10.1038/nature16183
Sea-level fingerprinting by GIA model is useful to detect ice-sheet change scenarios. Regardless of lacking direct ice-sheet data in near-field, sea-level fingerprinting can reconstruct timing and amplitude of ice-sheet change. Marine Isotope Stage 2 (MIS 2) is the latest glacial period (29,000-15,000 years ago), including the Last Glacial Maximum (LGM) at the timing of global ice volume maximum. Further understanding of the glacial earth climate system requires a comparison of various paleoclimatic records with sea-level and ice-sheet change in this period. However, Antarctica Ice Sheet (AIS) history during MIS 2 is still less understood due to lack of field data. Here we demonstrate AIS history during MIS 2 using sea-level fingerprinting analysis on observations in far- and intermediate-field. Our results indicate that far- and intermediate-field relative sea-level records provide the new insight of AIS history during MIS 2 through sea-level fingerprinting analysis.
In 1912 a Swiss expedition, leaded by the meteorologist Alfred de Quervain, crossed the inland ice of Greenland on a track from Disko Bay to Tasiilaq. It was the second successful crossing of the ice cap after Nansens expedition in 1888. De Quervain provided first good height data of the glacier surface. The accuracy of the heights is in the range of 2 m about 10 m. There are only a few such data sets available which are measured more than 100 years ago.

In 2002 a series of six geodetic expeditions started on the same traverse as 1912. The last measurements were made in August 2017. In result there are a lot of information available:

- very precise height changes for the last 15 years along a 700 km profile,
- height differences measured on more than 20 camp sites of the 1912 expedition
- very dense (spacing of some meters) profiles of heights of the rim of the inland ice.

The results can be used to answer different questions: Are there significant differences in the height changes and mass loss resp. between the 100 years after 1912 and the last decade? Is the speed of mass loss more or less stable or increasing? How the surface topography is changing (an analysis of remote sensing data is included)? An observed height change is mainly a mass change or a change of snow density?

And last but not least the data are usable for direct verification of altimetry data such as IceSat. Both the IceSat heights and the height changes can be compared.
Processes of 21st Century Ice Sheet Melt and their Global Consequences

Nicholas Golledge¹² (nicholas.golledge@vuw.ac.nz), Natalya Gomez³, Elizabeth Keller², Kaitlin Naughten⁴, Gabriel Tseng³, Jorge Bernales⁵

¹Victoria University of Wellington, Antarctic Research Centre, Wellington, New Zealand, ²GNS Science, Lower Hutt, New Zealand, ³McGill University, Montreal, Canada, ⁴University of New South Wales, Sydney, Australia, ⁵GFZ German Research Centre for Geosciences, Potsdam, Germany

Both external and internal processes drive ice sheet evolution over decadal to centennial timescales, yet the partitioning between these drivers is often hard to quantify. Here we present a new suite of high-resolution simulations of ice sheet evolution from present-day to 2100 based on CMIP5 climatologies. Our results predict the magnitude of possible sea level rise under different climate scenarios, but also highlight the spread of values that arises from differing parameterisations of key physical processes, such as grounding line behaviour or the calculation of surface melt. By quantifying mass changes in individual ice sheet drainage basins that arise from environmental processes such as surface and basal melt, we then derive an estimate of the dynamic component of the total discharge signal. In this manner we are able to attribute spatially-variable changes to regional differences in climate forcing and ice sheet dynamics.
This contribution focuses on the interplay between the solid Earth and the cryosphere with the aim of progressing knowledge of ice extent and retreat history, and Antarctica’s contribution to sea level change, via observation and modelling. Solid Earth-cryosphere interaction research requires an interdisciplinary approach which is facilitated through the Antarctic Gateway Partnership research program centred in Hobart, Tasmania, Australia. New observations are provided through onshore and marine basement rock and sediment sampling, and GPS, seismic and airborne geophysics data collection. These observations are carried out in the context of ice sheet modelling at both basin scale and continental scale.

We investigate the Earth deformation, including horizontal motion, associated with ice sheet evolution. We also improve constraints on geothermal heat as an ice sheet model input by combining information from geological, plate tectonic and geophysical inputs. The present day research findings are placed in the context of paleo ice sheet models which consider a coupled ice sheet / ocean / solid Earth framework. With a focus on East Antarctica, we find that the major ice sheets and their basement catchments behave with contrasting sets of controls. Through our combined approaches, we are better able to constrain model inputs, understand the impact of uncertainty in model inputs and investigate the impact of feedbacks between Earth systems.
Victoria Land (Antarctica) is located at the boundary between the Western Antarctic Rift System and East Antarctic Craton. This region is characterized by a complex tectonic architecture mainly dominated by NW-SE regional right-lateral strike-slip faults, block faulting, tilting along NE striking, and SE dipping extensional faults. In order to estimate the neo-tectonic geodynamics of the region, in 1999 Victoria Land Network for DEFormation control (VLNDEF) was established and repeatedly surveyed during the Australian summer seasons. The network nowadays is constituted by 27 sites in a region which extends over 500 km North-South and 300 km East-West, including the “Mario Zucchelli Station” Italian base. In this paper, GPS observations of VLNDEF, collected from DOY 349 of 1998 to DOY 365 of 2017, together with all free available geodetic observations for Antarctica (IGS and POLENET sites) were processed with Bernese 5.2 Software, using a classical double difference approach. Almost 100 IGS stations were used as a global frame and the IGS14 core network was adopted to align Antarctica’s stations into ITRF2014 reference frame. GPS time series for more than 80 Antarctic sites were analyzed to remove outliers and to estimate trends, annual/semiannual signals components and eventually offsets parameters. Finally, the principal component analysis (PCA) was applied to filter out the common mode component (CMC) of the calculated GPS time series.
Calibrated Projections of Jakobshavn Isbrae's Contribution to Sea Level Rise

Johannes H. Bondzio (jbondzio@uci.edu), Mathieu Morlighem, Helene Seroussi, Michael Wood, Jeremie Mouginot

1University of California Irvine, Earth System Science, Irvine, CA, United States, 2Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, United States

Jakobshavn Isbrae (JI), West Greenland, has become a major contributor to global sea level rise since the disintegration of its floating ice tongue in the early 2000's. Calving controls the evolution of the ice stream, but no robust calving rate parameterization for large-scale ice sheet models exists to date. Therefore, large uncertainties remain concerning the future evolution of this glacier.

Here, using the Ice Sheet System Model (ISSM), we perform a model sensitivity study on JI. We estimate its future evolution and mass loss by calibrating a calving rate parameterization based on a von-Mises yield stress criterion with available observations over the 1985-2017 period. First, we perform a large ensemble of model runs over the past 30 years, in which we vary several parameters that influence calving. Second, we introduce metrics to evaluate the agreement between model runs and observations of JI, and determine the parameter combinations that best reproduce the observed dynamic changes. Finally, we project JI's future evolution for each of the selected parameter combinations for the next 100 years.

We discuss the robustness of our results, the sensitivity of the glacier to the respective calving parameters, and future pathways for observations and model development. This ensemble study explores scenarios of JI's potential evolution and yields an informed estimate of JI's contribution to global sea level rise for the next century.
High-resolution, Global Ice Sheet/RSL Simulations using the Higher-order ISSM

Eric Larour\textsuperscript{1} (eric.larour@jpl.nasa.gov), Erik Ivins\textsuperscript{1}, Surendra Adhikari\textsuperscript{1}
\textsuperscript{1}Jet Propulsion Laboratory, California Institute of Technology, Pasadena, United States

Relative sea-level rise is driven by processes that are intimately linked to the evolution of glacial areas and polar ice sheets. So far, most Earth System models capable of projecting the evolution of RSL on decadal to centennial time scales have relied on offline interactions between RSL and ice sheets. In particular, grounding line and calving front dynamics have not been modeled in a way that is tightly coupled with Elasto-Static Adjustment (ESA) and/or Glacial-Isostatic Adjustment (GIA). Here, we present a new simulation of the entire Earth System in which both Greenland and Antarctica ice sheets are tightly coupled to an RSL model that includes both ESA and GIA at resolutions and time scales compatible with processes such as grounding line dynamics for Antarctica ice shelves and calving front dynamics for Greenland marine-terminating glaciers. The simulations rely on the Ice Sheet System Model (ISSM) SESAW module, which models RSL using an anisotropic meshing approach, as opposed to the more classic spherical harmonics approach. Using such an approach, one can show the impact of higher-order ice flow dynamics and coupling feedbacks between ice flow and RSL. We quantify the exact impact of ESA and GIA inclusion on grounding line evolution for large ice shelves such as the Ronne and Ross ice shelves, as well as the Agasea Embayment ice streams, and demonstrate how offline vs online RSL simulations diverge in the long run, and the consequences for predicting sea-level rise.
Calving-induced Tsunami Analyzed through Seismic Signals and Numerical Codes

Filippo Zaniboni\textsuperscript{1} (filippo.zaniboni@unibo.it), Stefania Danesi\textsuperscript{2}, Simone Salimbeni\textsuperscript{2}, Andrea Morelli\textsuperscript{2}, Stefano Urbini\textsuperscript{3}, Stefano Tinti\textsuperscript{1}
\textsuperscript{1}Università di Bologna, Bologna, Italy, \textsuperscript{2}Istituto Nazionale di Geofisica e Vulcanologia, Bologna, Italy, \textsuperscript{3}Istituto Nazionale di Geofisica e Vulcanologia, Roma, Italy

The dynamics of sizeable outlet glaciers in Greenland has been studied through the analysis of seismic data collected by the regional Greenland Ice Sheet Monitoring Network (GLISN), of satellite images and of local tide gauge data. With a particular focus on the Jakobshavn Glacier, West Greenland, major calving events have been identified by automatically detecting the ground flexure in response to sea waves generated by iceberg detachments.

In addition, numerical techniques simulating the propagation of a tsunami in the Ilullisat fjord have been applied. The tsunami source has been simply represented by means of a single, instantaneous sea-surface bump, localized approximately in the area where the calving event takes place. The main interest in this preliminary phase is focused on the assessment of the main tsunami features in the basin: propagation time, sea-surface maxima and minima distribution and frequency characterization of the waves reaching the fjord coasts.

The comparison of the seismograms spectra associated to calving events in the low-frequency window against the spectra of the simulated tsunami is encouraging and opens new perspectives in the study of the interaction between glaciers, fjords and oceans.
One of the recent climate changes is the temperature and precipitation increase in the Arctic. In an area of East Russia Arctic, loss of sea ice is large and glaciers shrink due to the temperature increase and sea ice decrease. We analyzed sea ice area, land weather and glacier mass balance of three areas in western Russian Arctic to evaluate the influence of sea ice distribution on glaciers.

The study area has three islands. Franz Josef (FJ), Severnaya Zemlya (SZ), Novaya Zemlya (NZ). FJ and SZ are surrounded by sea ice and has ice cap on the land. NZ is covered by a large ice cap. We used monthly mean temperature observed in July and NCEP reanalysis data for summer mean temperature as a climate indicator. The GRACE data was converted to water storage on land and regarded it as glacier mass change. Also, Sea ice distribution and sea surface temperature were analyzed with the satellite data.

The glacier mass balance has decreased during 2002-2004 in FJ and NZ, and 2011-2012 in all area. For 2004-2010, NZ showed the gradual mass balance decrease and FJ and SZ showed small change. NZ showed open seawater in early July, which is earlier than usual year. After 2011, sea ice was separated to coastline of NZ. Higher summer temperature was shown in FJ in 2011, SZ in 2004 and 2012, and NZ in 2004 and 2007-2008 and after 2011. Glacier mass loss and high air temperature was seen in the same period in all areas.
New radar data from the PolarGAP project reveal a broad area upstream of South Pole where >400m has been lost from the ice sheet due to enhanced basal melting. We estimate by modelling dated englacial layers that the geothermal heat flux required is 120 ±20 mW/m², indicating a previously undetected geothermal anomaly. Hydrological models show that subtle changes in the ice sheet can switch melt water flow from this region between glacial catchments. We propose that this mechanism helps explain past variability in flow deep in the ice sheet interior.
Mass Change in Greenland and Antarctica Derived from LAGEOS and GRACE

Ulrich Meyer¹ (ulrich.meyer@aiub.unibe.ch), Krzysztof Sosnica², Rolf Dach¹, Adrian Jäggi¹
¹University of Bern, Astronomical Institute, Bern, Switzerland, ²Wrocław University of Environmental and Life Sciences, Institute of Geodesy and Geoinformatics, Wroclaw, Poland

Large scale continental mass change in polar regions is sensed by Earth observation satellites dedicated to gravity field determination like the GRACE mission (2002 - 2017) and its successor GRACE-FO (scheduled for launch in spring 2018). But also other low Earth orbiters (LEOs) with high-latitude orbits may be used to assess the mass transport in polar regions. The spatial and temporal resolution of the derived mass estimates is much coarse than what we get from GRACE, but they may serve to extend the time-series before the start of GRACE and to bridge the gap to GRACE-FO. Satellite Laser Ranging (SLR) observations to the LAGEOS satellites allow polar mass change estimates back to the early 1990s. They indicate that major ice melting in Greenland started around 2002, so GRACE was launched just in time.

We present and compare time-series of Greenland and Antarctica mass changes derived by SLR and from GRACE and discuss limitations in temporal and spatial resolution. We also address the problem of spectral leakage due to the limited spatial resolution and of signal separation, because satellite gravimetry senses the integrated mass change including global isostatic adjustment (GIA), snow cover and ice dynamics.
POLENET GPS sites located in the Amundsen Sea Embayment (ASE) of the West Antarctic Ice Sheet (WAIS) are recording some of the fastest uplift rates seen anywhere in the world. This data strongly indicates that the glaciers in the ASE are undergoing drastic dynamic changes, having a significant impact on the WAIS contribution to sea level change. We use high resolution optical stereo imagery from the DigitalGlobe satellite cluster, co-registered with laser altimetry and RADAR data collected during the NASA IceBridge and ICESat missions, to generate a time series of digital elevation models (DEMs) spanning the time period between 2009 and 2017. These optically derived DEMs are extracted using the SETSM algorithm and are used to identify glacier surface elevation (dh/dt) changes. Volume changes (dV/dt) are calculated by combining dh/dt values and bed elevations from Bedmap2. GoLIVE data is used to identify surface velocity speeds of glaciers in the ASE using a fixed fluxgate. We expect to see significant changes in the surface elevation, velocity and mass balance of glaciers in the ASE and will compare our results with data obtained from studies using Cryosat-2 and ICESat. Establishing the nature of load changes in the vicinity of the POLENET GPS sites will enable the identification of the extent to which uplift is dominated by instantaneous elastic response due to ice mass changes.
Since 1995 our group has been working in Greenland. In Northeast Greenland, between 72 and 81 North, geodetic GNSS measurements on bedrock were started in 2008 and carried out lastly in 2016 and 2017 during campaigns based on the German research vessel “Polarstern” as well as on a field camp. Results of the GNSS data analysis will be presented together with the inferred correction for the immediate elastic response to recent ice-mass changes in order to link the vertical uplift rates to glacial-isostatic adjustment (GIA). A focus will be given to Nioghalvfjerdsbraen, the northern branch of the major outlet of the Northeast Greenland Ice Stream (NEGIS). This region is subject to a new joint research project “Greenland Ice Sheet - Ocean Interaction” (GROCE) that a number of German universities and research centres are cooperating on. We will shortly introduce this project that aims at investigating in detail the processes which interlink atmosphere, ocean and ice sheet. Within the GROCE project our group deals with GIA, mass balance and dynamics of the Greenland Ice Sheet in that focus area. The GIA effect will be determined also by the combination of satellite altimetry and gravimetry, which then can be compared to the results of the in-situ GNSS measurements. We will discuss the benefit of utilizing additional methods and observations to support the separation of the effects of surface mass balance and ice dynamics.
Geothermal Heat Flux and Predictability of West Antarctic Ice Sheet Evolution

Slawek Tulaczyk¹ (stulaczy@ucsc.edu), Carolyn Braney Begeman¹, Andrew Fisher¹
¹University of California, Santa Cruz, Earth and Planetary Sciences, Santa Cruz, United States

Climate changes are overall the primary driver of West Antarctic Ice Sheet (WAIS) variability over time. However, climate sensitivity of a marine ice sheet should be strongly modulated by the magnitude and spatial pattern of subglacial geothermal heat flux (GHF). Low GHF values favor development of slow-moving ice rises and inter stream ridges which are frozen to their beds and offer buttressing for ice shelves and ice streams. High GHF values hinder or prevent development of such slow-moving features because they make it hard, or impossible, to reach freezing conditions at the bed. In general, high GHF values will favor marine ice sheet instability. A number of recent publications reported data and modeling results indicating zones of high GHF beneath the WAIS, purportedly related to subglacial volcanic or magmatic activity in the West Antarctic Rift System (WARS). Diffuse continental rift zones, such as the WARS, are characterized by elevated and spatially highly variable GHF. For instance, GHF within the Basin and Range Province has a modal value close to the average continental GHF (ca. 60 mW per meter squared) but also a long tail of high values that reach over 300 mW per meter squared. Regional differences in GHF of such large magnitude should play a significant role in evolution of fast/slow ice flow patterns during WAIS thinning, making it necessary to incorporate realistic GHF fields in predictive ice sheet models.
The Antarctic ice sheet plays a key role in control of the global climate and sea level. Then its ice mass changes have been estimated from in-situ geodetic observations, satellite observations such as satellite gravimetry and satellite altimetry as well. These estimations, however, include an uncertainty arising from the effects of GIA, where GIA is the rheological response of the solid Earth to the ice mass changes. With objective of observing the GIA effects, JARE (Japanese Antarctic Research Expedition) have conducted the repeated absolute gravity (AG) and continuous GNSS measurements and other geodetic observations in Dronning Maud Land (DML), East Antarctica. Especially, the repeated AG and continuous GNSS measurements at Syowa Station have been carried out since 1995, and these data reveal the temporal variations in both gravity and crustal deformation due to the GIA. JARE also succeeded the AG measurement at Langhovde during 2011/2012 austral summer, which was the first outdoor measurement in the JARE activity. Subsequently, we performed the outdoor AG measurement at Selungen, the central parts of the Sør Rondane Mts., during 2013 austral summer. Furthermore, we plan to conduct the combination of repeated AG and GNSS measurements at several sites on the bare rock area around Lutzzow-Holm Bay, DML in 2017/2018 austral summer. In this presentation, we will report the geodetic observations by JARE.
Quantifying the Antarctic Ice Sheet (AIS) mass balance remains challenging as several processes compete to differing degrees at the basin scale with regional variations, leading to multiple mass redistribution patterns. For example, analysis of linear trends in surface-height variations from 1992-2003 and 2002-2006 shows that the AIS is subject to decimetric scale variability over periods of a few years. Every year, snowfalls in Antarctica represent the equivalent of 6 mm of the mean sea level. Therefore, any fluctuation in precipitation can lead to changes in sea level. Besides, over the last decade, several major glaciers have been thinning at an accelerating rate. Understanding the processes that interact on the ice sheet is therefore important to precisely determine the response of the ice sheet to a rapid changing climate and estimate its contribution to sea level changes.

We estimate seasonal and interannual changes of the AIS between 01/2003 and 10/2010 and 09/2016 from a combined analysis of surface-elevation and surface-mass changes derived from Envisat data and GRACE solutions, respectively. While we obtain a good correlation for the interannual signal between the two techniques, differences in amplitude, phase, and spatial pattern are obtained for the seasonal signal. We investigate these discrepancies by comparing the crustal motion observed by GPS and those predicted using monthly surface mass balance derived from the regional atmospheric climate model RACMO.
Understanding the long-term changes in the ice sheets of Greenland and Antarctica has global climate significance, especially on long term global sea level rise predictions. We present results of satellite-derived ice sheet change time series of Greenland and Antarctica, covering up to a 25 year time span, and highlight the dynamic nature and of the ice sheet changes, including the large interannual variations and regional accelerations of major ice mass loss regions. We also highlight, using satellite data from a.o. the ESA Climate Change Initiative, how the combination of multiple satellite measurement types, such as mass change, ice velocities, elevation changes and solid earth land uplift from GNET and ANET, may improve the overall spatial and temporal monitoring the ice sheet changes.
Laboratory Observations of the High Temperature Creep of Polycrystalline Ice

Adam Treverrow\textsuperscript{1} (adam.treverrow@utas.edu.au), Bridie Le’Gallais\textsuperscript{2}, Jason Roberts\textsuperscript{3}
\textsuperscript{1}Antarctic Climate and Ecosystems Cooperative Research Centre, University of Tasmania, Hobart, Australia, \textsuperscript{2}University of Tasmania, Hobart, Australia, \textsuperscript{3}Australian Antarctic Division, Hobart, Australia

The largest source of uncertainty in predictions of future sea level is the contribution arising from the discharge of ice from the polar ice sheets. A key factor in reducing this uncertainty is to improve the numerical models used to predict ice sheet evolution. One important aspect of model development is to improve the constitutive relationship that describes the rheological properties of ice.

Factors influencing creep deformation rates include: the magnitudes of the stresses causing ice to deform; strain-induced anisotropy of polycrystalline ice, and temperature. Creep rates at high temperatures, within 2 degrees (K) of the melting point, are constrained by a relatively small number of laboratory observations due to the inherent difficulties in conducting experiments at such temperatures.

We present results from a series of laboratory ice deformation experiments conducted in simple shear at temperatures between -2°C and -0.3°C at 0.1 MPa (octahedral shear stress). Unlike previous experimental studies conducted at temperatures close to the melting point, these experiments were continued through to high shear strains (>10% strain) to ensure that anisotropic flow, compatible with the stress configuration, had developed.

These data contribute to the continued development of a constitutive relationship for polycrystalline ice that will improve the accuracy of ice sheet models and are relevant to model studies utilizing inverse methods to infer the spatial extent of basal sliding.
The Influence of Close-field Snow and Ice on Absolute-gravity Measurements

Jaakko Mäkinen¹ (jaakko.maken@nls.fi), Jyri Näränen¹, Antero Kukko¹, Hannu Koivula¹
¹Finnish Geospatial Research Institute, Masala, Finland

Often it is assumed that the change in gravity observed with absolute gravimeters in the Antarctic primarily depends on solid earth motion caused by Glacial Isostatic Adjustment and/or by elastic deformation due to changes in contemporary regional ice mass balance. However, variation in the close-field snow and ice masses can be caused for instance by local wind ablation/accumulation and does not necessarily reflect the regional mass balance. As the gravity stations typically are on nunataks well above the surrounding glaciers, the variation in the gravity effect by local masses may be considerable and it can mask the large-scale solid-earth phenomena of interest. The Finnish Geospatial Research Institute maintains time series of absolute gravity at five stations in Dronning Maud Land, starting at the Finnish base Aboa in 1994 and continuing later at Sanae IV, Novolazarevskaya, Maitri and Troll. We describe the various measurements used to monitor the near-field masses, from tachymetry and snow stake lines to GNSS, altimetry and Lidar, the calculation of corrections to observed gravity, and the influence of these corrections on the time series.
The Boulder Clay Glacier is a partially debris-covered glacier belonging to the Northern Foothills (Victoria Land, Antarctica) placed close to the Italian base Mario Zucchelli Station. In the frame of XXIX, XXX and XXXI Italian Antarctic Expeditions (from 2013-14 to 2015-16 summer seasons), several investigations, such as Ground Penetrating Radar (GPR), Geodetic Global Positioning System (GPS) network, multi-temporal satellite SAR interferometry (by means of Differential Interferometric Synthetic Aperture Radar, D-InSAR, methodologies), were carried out with the main aim of determining the general assessment of this glacier. The scientific tasks assigned to each single technique were: i) GPR: to investigate the main glacier features (i.e. superficial frozen lakes, shear zones and ice thickness); ii) GPS: to determine the ice flow speed vectors over 12 points spread over the moraine covered area; iii) D-InSAR: to estimate deformation trends and surface displacements evolution.

The image provided by the integration of the results pointed out that glacier deformation behavior is dependent, other than the bedrock shape, by also the relationship between the glacier, the moraine (that exhibits different deformation patterns) and the interaction with the ablation due to the strong katabatic winds blowing in the area.
Radio Echo Sounding and Seismic Observations at the David Glacier, Antarctica

Stefania Danesi\(^1\) (stefania.danesi@ingv.it), Simone Salimbeni\(^1\), Stefano Urbini\(^2\)

\(^1\)Istituto Nazionale di Geofisica e Vulcanologia, Bologna, Italy, \(^2\)Istituto Nazionale di Geofisica e Vulcanologia, Roma, Italy

Integrated geophysical observations in polar regions make it possible to study the interaction between lithosphere and cryosphere and their evolution in the framework of a global climate system. We have collected Radio Echo Sounding (RES) measurements combined with passive continue seismic observations in the area of the David Glacier (Victoria Land, Antarctica) in order to improve our knowledge about changes in basal conditions due to melting processes. This work provides detailed maps of the bedrock morphologies, ice thickness and physical condition at ice/bedrock interface in the domain of the David Glacier. The inferred 3D structural model of the ice and bedrock is integrated into the inversion algorithm in order to improve the accuracy of local seismicity location. In continuity with previous seismic monitoring experiments in the area, we analyze the seismicity induced by the glacier flow and we discuss the characteristic of seismic occurrences in terms of location, frequency and possible seasonal cycling.
Consistency between Changes in Simulated Climate and European Glacier Length

Hugues Goosse\textsuperscript{1} (hugues.goosse@uclouvain.be), François Klein\textsuperscript{2}, Ben Marzeion\textsuperscript{3}, Fabien Maussion\textsuperscript{4}, Paolo Pelucchi\textsuperscript{5}, Anouk Vlug\textsuperscript{3}

\textsuperscript{1}Université Catholique de Louvain (UCL), ELIC/TECLIM, Louvain-la-Neuve, Belgium, \textsuperscript{2}Université catholique de Louvain (UCL), ELIC/TECLIM, Louvain-la-Neuve, Belgium, \textsuperscript{3}Univ. Bremen, Bremen, Germany, \textsuperscript{4}Univ. of Innsbruck, Innsbruck, Austria, \textsuperscript{5}Imperial College, London, United Kingdom

It is standard to compare climate model results covering the past millennium to reconstructions based on various archives to test the ability of models to reproduce the observed climate variability in conditions close to the present ones. Up to now, glacier length fluctuations have not been used in this framework while it offers information on multi-decadal to centennial variations complementary to other records. One reason is that glacier length depends on several factors and so cannot be simply linked to simulated climate. However, climate model skill can be evaluated by comparing the glacier length provided by a global glacier model driven by the simulated temperature and precipitation to observations. This is done here using the version 1.0 of Open Global Glacier Model (OGGM) forced by fields derived from a range of simulations with global climate models over the past millennium. The focus is first on European glaciers. Sensitivity experiments are performed to estimate the uncertainty that can be related to the glacier model itself compared to the one that is due to the forcing derived from the climate model. These experiments are dealing with the initialisation of the glaciers in 850 CE, the uncertain creep parameter needed to compute ice dynamics, key parameters in the surface mass balance model, the way climate model biases are taken into account and the downscaling of model results at the location and altitude of the glaciers.
This study uses aerial photographs and LANDSAT and Sentinel 2 satellites images to determine the retreat dynamics of two tidewater glaciers from 1957 to 2016, Drummond (66°40´S, 65°43´W) and Widdowson (66°43´S, 65°46´W), in the Antarctic Peninsula western coast. A modified digital elevation model AsterDEM2 was used to characterize the morphology and the morphometry of their drainage basins. The two ice fronts have retreated during the period; however, the Widdowson Glacier had a more significant loss (36.37 km², 16.97% of the original area) and a higher snow line elevation (200 m a.s.l. in 2016) than the Drummond Glacier (19.11 km², 4.33% of the original area; snow line at 100 m a.s.l. in 2016). These differences, of two ice masses side by side and with the same flow orientation, are attributed to different surface slopes and proportion of accumulation areas. The smaller glacier has been more sensitive to environmental changes (e.g., increase in the regional mean annual temperature), and reached a stabilization point (supported to the lateral bedrock) only in 2001, while the Drummond front stabilized in 1974. The Widdowson Glacier has a steeper frontal sector, which may have influenced on the calving rate and generated a more efficient basal slip. The dynamics of these glaciers is also influenced by changes in ocean forcing, precipitation rates, surface melting and bedrock morphology.
Glacier Flow Acceleration in Response to the Local Climate Change

Songtao Ai¹ (ast@whu.edu.cn), Zemin Wang¹, Jiachun An¹, Yuande Yang¹
¹Wuhan University, Chinese Antarctic Center of Surveying and Mapping, Wuhan, China

Based on in-situ collected GPS data, high-precision ice velocities of a Svalbard glacier, Austre Lovénbreen, were observed over a decade during 2005-2017, including both horizontal and vertical annual surface ice velocities. GPS results indicate that the mass balance of this glacier is negative, which is identical to other neighbor glaciers. GPS data analysis revealed that the surface ice flow was stable in the beginning surveyed years, however, the ice flow velocities increased in recent two years.

A 3D finite element simulation proves that the ice flow acceleration is a response of the glacier to the warming local climate, but the glacier ice flow will slow down soon in the next decade suppose the current climate keeping steady.

Chukotka: Climate and Glacier Change

Maria Ananicheva¹ (maria_anan@rambler.ru)
²Institute of Geography RAS, Glaciology, Moscow, Russian Federation

The paper presents the assessment the current state of the Chukotka highlands' glaciers by satellite images at the background of climatic change, projection of glacier evolution in the near future. It also gives the general description of the regional socio-economic drivers of the region of study as a part of AACA-BCB (AMAP) cluster. Trends of the mean annual and summer temperature for entire Chukotka Peninsula within 1966-2012 are positive. Precipitation trends of annual sum and for cold period are negative in coastal regions, and positive on the continent between the Cross Gulf of Anandyrsiy estuary. Thus, climate processes occurring over Chukotka, do not contribute into the development and extension of glaciation.

Estimation of the evolution of the Chukchi Highlands' glacier was an objective to assess possible variant of evolution of the Chukotka glaciers consisted in construction of balance schemes for each glacier system by climatic data, which is the only available for this poorly studied region and in involving climate scenario, in our case for the time period up to 2030 (Ensemble of 31 scenario from SMIP5, RCP4.5).

Up to this time the glaciation of the Iskaten ridge and Provedensky Massif will greatly reduce, and glaciers of the Pekulney Range will disappear; the glaciers of Chantalsky Ridge (Amguema River Basin) will save their area by maximum.
Radioglaciological studies commenced relatively late in China. During CHINARE 21 (Chinese National Antarctic Research Expedition, 2004/05), Chinese glaciologists traversed to Dome A from the coastal Zhongshan Station for the first time and were able to survey the region on a detailed surface RES grid. Since then, different kinds of radar systems have been deployed for both fine-scale surveying networks in the Dome A and along the traverse route for multiple scientific purposes, such as mapping subglacial conditions, distinguishing crystal orientation fabric types, measuring internal layers and freeze-on ice. Significant motivation has been to search for the oldest ice on Earth and to map the unknown bedrock topography of the Gamburtsev Subglacial Mountains and infer the early origin and evolution of the AIS and the GSM. In 2015, China deployed its first fixed-wing airplane named “Snow Eagle 601” for Antarctic expeditions, and an international campaign of International Collaborative Exploration of the Cryosphere through Airborne Profiling in Princess Elizabeth Land was initiated. It has great implications for investigation of ice sheet expansion, stability and the subglacial geology of East Antarctica. In future, we will engage in and make Chinese contributions to more science issues, such as subglacial water and lakes, subglacial canyons and channels and the subglacial hydrological system, basal processes across grounding zones, bathymetry under ice shelves etc.
This paper investigates the current dynamics in proglacial geomorphology systems and glacier fluctuations in King George Island (KGI), South Shetland Islands, Antarctica, since 1956. The glaciological, sedimentary and remote sensing data analyses evidenced recent environmental changes. COSMO-SkyMed (Constellation of Small Satellites for Mediterranean Basin Observation), Wordview 2 and Sentinel 2 images were used for temporal analysis of glaciers outlines and recognition ice-marginal geomorphological features. From 1956 to 2017, the glaciers in Kraków and Warszawa Ice Fields presented a continuous retreat processes. Due to its small size and thermal conditions, these glaciers respond rapidly to climatic changes. The marine terminating outlet glaciers presented more lost area than land-terminating glaciers. A rapid ice-marginal evolution is evidenced in land-terminating glaciers as consequence of the glacial retreat processes. The geomorphological map of the recent ice-marginal areas showed several types of glacial deposits, such as frontal and lateral moraines, flutes, meltwater channels and erosional features like rock moutonnés, striations and U-shaped valleys. The results evidenced recent changes in proglacial and periglacial successional patterns for Wanda, Potter, Ecology, Znosco and Collins Glaciers. The Znosco Glacier changed the marine-land terminating for land-terminating conditions in last decade and reveal the rapid ice-marginal evolution.

Monitoring Recent Glacier Changes in Melimoyu Mount - Chile

Filipe Daros Idalino¹ (filipe.daros.idalino@gmail.com), Kátia Kellem da Rosa¹, Francisco Ferrando Acuña², Bijeeah Kozhikkadan Veettil³, Jefferson Cardia Simões³, Enoil de Souza Jr.⁴
¹Universidade Federal do Rio Grande do Sul / INCT da Criosfera, Geography, Porto Alegre, Brazil, ²Universidad de Chile, Santiago, Chile, ³Universidade Federal do Rio Grande do Sul / INCT da Criosfera, Porto Alegre, Brazil, ⁴University of Manitoba, Winnipeg, Canada

This work analysed the application of Sentinel-2 MultiSpectral images and GLIMS data in retreat mappings for to detect and estimate glacier area changes, between 1970 and 2017, in Melimoyu Mount, located in northern Patagonia, Chile. The results presented a decreased glaciers area of approximately by 35.61% in analysis period and there is an overall trend of glacial retreat. Majority of area loss has been identified for glaciers with mean elevation around 1700-1725 m. The decreasing trend in mean annual precipitation presented a possible connection with the recent glaciers changes in the study area, which indicates a large sensibility for meteorological variabilities on the region. This sensitivity also influenced by hypsometry, slope of the terrain and total area of glaciers. The glacier mapping using sentinel 2 data in 2017 provided conditions for new observations of rock glaciers in study area. Analysis of outline glaciers by manual delineation showed satisfactory results with application of Sentinel-2 MSI data to these environments, and use of these enables the continuity of retraction monitoring with greater accuracy of mapping.
This paper examines the influences of topographical factors on glaciers between 1971 and 2016 for 127 glaciers in Jankar Chhu watershed, north-west (NW) Himalaya using satellite remote sensing data and limited field observation. Change detection was done based on Corona KH-4B (1971), Landsat ETM+ (2000) and Sentinel 2A (2016) imageries restricted only to a set of 127 glaciers due to cloud masking. The relationship between the magnitude of glacier changes and a set of local factors was carried out using multivariate statistical techniques. Cumulative influence of this factors was evaluated for each glacier using Topographic Influence Index (TII) proposed by Garg et al., (2017). Our result show that:

1. glacier area decreased by 7.48 ± 2.17% between 1971 to 2016; whereas glacier retreated at an average rate of ~4.82 ± 0.35 m a⁻¹;
2. The debris cover area increased by 56.77 ± 3.33%, and the average ELA changed to ~20 m;
3. Δ Area (%) and Δ retreat (m) of glacier are strongly affected by local factors while Δ ELA does not show any significant relationship, indicating that it may be controlled by climatic factors and;
4. More than 75% of glaciers show moderate to high influence of local factors on Δ area based on TII values.

This study provides important insight into the local controls on recent de-glaciation which are of critical importance to assess the future glacier dynamics on a regional scale.
Snow Accumulation, Melting and Ice Thickness Variability on a Himalayan Glacier

Bhanu Pratap¹ (bhanu@ncaor.gov.in), Parmanand Sharma², Lavkush Patel², Ajit Singh², Vinay K Gaddam², Sunil Oulkar², Meloth Thamban³
¹National Center for Antarctic and Ocean Research, Himalayan Cryosphere, Vasco, India, ²National Center for Antarctic and Ocean Research, Himalayan Cryosphere, Vasco, India, ³National Center for Antarctic and Ocean Research, Polar Cryosphere, Vasco, India

Knowledge of different aspects of glacier dynamics is significant to understand the variety of glaciological processes and its characteristics. In this study, an attempt has been made to relate accumulation and ablation rate, and ice thickness pattern over Sutri Dhaka Glacier in Chandra basin, Western Himalaya. To investigate ice thickness, ground based radar survey has conducted using 16 MHz frequency in a distance mode. The radar derived ice thickness varies from 65 m to 310 m for the surveyed area on this glacier, respectively. Transverse profile of the survey formed the higher order of parabola due to friction forces at the margin against bedrock constraints. The study also revealed that the tributaries margin of the glacier had a greater thickness as compared to its main valley margin. The frequent avalanches on the side valley have a strong influence on the glacier behavior and ice thickness.

Sutri Dhaka is a debris free glacier and the observed snow accumulation rate during the last one decade at 5500 m asl varies from 16 cm to 34 cm w.e. and the standard deviation is 5.6 cm w.e. The Glacier has strong mass wasting during four consecutive negative balance years (2013-17) with the average melting of 0.74 m w.e. a⁻¹. Overall, the signature of accumulation, ice volume and mass balance reflect enhanced melting rate of Sutri Dhaka Glacier during last decade.
Variability of Thermal Regime and Snow Water Equivalent of Glaciers in Svalbard

Parmanand Sharma¹ (pnsharma@ncaor.gov.in), Lavkush Kumar Patel¹, Ajit Singh¹, Thamban Meloth¹
¹National Centre for Antarctic and Ocean Research (ESSO-NCAOR), Polar Science, Vasco da Gama, India

Many Arctic glaciers have been experiencing enhanced melting in response to ongoing global warming and are predicted to shrink faster over the next few decades. Vestre Broggerbreen (VB) and Feiringbreen (FB), two valley glaciers in Ny-Ålesund, Svalbard, Arctic have been monitored for annual mass balance, ice flux, surface ice movement and terminal retreat since last six years. As part of this, both the glaciers have been mapped for snow and ice thickness, sub glacier channel and distribution of warm and cold ice across the glacier tongue by using radar. Apart from radar derived snow depth, variability in snow accumulation pattern over both the glaciers has also been measured by snow pits, snow cores and snow probe. Results reveal that both the glaciers having mostly cold ice (below 0°C), except in the interior part of the glacier. There is small area (12% area) with warm ice (at 0°C) in the deep interior where ice is thicker than 130m and is warmed to the pressure melt point. We have also observed that while the glacier terminal has retreated, the warm ice area has reduced significantly (30%) during last six years. The mean average Snow Water Equivalent (SWE) for VB and FB were 600 ± 172 kgm⁻² during 2012-2017 and 382 ± 187 kgm⁻² during 2015-16 respectively. The strong correlations between snow depth and SWE for both the glaciers reflect the significant control of snow depth and altitude on SWE across the Svalbard valley glaciers.
In this contribution we summarize our glaciological investigations on the ice cap, which is covering the Mocho-Choshuenco Volcanic Complex located in the Northern Patagonian Andes. The climate on Mocho Ice Cap is relatively mild (+2.6°C annual mean temperature near the equilibrium line) and is marked by very high rates of accumulation. The Annual Surface Mass Balance of Mocho Glacier (one of the catchments of the ice cap) shows very high interannual variability. On average the balance is negative which coincides with the observed thinning and retreat of the glacier. Our research on the Mocho-Choshuenco Ice Cap includes surface mass balance and energy balance modelling, observation of the formation and drainage of glacial lakes and ice-flow modelling. Due to its easy access the ice cap is an ideal research laboratory for Patagonian Glaciers, which are usually hard to reach because of their remoteness and the extreme weather conditions.
Simulating the Surface Mass Balance of Ice Sheets in the ModelE2 GCM

Patrick Alexander1,2 (pma2107@ldeo.columbia.edu), Marco Tedesco1,2, Allegra N. LeGrande3, Elizabeth Fischer3, Maxwell Kelley2,4, Xavier Fettweis5, Gavin Schmidt2, Sophie M. J. Nowicki6

1Lamont-Doherty Earth Observatory of Columbia University, Marine Geology and Geophysics, Palisades, United States, 2NASA Goddard Institute for Space Studies, New York, United States, 3Columbia University, Center for Climate Systems Research, New York, United States, 4SciSpace LLC, New York, United States, 5University of Liège, Liège, Belgium, 6NASA Goddard Space Flight Center, Greenbelt, United States

Simulating the surface mass balance (SMB) of ice sheets in General Circulation Models (GCMs) is a challenge because of the coarse resolution and simple physics used to efficiently simulate global processes. However, algorithmic advances have allowed for a more sophisticated physical representation of ice sheets in GCMs. We have applied two improvements to the ice sheet surface in the NASA GISS ModelE2 GCM: an elevation class scheme, in which the surface model is run at multiple elevations within a single grid cell, and a sophisticated multi-layer snow model. We compare surface mass balance simulated for the Greenland ice sheet with state of the art regional climate model (RCM) simulations from the Modèle Atmosphérique Régionale (MAR), and satellite measurements. The simulated SMB is particularly sensitive to the representation of surface albedo and refreezing. Using a more realistic surface albedo consistent with satellite measurements more than doubles surface melt. Refreezing can prevent 50% of meltwater from leaving as runoff, but can also warm the snowpack, increasing the likelihood of melt. The addition of elevation classes has a more muted impact on SMB, resulting in changes of less than 10%. Over the Antarctic ice sheet, sublimation and precipitation play a more important role because runoff is a minor component of overall mass balance, highlighting the need for accurately capturing all components of SMB in a global model.
Land Surface Temperature Analyses of Miyar and Gangotri Glacier (2000 - 2016)

Ishita Manna¹ (mannaishita9@gmail.com), Milap Chand Sharma², Elora Chakraborty²

¹Jawaharlal Nehru University, Center for Study of Regional Development, School of Social Sciences, New Delhi, India, ²Jawaharlal Nehru University, New Delhi, India

In the absence of weather stations in the remote areas of the Lahaul District of Himachal Pradesh, satellite derived Land Surface Temperature data can supplement for the lack of data. The MOD11B3V6 images were processed for 17 years (2000-2016). The aim of this paper is to bridge the aspects of Temperature and the Frontal changes noted in the Glaciers of the Miyar Basin. Iso-lines showing temperature pattern of each year have been interpolated according to LST values of 78 geographical points on the Miyar and Bhagirathi watershed map. Major Findings- 1. Extent of Miyar Glacier shows a decrease of 0.11sqKm, a retreat of 0.15% in 16 years; Gangotri Glacier decreased by 0.07sqKm. 2. The LST shows a decreasing trend in the yearly averages at the Miyar Accumulation Area; negatively sloped graph at the R2 value of 0.13. Similarly, the Miyar Snout region shows a land surface temperature of -6.54°C in the year 2009 and the trend is negative with the R2 value of 0.12. Similarly in all of the tributary glaciers this trend has been seen. The range of temperature however has increased in the recent years and the R2 value is calculated to be 0.10 at the accumulation area and at the Miyar Glacier Snout, it is 0.08 with a positively sloped trend over the years. In Gangotri Glacier a there is little or no change, near accumulation area slight negative trend of 0.008 and 0.002 at snout. The study will be very helpful in understanding the glacier dynamics in relation temperature variation.
Modeling the Effect of Water-filled Crevasses on the Flow of Calving Glaciers

Eef van Dongen1 (vandongen@vaw.baug.ethz.ch), Guillaume Jouvet1, Daniel Farinotti1,2

1ETH Zurich/VAW, D-BAUG, Zürich, Switzerland, 2WSL Swiss Federal Institute for Forest Snow and Landscape Research, Birmensdorf, Switzerland

Observations in Greenland show that large-scale occasional calving events often contribute more to the mass loss of tidewater glaciers than small frequent events (Medrzycka et al., 2016). Large-scale calving events primarily result from the propagation of fractures triggered by high stresses and sustained by the presence of water, which causes the crack to deepen (Benn et al., 2007).

Here, a 2D Shallow Shelf Approximation (SSA) model is implemented with an ad-hoc boundary condition that accounts for the effect of water-filled crevasses on the ice flow and is applied to the calving front of Bowdoin glacier, North-West Greenland. Using the SSA instead of the more computationally expensive 3D Full Stokes (FS) model is justified since the contribution of the ice deformation to the total motion is small compared to the basal motion for the calving front of Bowdoin glacier. The SSA model is validated against the FS velocity field computed with Elmer/Ice and ice flow fields inferred by Unmanned Aerial Vehicle photogrammetry and feature-tracking techniques (Jouvet et al., 2017).

Seasonally Predicting European Glacier Mass Balance using the Arctic Oscillation

Matthias Huss1,2 (huss@vaw.baug.ethz.ch), Daniel Farinotti1,3
1ETH Zurich, Laboratory of Hydraulics, Hydrology and Glaciology (VAW), Zurich, Switzerland, 2University of Fribourg, Department of Geosciences, Fribourg, Switzerland, 3Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Birmensdorf, Switzerland

Estimates of the magnitude of glacier melt during the coming summer season are highly beneficial for water resource management but predicting meteorological conditions with a lead time of several months is challenging. Here, we explore the potential of large-scale atmospheric indices to explain and predict observed variations in long-term mass balance of Swiss glaciers. We rely on a comprehensive 70-year data set of seasonal mass balance observations from up to a dozen Swiss glaciers. Monthly indices of the major atmospheric/ocean modes (NAO, AO, AMO, ENSO) are available for the entire study period. By correlating aggregates of the indices over various combinations of months against observed winter, summer and annual glacier mass balance anomalies, we investigate the skill of the large-scale indices to explain mass balance variability. No significant correlations with Alpine winter mass balances were found. Also, indices averaged over the summer season or annual periods did not correlate with annual or summer balances. However, we found a significant correlation between the January-to-May Arctic Oscillation Index (air pressure differences in the North Atlantic) and glacier melt during the subsequent summer season. Fitting a regression model based on the AO index over 1948-2008 enables to correctly predict the sign of summer balance anomalies of the last decade in 90% of the cases and with a lead time of four months.
Response of Glaciers on James Ross Island to Regional Climate Variability

Kamil Láška¹ (laska@sci.muni.cz), Zbyněk Engel², Daniel Nývlt¹, Zdeněk Stachoň¹, Jan Kavan¹, Michael Matějka¹
¹Masaryk University, Faculty of Science, Department of Geography, Brno, Czech Republic, ²Charles University, Faculty of Science, Department of Physical Geography and Geocology, Praha, Czech Republic

Air temperature records from the Antarctic Peninsula (AP) region show prominent warming trend over the second half of the 20th century and a significant temperature decrease over last 10 years. Magnitude of interannual to decadal-scale climate variability, however, differs significantly between western and eastern side of the AP, reflecting the extreme internal variability of regional atmospheric circulation. In order to describe a response of glaciers to climate variability, we analyse surface mass-balance, equilibrium line altitude and air temperature data from Whisky Glacier and Davies Dome in the northern part of James Ross Island on the eastern side of the AP. The surface mass-balance changes were estimated using the glaciological method based on ablation stake measurements over the seven years period (2009/10-2016/17). Our results indicate a change from surface mass loss that prevailed on James Ross Island during the late 20th century to predominantly positive surface mass balance after 2009/10. We attribute the deceleration of the mass loss and the spatial pattern of surface mass-balance distribution to the snow redistribution by wind on both glaciers rather than to temperature changes.

Quantifying Greenland Water Budget from Top to Bottom using Radar Sounding

Winnie Chu¹ (wchu28@stanford.edu), Dustin Schroeder²
¹Stanford University, Department of Geophysics, Stanford, United States

On the Greenland ice sheet, drainage of surface meltwater produces complex velocity changes that vary temporarily and spatially. These differential responses likely relate to what happens to the water once it enters the ice and its interaction with both the englacial and subglacial drainage systems. However, most hydrologic studies using radar sounding focus on what happens at the bed, neglecting the role of the englacial system. Also, most radar observations only provide information at a single snapshot in time. The absence of continuous observations, along with separate treatment of different hydrologic components, makes comprehensive assessments of melt influence on velocity difficult. Here we demonstrate the application of a high-resolution ground-based radar system in Store Glacier in western Greenland to continuously measure hydrologic changes through the ice column to the bed. We capture the development of englacial water storage from spring to winter. We show how these seasonal changes in englacial storage coincide with basal drainage. We also present new techniques to quantify and constrain the amount of basal water storage from airborne radar sounder by merging reflectivity and specularity content of the bed echoes in their subglacial hydrologic context. By comparing bed echo properties with surface runoff models, we place observational constraints on the portion of surface water that is drained to the bed versus stored englacially along west coast of Greenland.
Assessing Patterns and Drivers of Surface Elevation Change on Devon Ice Cap

Claire Bernard-Grand'Maison¹ (cbern085@uottawa.ca), Luke Copland¹, David Burgess²

¹University of Ottawa, Geography, Environment and Geomatics, Ottawa, Canada, ²Natural Resources Canada, Geological Survey of Canada, Ottawa, Canada

Strongly negative mass balances have been observed for glaciers and ice caps in the Canadian Arctic over the past three decades, with a notable increase since 2005. Major uncertainties in current climate assessment reports include how glacier dynamics will change under these conditions, and the representativeness of in-situ surface mass balance point data extrapolated over broad spatial scales. In this study, we co-register a suite of digital elevation data of various resolutions (i.e. ArcticDEM, TanDEM-X, CryoSat-2, IceSAT and NASA airborne laser altimetry) available for Devon ice cap. From these datasets, we calculate volume change and estimate the geodetic mass balance of Devon ice cap for distinct time periods over the past 20+ years. Our focus is primarily over the northwest basin of the ice cap where in-situ surface mass balance has been measured since 1961. An integrated analysis of available ice surface velocities and derived surface elevation change is used to isolate thickness change solely due to surface mass balance (accumulation and melt), providing an independent validation to the long-term glaciological mass balance dataset. Results from this study will increase our knowledge of the reliability of this historical mass balance dataset, and associated estimates of the contribution of Devon ice cap to non-steric sea level rise since the 1960s.
Choosing the Puruogangri ice field in central Tibet where tectonic is stable, surface erosion is low and Quaternary glacial relicts are well preserved, and using calibrated $^{10}$Be surface exposure dating techniques, we compare the dates of Quaternary glaciations of the Puruogangri with those of cold records from the ice core and Quaternary glaciations in the Arctic and Antarctic and find that the major events were coeval in three regions, suggesting that they are controlled by the same mechanisms in a same climatic system.
Reconstructing the Evolution of Glacier Surface using Mass Balance Data

Javier Lapazaran\textsuperscript{1}, Jaime Otero\textsuperscript{1}, Darlington Mensah\textsuperscript{1}, Cayetana Recio-Blitz\textsuperscript{1}, Francisco Navarro\textsuperscript{1} \\
\textit{francisco.navarro@upm.es} \\
\textsuperscript{1}\textit{Universidad Politécnica de Madrid, Mathematics Applied to ICT, Madrid, Spain}

The availability of sufficiently accurate surface topography of glaciers is essential for a variety of glaciological studies, including glacier dynamics modelling and mass balance studies. In particular, for glacier dynamics modelling the surface topography data is necessary for inferring the bed topography from ice-thickness data collected using ground-penetrating radar. For surface mass balance estimates (SMB) using the glaciological method, surface topography is required for integrating to the entire glacier the observations performed at individual points (mass-balance stakes, snow-probing points, snow pits). However, quite often the dates of these observations do not coincide with that of the surface topography, which implies errors in the derived estimates. We present a method to estimate the elevation at any point on the glacier surface and at any date between those of two existing surface topographies, using the seasonal SMB data during the time period between the two available topographies. From the spatial interpolation of the surface elevation data at the initial and final dates, the proposed method reconstructs the surface elevation at any date within that period, in two steps: first, it estimates the elevation change due to the SMB, and second, it estimates the elevation change due to glacier dynamics.
Snow Accumulation Processes on a Retreating Antarctic Tidewater Glacier

Shelley MacDonell¹ (shelley.macdonell@ceaza.cl), Martin Sharp²
¹Centro de Estudios Avanzados en Zonas Aridas (CEAZA), La Serena, Chile, ²University of Alberta, Edmonton, Canada

The glacier complex on King George Island in the South Shetland Islands has been exhibiting accelerated rates of retreat over the last decade. Several studies have investigated the response of the upper parts of the ice cap, but the outlet glaciers have received less attention. The Ecology Glacier is a polythermal outlet glacier of the Warzawa ice field, which is located in the southern quadrant of King George Island. Even though a positive surface mass balance has been recorded, this glacier has been retreating at a relatively high rate, and analysis of bathymetry data suggests that there is an overdeepening at the current front of the Ecology Glacier, which might lead to enhanced retreat rates. As the glacier is sensitive to changes in climate and oceanic conditions, it is necessary to understand mass balance sensitivities. This study aims to understand accumulation processes on the Ecology Glacier during a winter season using a multi-method approach. We combine accumulation stake, snow probing, snowpit, glaciochemical and meteorological datasets taken over the course of one year with results from related mass balance modelling to understand snow deposition patterns, accumulation processes and biogeochemical cycling.
Spatial and Temporal Changes of the Snow Cover in Greenland

Martin Schneebeli¹ (schneebeli@slf.ch), Sascha Bellaire², Masashi Niwano³, Konrad Steffen³

¹WSL Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland; ²MRI/ JMA, Climate Research Department, Tsukuba, Japan, ³Swiss Federal Institute for Forest- Snow and Landscape Research WSL, Birmensdorf, Switzerland

The Greenland ice sheet (GrIS) is known to have the potential to contribute to sea level rise in a warming climate. The snow cover on the ice sheet, which is the direct link between a potentially warmer atmosphere and the ice itself, is, however, poorly investigated and little is known about the microstructure and especially about the spatial and temporal variability of the snowcover, except from indirect evidence from remote sensing. The dataset gathered during two campaigns in spring 2015 and 2016 are analyzed in detail. It represents the first detailed spatially distributed observation of the GrIS snowpack since the 1950ies. The current dataset consists of high-resolution snow profiles located at stations of the Greenland Climate Network. We link snow physics with snow cover modeling through the evaluation of the snow cover models with high-resolution snow microstructure measurements. Further, the measured variables are essential for remote sensing applications (e.g. correlation length for microwave remote sensing, snow surface SSA) and therefore provide the unique opportunity to unambiguously investigate the microwave emission as well as the albedo of the snowpack on an ice sheet.
Tidewater Glacier Retreat Throughout the Canadian Arctic Archipelago since 1958

Alison Cook¹ (alison.cook@durham.ac.uk), Luke Copland², Brice Noel³, Chris Stokes¹, Mike Bentley¹, Martin Sharp⁴
¹Durham University, Geography, Durham, United Kingdom, ²University of Ottawa, Geography, Ottawa, Canada, ³Utrecht University, IMAU, Utrecht, Netherlands, ⁴University of Alberta, Earth and Atmospheric Sciences, Edmonton, Canada

Recent studies of post-2000 observational data have shown variability in the dynamic ice discharge of tidewater glaciers throughout the Canadian Arctic Archipelago (CAA). Expanding this to all tidewater glaciers in the region on a decadal time scale can help identify when glacier retreat began, and determine longer-term temporal trends in mass balance.

Our study shows that over 94% of 300 tidewater glaciers in the CAA (from southern Baffin Island to Ellesmere Island, excluding those on the northern coast) have retreated since the earliest observational records (1958-1960). Mean overall length change between the 1950s and 2015 is -9.3 ma⁻¹ (± 1.38 SE) for the 211 glaciers in the Queen Elizabeth Islands, and -7.1 ma⁻¹ (± 0.72 SE) for the 89 glaciers on Baffin and Bylot Islands. Length change rates have been calculated across 6 time intervals, and results indicate a similar trend throughout the CAA: glaciers show slow retreat in early years, followed by acceleration in retreat rates since the early 2000s.

To understand the primary control behind regional changes, the results have been analysed alongside ocean temperature records and surface mass balance from the latest atmospheric climate model. Statistical analysis reveals that on a regional scale ocean temperatures have had little control on the frontal change rates. The clear correlation with ablation and runoff, however, shows the significant impact that atmospheric temperature has had on glacier fronts in this region.
Features of the Kolka Glacier Recovery after the Karmadon Disaster

Gennady Nosenko¹ (gnosenko@gmail.com), Oksana Rototaeva¹, Stanislav Nikitin¹
¹Institute of Geography Russian Academy of Sciences, Dept. of Glaciology, Moscow, Russian Federation

There were events that attracted attention by the grand scale of the glacial catastrophe and its consequences in the North Ossetia (Caucasus Mountains) in 2002. The Kolka Glacier was completely thrown out of its bed. The recovery of a new glacier in the empty circus of the Kolka glacier began almost immediately. This report describes the next stage of the state of the new Kolka glacier - relative stabilization - and analyzes the features of the process of its recovery based on the field observations data, modern space images and the data of changes in summer air temperatures and winter precipitation on the glacier area at the beginning of the 21st century. In recent years, the rate of increase in the area of the glacier does not exceed 0.015 km² per year. By September 2016, its area reached 1.11 km², the volume - about 0.044 km³. The conditions for the formation of a new glacier on the empty bottom of the circus differ significantly from the previous ones. In addition to increase in the summer air temperatures, the thermal balance in the circus has changed due to the increase of the open surface area of the bed and the lateral moraine. At the same time, the growth of the debris cover on the glacier restrains the melting process. Fumarolic activity in the crown area of the starboard side of the circus is preserved and this circumstance the restoration of the Kolka glacier.
Almost exactly 200 years ago, on 16 June 1818, the ice-dammed Mauvoisin lake drained catastrophically causing 44 fatalities and considerable damage in the Rhone Valley, Switzerland. We take the opportunity of this anniversary to analyze this remarkable glacier lake drainage with numerical simulations.

The Mauvoisin lake formed due to the advance of the Gietro glacier, which is located in a hanging side-valley of the Val de Bagnes. This advance caused ice avalanches to build up a regenerated glacier behind which a lake started to form in spring 1818. The authorities of the Canton Valais, under the lead of the engineer and early glaciologist Ignaz Venetz, decided to artificially drain the lake with a tunnel dug through the ice dam. The early phase of this mitigation measure was successful: the lake started draining through the tunnel on 13 June 1818 and its level lowered by 10m until 16 June. However, a backward incision of the spillway led to the failure of the ice dam and subsequent catastrophic drainage of the remaining lake water. The flood wave propagated down the Val de Bagnes and then down the Rhone valley.

We first give an overview over the historical events. We then present a model of the hydraulics of the lake drainage based on the melt enlargement and the backward incision of the spillway. We compare model results for a lake drainage with and without artificial tunnel to assess the effectiveness of the mitigation measures.
Glacier Changes in Western Greenland Derived from New Satellite and DEM Data

Frank Paul¹ (frank.paul@geo.uzh.ch), Philipp Rastner¹
¹University of Zurich, Department of Geography, Zurich, Switzerland

The region to the NW of Jacobshavn Isbrae (Disko Island to Svartenhuk Peninsula) in western Greenland is hosting >1000 glaciers and ice caps that receive comparably little attention. With the now available image as well as DEM data from the mid1980s (Landsat TM, Greenland Orthomap and AeroDEM) and ~2015 period (Landsat 8, Sentinel 2, TanDEM-X DEM and ArcticDEM), it is now possible to study past glacier fluctuations in detail. However, the region is well known for its surge-type glaciers of which the largest one had a massive surge in 1995/96 (advance >10 km). Their changes have to be excluded when interpreting length, area or volume changes in climatic terms as they easily dominate the overall change for the entire region.

In this study, we present a new glacier inventory derived from Landsat 8 and Sentinel 2 satellite scenes (2015-2017), as well as area and volume changes since the mid1980s using the above datasets. Glaciers were mapped with the band ratio method and subsequent manual correction (debris, water, shadow, seasonal snow, sea ice). Drainage divides and topographic data for all glaciers are derived from the TanDEM-X DEM. DEM artefacts required analysing elevation changes on selected glaciers only. We found generally retreating valley glacier tongues, a strong area decrease for ice caps at higher elevations, and volume loss (and/or gain) being strongest for glaciers that have surged. Their elevation changes (>150 m) can be well recognized despite DEM artefacts.
Glaciers cover about 36600 sq km area of the Svalbard Archipelago. Amongst the various types of glaciers present in the region, the most dominant ones are the continuous ice masses/sheets which are divided into smaller ice-streams by ridges, nunataks etc. Vestre Breggerbreen (VB) (~4.69 sq km) glacier has been studied over the period 2009 to 2016. Traditional methods of monitoring/mass balance estimation applied to studying the glacial dynamics and nature of ice body. Over the last seven years, VB-I shows negative mass balance with a striking similarity in pattern to that of Austre Breggerbreen. The moraines depicts that a probable recession of 1.2 km of VB snout has taken place over a century. Recent data also show regular retreat of the order of 12 m/yr, giving credence to the fact that low altitude glaciers are shrinking faster. The data show the variable surface velocity vector with the highest of 5m/yr at the central part of the glacier. The ice thickness estimated over large areas on VB-I glacier shows a maximum ice thickness of 105m. Basal stress pattern shows differential stress distribution developed within the glacier. Snow pit data shows numerous refreeze layers which could be correlated with the local temperature variations. The glacial melt water analysis shows possibility of the presence of elements like Th, U, which can be aid to thermal heating of the sub-surface of glaciers thereby adding to the list of causes for their diminishing in this area.
A 3D-assessment of Basal Freeze-on for a Greenland Ice-sheet Ablation Region

Gwendolyn J.-M. Leysinger Vieli (gwendolyn.leysinger@geo.uzh.ch), Mauro A. Werder, Andrea Walter, Martin P. Lüthi, Andreas Vieli

1University of Zurich, Geography, Zurich, Switzerland, 2ETH Zurich/VAW, Zurich, Switzerland

Recent ground penetrating radar observations have revealed plume-like englacial structures, rising from the ice-sheet base reaching up to half of the ice sheet thickness. Such structures are found in the interior as well as at the margin of the Antarctic and Greenland ice sheet and coincide with a rise in basal topography along ice flow. We undertake a detailed spatial analysis of basal water flow paths and the 3D-radar-structure of a plume-like feature in the ablation area of Eqip Sermia in West Greenland and suggest that this structure originates from basal freeze-on of ascending water flowing along the hydraulic gradient at the ice-sheet base. As the water at the base is abundant in the ablation region, the amount of water available for freeze-on may be quite substantial. By means of numerical modelling we investigate the effect of basal-freeze-on and the resulting 3D-structure. Further, this allows us to make some estimates about the total mass added due to basal freeze-on and to put it in the context of the catchment mass balance. Such refreezing of melt water at the base is currently not accounted for in traditional mass-balance assessments.
Marginal Lake Drainage and Implications at a Tidewater Glacier in Greenland

Andreas Vieli1 (andreas.vieli@geo.uzh.ch), Martin Luethi1, Philipp Rastner1, Christoph Rohner1, Luc Moreau2, Remy Mercenier1, Andrea Walter1,3, Nick Beaird4
1University of Zurich, Department of Geography, Zurich, Switzerland, 2Laboratoire CNRS EDYTEM, Chamonix, France, 3ETH Zurich/VAW, Zurich, Switzerland, 4Woods Hole Oceanographic Institution (WHOI), Woods Hole, United States

In summer 2014 a lake at the margin of the Greenland ice sheet drained irreversibly into the relatively shallow fjord of tidewater outlet glacier Eqip Sermia. Using time series of high resolution digital elevation models from the ArcticDEM project and UAV surveys, we investigate the evolution of the lake level, the geometric adjustment of the bounding calving front and the thinning trend of the main outlet glacier trunk between 2011 and 2014. We combine these data with time series of meteorological data, ground surface temperatures, satellite imagery, time-lapse photographs and fjord surface temperatures in order to reconstruct the timing and discharge rates of the drainage event and investigate potential triggering mechanisms. We find that the lake level dropped by 70m and drained subglacially a volume of 70 Mio m³ within 1 to 3 days. The lake drainage is unprecedented in the satellite era and seems to be preconditioned by the recent rapid thinning of the outlet glacier Eqip Sermia and triggered by a strong precipitation event. The large pulse of freshwater and entrained sediment had a profound impact on the circulation and water properties of the fjord and likely enhanced oceanic melt at the calving front. Further, the drainage event provides an excellent natural experiment for studying the geometric adjustment of the calving front that bounds the lake to sudden changes in lake level.
East-Antarctic Ice Stream Dynamics Inferred from Monitoring Icequake Activity

Denis Lombardi\textsuperscript{1} (lombardi@ipgp.fr), Thierry Camelbeeck\textsuperscript{2}, Lionel Benoit\textsuperscript{1}, Olivier Martin\textsuperscript{4}
\textsuperscript{1}Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Paris, France, \textsuperscript{2}Royal Observatory of Belgium, Brussels, Belgium, \textsuperscript{3}Université de Lausanne, Lausanne, Switzerland, \textsuperscript{4}Institut National de l’Informaton Geographique et Forestiere, Paris, France

In Antarctica, investigations of the interactions of fast moving ice streams with the underlying bedrock and coastal ice shelves provide crucial information about the ice sheet dynamics. Monitoring cryo-seismic activity sheds new perspectives on cryosphere studies. Since 2010 a permanent seismic station is installed at the Princess Elisabeth base, in the eastern Dronning Maud Land, East-Antarctica. During the 2014 campaign, 5 other temporary stations were deployed in the nearby Sør Rondane Mountains. Most of the recorded seismicity is of small magnitude (ML< 1.5) and restricted to the few small outlet glaciers cutting through the mountain chain. It is associated with largest ice flow speed and significant ice surface topography suggesting a source origin related to surface crevassing. Two other spots of seismicity are found 80 km westwards along a 30 km wide and flat ice stream. They are distributed upstream and downstream of a 1000 m high bedrock topography associated with a 75% ice flow speed decrease over an along-flow 25 km distance. While the seismicity upstream of this bedrock topography may be caused by the ice flow resistance on hard bedrock, the one downstream may be linked to the rapid increase of ice load over a sediment-covered bed. Investigations of time occurrence of seismic events confirm two distinct patterns and highlight seasonal variations of the ice stream dynamics.
Regional Modeling of the Antarctic Surface Mass Balance from Multiple Reanalyses

Cécile Agosta1,2,3 (cecile.agosta@gmail.com), Xavier Fettweis1, Christoph Kittel1, Charles Amory1, Hubert Gallée2
1Université de Liège, Laboratory of Climatology, Liège, Belgium, 2Université Grenoble Alpes / Institut des Géosciences de l’Environnement (IGE), CNRS - UMR 5001, Grenoble, France, 3LSCE (UMR 8212 CEA-CNRS-UVSQ/IPSL), Université Paris Saclay, Paris-Saclay, France

Given the scarcity of ground-based observations of the Antarctic surface mass balance (SMB) and the lack of remote sensing products covering the entire continent, outputs from regional climate models (RCM) have been extensively employed for mass balance studies of the Antarctic ice-sheet. The most reliable and used products are currently from the RCM RACMO2 at 27km resolution forced by ERA-Interim. Here we set up the polar-oriented regional climate model MAR for the Antarctic region at 35 km resolution and used 6 reanalyses as lateral boundary conditions (ERA-Interim, MERRA2, JRA-55, NCEP1, NCEP2 and 20CRv2) for 1979-2015.

Spatial differences in SMB between reanalyses and RCMs are primarily driven by differences in precipitation. Whereas SMB patterns are significantly divergent between reanalyses, this is no longer the case after the downscaling step with RCMs, which all show similarly good performances against ground-based SMB observations. Regional climate modeling is consequently a valuable step to obtain realistic Antarctic SMB patterns. A major uncertainty remain in katabatic channels at the ice-sheet margins, where MAR is significantly dryer than RACMO2 but where there is hardly no observation.

Finally, we show that the interannual and seasonal variability of RCM-downscaled SMB is mostly driven by the forcing reanalyses, with agreeing results between ERA-Interim, MERRA2 and JRA-55, whereas NCEP1, NCEP2 and 20CRv2 show dissimilar (spurious) temporal variabilities.
We present data from an array of airborne radar lines collected in the 2016/2017 Antarctic season in the region around Dome Fuji, Antarctica. The radar campaign is part of the Beyond EPICA - Oldest Ice (BE-OI), and aims to determine a suitable drilling location to reach undisturbed ice older than 1.5 Ma to extend the record of climate proxies derived from ice cores. The nearly 20,000 km of radar lines cover an area of about 170,000 km², with a spacing of 10 km for most lines and 15 km for the five southernmost lines. The data were measured with the AWI Electromagnetic Reflection (EMR) system on board the DC-3 aircraft Polar 6, with a 600 ns pulse at a frequency of 150 MHz. The processed and filtered radargrams were used to handpick prominent internal reflectors, and the upper boundary of the echo-free zone, a depth in which most internal radar reflections are lost, leaving a transparent layer between this depth and the bedrock. The setup of the radar system results in a vertical resolution of about 50m, with excellent returns from the bedrock, and also good results for internal reflections. Several consistent reflectors could be picked throughout most of the lines, allowing for tying in the results to the ice core at Dome F. Preliminary results show a varying thickness of the echo-free zone over the survey area, with an approximate thickness of 400 m in regions with thicker ice, and approximately half of this over the more rugged terrain with thinner ice.
A 30-year Mass Balance Data Set from the Hofsjökull Ice Cap, Central Iceland

Thorsteinn Thorsteinsson¹ (thor@vedur.is), Tómas Jóhannesson¹, Bergur Einarsson¹, Oddur Sigurðsson¹
¹Icelandic Meteorological Office, Reykjavík, Iceland

Temperate ice caps cover 10% of Iceland. They are located mainly in high-precipitation regions in the central highlands or near the southern coast and their total volume corresponds to a sea-level equivalent of 9 mm. A mass-balance program has been operated annually on Hofsjökull in the period 1989-2018. Standard measurements of winter and summer mass-balance have been conducted on three ice-flow basins comprising 40% of the ice cap, which currently has a total area of 825 km² and an estimated volume of 186 km³. The annual mass balance has been negative in all but five of the thirty years of measurements and mass loss occurred every year in the 20-year period 1995-2014. In total, Hofsjökull has lost more than 10% of its total volume since 1989. In recent years, digital elevation models of the ice cap have allowed more precise estimates of volume changes of the ice cap during 2-13 year time windows in the period 1986-2015. Comparison with the mass balance data set indicates that the traditional winter snow thickness and summer ablation measurements at ground locations overestimate the annual mass balance by 0.4 m w.eq. on average. We describe main results from the mass balance program, including data from snow-radar studies which have increased our knowledge of the precipitation distribution over Hofsjökull and helped explain the origin of the bias in ground-based measurements.
Mass Balance Modelling of Austre Grønfjordbreen Glacier, Svalbard

Nelly Elagina1, Stanislav Kutuzov1, Robert Chernov1, Ivan Lavrentiev1, Bulat Mavlyudov1, Arseniy Kudikov1

1Institute of Geography, Russian Academy of Sciences, Department of Glaciology, Moscow, Russian Federation

Recent efforts by the Institute of Geography RAS have been aimed at establishing mass balance observation at Austre Grønfjordbreen (7.6 km2) located 16 km south of Barentsburg. The Arctic archipelago Svalbard consists of a vast glacierized area which contributes significantly to the sea level rise outside of Greenland and Antarctica due to recent warming. The glaciers of Svalbard have already experienced an unprecedented increase in average summer temperatures, melt periods, and rainfall in late autumn and early summer. Noteworthy a full absence of Austre Grønfjordbreen accumulation zone was pointed out in recent years. Current goal is to determine the most suitable approach for mass balance simulations and its application for long time periods assessments.

The physical and mathematical modelling of the internal and external mass transfer of Austre Grønfjordbreen glacier were carried out using the field work data and remote observations. The dependence of the mass balance from the certain climatic factors is revealed. We apply spatially distributed model A-MELT (Rets et al., 2012) using all available glaciological and meteorological measurements carried out since 2012 and energy balance determination according to spatial grid. The snow line level has been reconstructed using all available satellite images from 1986 to 2016.

The obtained mass balance gradients are compared with the results of temperature-index simulations and traditional glaciological methods.
Reconstructing the Deglaciation of Ice-free Areas in the Antarctic Peninsula

The chronology of the deglaciation of the ice-free environments in the Maritime Antarctica has significant geomorphological and ecological implications. In the Antarctic Peninsula, most research has focused on lake sediment records to reconstruct the onset of deglaciation. This is the case for Byers (Livingston Island) and Barton peninsulas (King George Island). The dating of basal sediments collected from different lakes from these peninsulas enables inferences of the age of formation of each lake. The integration of multiple ages based on radiocarbon dating and thermoluminescence permits the reconstruction of regional spatial and temporal deglaciation patterns. In both peninsulas the deglaciation started at 8 ka cal BP, with the central parts progressively deglaciated at 5-6 ka cal BP. Finally, during the Late Holocene, glacier fronts remained confined to their current positions defined by the present frontal moraines, with minor advances and retreats. We are also conducting research in different ice-free areas using a multiple-dating approach combining absolute (cosmogenic, lichenometry) and relative dating techniques to reconstruct the spatio-temporal patterns of glacial oscillations since the Last Glacial Maximum. We will discuss the potential of these techniques as well as of key areas (nunataks) that will allow comparisons between present and past glacial thinning rates in order to evaluate the significance of recent patterns within the paleoenvironmental record.

Modelling the Drifting Snow Climate of the Antarctic Ice-sheet

Charles Amory¹ (charles.amory@uliege.be), Christoph Kittel¹, Hubert Gallee², Xavier Fettweis³, Cécile Agosta³
¹University of Liège, Liège, Belgium, ²Université Grenoble Alpes / Institut des Géosciences de l’Environnement (IGE), CNRS - UMR 5001, Grenoble, France, ³LSCE (UMR 8212 CEA-CNRS-UVSQ/IPSL), Université Paris Saclay, Paris-Saclay, France

Drifting snow is an important component of the Antarctic near-surface climate, particularly pronounced in windy coastal regions of the ice sheet. However, drifting snow measurements suffer from a high scarcity both in space and time, making it difficult to evaluate model results. This study evaluates the ability of the regional atmospheric model MAR to reproduce the drifting snow climate of Antarctica. MAR has been run at a fine spatial (15 km horizontal and 1 m vertical) resolution over the entire continent and forced by ERA-Interim (1979-2016) at its lateral and ocean boundaries. Model results are evaluated against a compilation of recent drifting snow data including visual observations, sensor-based measurements and continent-wide remote sensing products. Seasonal cycle, intra- and inter-annual variability of drifting snow frequency and, when available, horizontal snow mass transport are discussed.
Importance of Snow Cover for Changes in Glacier Geometry, Hansbreen, Svalbard

Mariusz Grabiec¹ (mariusz.grabiec@us.edu.pl), Michał Laska¹, Aleksander Uszczyk¹, Leo Decaux¹, Dariusz Ignatiuk¹, Tomasz Budzik¹
¹University of Silesia, Faculty of Earth Sciences, Sosnowiec, Poland

Snow is the material forming glaciers and ice caps, hence its supply, spatial distribution, metamorphism and decay are factors influencing geometry changes of ice masses all over the world. Regular studies on interseasonal snow depth variability have been carried out using radar sounding on Hansbreen since 2011. The results show strongly irregular snow distribution, with the thickest snow cover in the western section of the glacier. The conditions of snow deposition on remaining parts of the glacier are less favourable, but, at the same time, interseasonal variability of the snow depth is smaller there.

Asymmetric pattern of snow cover distribution on Hansbreen is not reflected in observed in the years 2011-2014 changes of surface geometry. Despite the fact that the western section of Hansbreen gets maximum snow accumulation, the actual reduction of the elevation in this area is the greatest. This demonstrates that the winter mass balance is not a decisive factor determining changes in glacier surface geometry. Hence, the change in geometry is largely controlled by spatially variable summer ablation and glacier dynamics. Asymmetric snow distribution only modifies the influence of the above factors on the glacier shape.
Based on measurements obtained from the deep ice wells, radar and space-based geodetic observations in Antarctica and Greenland, a number of phenomena of mass transfer in ice were registered which did not fit into the traditional, albeit hypothetical, ideas of monotonous uniform change in the dynamics of ice sheets. The availability of new experimental data calls for a review of the existing models of ice sheet dynamics, taking into account the following features:

1) The ice flow is characterized by sub-horizontal pullback according to the structure, properties and velocity of ice movement;
2) radar cross sections reflect “isochronous” as well as “isorheological” surfaces;
3) the upper layer of firn “runs down” the lower stratum;
4) the lower masses of ice in the ice sheets move faster, which leads to, among other things, formation of discharge structures;
5) the bottom third cross section contains structures of the infolded turbulent ice flow;
6) the general spreading of ice sheet represents an array of local glacial streams.
In recent years, the Karakoram Anomaly has attracted much attention. In order to better understand the causes of this phenomenon, the spatial pattern of the variations of the glaciers in the whole Tibetan Plateau should be explored on a longer time scale. During the Little Ice Age (LIA), the glaciers over the Tibetan Plateau advanced and formed easily recognizable end and lateral moraines, which could be used to identify the extents of glaciers. We recognized the distributions of the LIA’s moraines of about 2000 glaciers over the Tibetan Plateau. It was found that the glacier areas have reduced by larger than 25% in the southeast Tibetan Plateau and the northeast margin of the Tibetan Plateau while less than 10% in the northwest Tibetan Plateau (including the Karakoram) since the LIA. It's noted that the summer freezing level is much higher than the glacier median elevation in the southeast Tibetan Plateau while much lower in the northwest Tibetan Plateau, and the summer freezing level showed a decreasing trend in the northwest Tibetan Plateau (including the Karakoram) while increasing in the southeast Tibetan Plateau over the past decades. These imply that the summer freezing level play an important role in the spatial variations of the glaciers over the Tibetan Plateau.
One important but underestimated anthropogenic impact observed in polar deserts such as the McMurdo Dry Valleys is that of human movement. The unique glacial and lacustrine sediments found within the valley floors are typically associated with well-developed lag gravels and desert pavements. As footprints and walking tracks disrupt and break through these protective surfaces, the underlying fine-grained material is exposed and becomes susceptible to erosion and transport by wind. Therefore, the method in which field parties' travel across these surfaces is directly related to the long-term impact that may be observed.

To quantify such disturbances, we apply structure from motion photogrammetry (SfM) to map surficial impacts. A computation technique that analyses groups of overlapping input images, SfM creates a 3D point cloud of elevation values, similar to those produced from scanning laser systems. Combined with accurately measured ground control points, SfM-MVS allows high resolution, low error 3D models to be created at a 1:1 scale at a low cost.

Our initial results show that extremely high resolution digital terrain models (DTMs) of human impacts can be produced, from SfM-MVS derived clouds of up to 120 million points per square metre, using simple methodologies and equipment. The production of such DTMs at the sub-millimetre vertical scale can provide a wealth of information about the distribution of surface clasts and post disturbance morphology.
The Polar Rock Repository: Preservation of Geological Samples from Antarctica

Anne Grunow¹ (grunow.1@osu.edu)
¹Ohio State University, Byrd Polar and Climate Research Center, Columbus, United States

Geological field expeditions in polar regions are logistically difficult, financially expensive and can have a significant environmental impact on pristine regions. The scarcity of outcrop in Antarctica (98% ice-covered) makes previously collected rock samples very valuable to the science community. Samples from areas of unique geological heritage and sites of special scientific interest are available for research from the Polar Rock Repository (PRR), helping to lessen the impact of proposing additional field work in these distinctive and potentially fragile areas. The PRR was created by the US National Science Foundation, who recognized the need for preserving rock, dredge, and terrestrial core samples from polar areas. The PRR curates geological samples collected primarily from Antarctica and the southern oceans, providing full and open access to both samples and metadata via the PRR website. More than 44,000 samples are available from the PRR for scientific analysis to researchers around the globe. In addition to the samples and their basic metadata, the PRR archives supporting materials from the collector, images of the samples, field maps, air photos, thin sections and any associated bibliography/DOI's. An advanced search engine for the PRR website allows scientists to “drill down” into search results using categories and look-up object fields similar to websites like Amazon.
Peary Land of North Greenland is a land of the highest latitude in the northern hemisphere, but has received limited attention due to its extreme remoteness. Nevertheless, this area holds a celebrated Cambrian fossil locality, Sirius Passet (82° 47.603′ N, 42° 13.394′ W), which is a conservation Lagerstätte, producing soft-bodied marine animal fossils of ca. 520 Ma. Since the first discovery of Sirius Passet in 1984, there have been only seven times of palaeontological expeditions to the area. In 2016 and 2017 seasons, expeditions led by Korea Polar Research Institute collected ca. 1.5 tons of fossil slabs from the outcrop and the scree of the Lower Cambrian Buen Formation. The fossils include various metazoans, such as sponges, arthropods, stem-group arthropods, primitive mollusks, annelids, cycloneuralians including priapulids and loriciferans, primitive deuterostomes, and possible chordates, which would help reveal the aspect of the ‘Cambrian explosion’ of the animals. This area is part of the Northeast Greenland National Park which is the world’s largest protected land area with almost no permanent human settlement. North Greenland needs to be more understood in terms not only of geology, but also of ecology and other research fields. Korea Polar Research Institute is planning to visit the area for the next two years, which would bring more information on the palaeontology, geology, and ecology of this remote part of the world.
Geospatial Analysis of Protected Areas in Arctic Regions of Russia

Vladimir Kudrjashov

Russian State Hydrometeorological University, Department of Ecology, Saint Petersburg, Russian Federation

Geospatial analysis of the Russian Arctic protected areas (PA) has been carried out by specially developed information analysis system (IAS). Information support of PA system in the arctic region of Russia was fulfilled by the IAS. Performance of the IAS can be carried out under management of several operating systems. The IAS was characterized by the four structural organization levels connected with work flows and information exchange in the system. Geoinformation system (GIS) was applied as a background and intelligence core of the IAS. Spatial data base (DB) of the PA system was designed in terms of three freeware DB:
(i) WDPA World Database on Protected Areas of UNEP-WCMC,
(ii) CAFF DB of Conservation Arctic Flora and Fauna organization,
(iii) DB of organizations: Russian Social and Ecological Union, World Wildlife Fund, World Resources Institute, and the Transparent world. It was fulfilled through retrieving, processing, analysis and modeling on the spatial and attributive data of the PA. Protected areas were divided into the six arctic physical geography provinces. The PA system was described by means of the data analysis classical methods such as descriptive statistic parameters and several models of cluster-analysis with bootstrap replication approach. Artificial neural networks (ANN) were also used for the analysis, classification and modelling of the PA system.
Antarctica is the least developed and populated continent on Earth. But does the degree of human activity and impacts present challenge the imagination and preconceptions of a continent of wilderness? Continually increasing accessibility has seen research stations, historic sites, runways, field huts, weather stations, tourism landing areas, maintained traverse routes, and even lighthouses spread across the continent. Occupying these are a peak population of nearly 5,000 national program personnel and in excess of 35,000 tourists landing per year resulting in substantial human activity. The history of activity at these sites vary, with some exceeding 115 years. This human presence has resulted in localised modification to the environment with impacts to biological, scientific, aesthetic and wilderness values. This paper presents the first continent-wide measurement of these impacts, in the form of spatial datasets of the disturbance and building footprint. These pioneering data will help to present the actual scale of human impacts on protected Antarctic values, and will have implications and wide-reaching application for management of conservation and protected areas, policy, future development, and operations.
An Analysis of Environmental Incidents for a National Antarctic Program

Shaun Brooks¹ (stbrooks@utas.edu.au), Julia Jabour¹, Andy Sharman², Dana Bergstrom²
¹University of Tasmania, Institute for Marine and Antarctic Studies, Hobart, Australia, ²Australian Antarctic Division, Hobart, Australia

Research stations in Antarctica are concentrated on scarce ice-free habitats. Operating these stations in the harsh Antarctic climate provides many challenges, including the need to handle bulk fuel and cargo increasing the risk of environmental incidents. We examined 195 reports of environmental incidents from the Australian Antarctic Program, spanning six years, to investigate the impacts and pathways of contemporary environmental incidents. Fuel and chemical spills were most common, followed by biosecurity incursions. The majority of reports were assessed as having insignificant actual impacts. Either the incidents were small or rapid response and mitigation procedures minimised impact. During the period only one spill report (4000 l) was assessed as a ‘high’ impact. This is despite over 13 million litres of diesel utilised. The majority of incidents occurred within the existing station footprints. The pathways leading to the incidents varied, with technical causes predominately leading to spills, and procedural failures leading to biosecurity incursions. The large number of reports with inconsequential impacts suggest an effective environmental management system with a good culture of reporting environmental incidents. Our findings suggest that the key to continual improvement in an ongoing environmental management system is to learn from incidences and take action to prevent them occurring again, with an end-goal of minimising the residual risk as much as possible.
In October of 2016, nations made history by coming together to adopt the world's largest marine protected area (MPA) in the Ross Sea, Antarctica. This feat required the consensus of the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR), comprised of 24 countries plus the European Union, and took five years of intense international negotiations, and more than 10 years of scientific planning. But what actually led to consensus in 2016? I will present on a five-year case study of the Ross Sea MPA process to reveal what conditions led to success in the ultimate adoption of the MPA. Some key factors included high-level diplomacy between Russia and the United States, a decade of scientific effort that involved hundreds of scientists from all over the world, and a wave of targeted international media and the resulting pressure from millions of global citizens. This talk will also reflect on CCAMLR’s ability to find the political will to protect 1.55 million km² of the Ross Sea region, demonstrating international leadership and inspiring hope that despite political tensions in other parts of the world, the Antarctic continues to be a global commons dedicated to peace, science and conservation.
Development of a CCAMLR Marine Protected Area in the Antarctic Weddell Sea

Katharina Teschke\textsuperscript{1,2}, Hendrik Pehlke\textsuperscript{1,2}, Thomas Brey\textsuperscript{1,2} (thomas.brey@awi.de)
\textsuperscript{1}Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, \textsuperscript{2}Helmholtz Institute for Functional Marine Biodiversity (HIFMB) at University Oldenburg, Oldenburg, Germany

The Antarctic Ocean may contribute considerably to the global network of Marine Protected Areas (MPA), as proposed by the World Summit on Sustainable Development in 2002. The Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) is responsible for establishing Antarctic MPAs. Within the CCAMLR framework, Germany leads the initiative to establish a MPA in the Weddell Sea region and our group develops the scientific foundation for this task. Here, we describe the development of the Weddell Sea MPA proposal within the political context, albeit with emphasis on its scientific foundation. Our intention is twofold, (i) to explain the science involved and its specifics in the Antarctic region, and (ii) to visualize how our scientific work is embedded in the political framework constituted by the diverse interests present within CCAMLR. We will highlight those issues and steps in particular that represent the most sensitive obstacles on the road towards a CCAMLR Weddell Sea MPA.
Since 2011, the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) has been working on the development of a representative network of Marine Protected Areas (MPA) around the southern oceans, with the main objective of the protection of biodiversity. In order to achieve this, during CCAMLR’s annual meeting 2017, Argentina and Chile introduced a preliminary proposal for a MPA in the West Antarctic Peninsula and the southern Scotia Arc (D1MPA). The D1MPA proposal is the outcome of an inclusive, multinational process that started in 2012, based on 143 spatial data layers and associated conservation objectives and conservation targets. Priority Areas for Conservation have been identified taking into account potential threats posed by climate change and krill fishery. Preliminary boundaries for the D1MPA were introduced, in order to assist with the planning process and future management of the area. The aims of this presentation are to introduce the D1MPA to a wider scientific community, and to look for synergies amongst different actors/stakeholders involved in the Antarctic Treaty System.
The register of Antarctic Species (RAS) is an essential taxonomic compilation system, which serves the scientific community by providing all authorised taxonomic information for Antarctic and the Southern Ocean biota. RAS builds upon the Register of Antarctic Marine Species (RAMS) and forms an integral Antarctic component of World Register of Marine Species (WoRMS).

Here we highlight our recent achievements in harmonising and updating the taxonomy in RAS by cross-referencing information from databases of species. Information from the Oceanic Biogeographic Information System (OBIS), Global Biodiversity Information Facility (GBIF) and ANTarctic Algae DATAbase (ANTADATA) are currently being examined by the taxonomic editors of WoRMS, Interim Register of Marine and Nonmarine Genera (IRMNG) and RAS for this purpose.

RAS is the most complete and thorough authorised compilation of the taxonomic diversity of Antarctica and the Southern Ocean. With a cleaned-up authorised backbone, it aims to serve the scientific community by, for instance, providing knowledge on the taxonomic accumulation at a spatiotemporal scale, identifying taxonomic groups that are under-represented, and offering an open source analytical tool for scientists with similar interests in this and other regions.
Antarctic Marine Spatial Protection in Black and White

Ricardo Roura\textsuperscript{1} (ricardo@antarcticocean.org), Claire Christian\textsuperscript{1}, Nicole Bransome\textsuperscript{2}

\textsuperscript{1}Antarctic and Southern Ocean Coalition, Washington, DC, United States, \textsuperscript{2}The Pew Charitable Trusts, Washington, DC, United States

Spatial protection is one of the tools used to protect polar marine environments. In the Southern Ocean, the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) and related technical bodies use several forms of area-based instruments to meet the objectives of the 1980 CAMLR Convention. These include Small Scale Research Units (SSRUs), Vulnerable Marine Ecosystem (VME) areas, and Marine Protected Areas (MPAs), the latter having been considered by CCAMLR since 2009. Two CCAMLR MPAs have been adopted, and three more have been proposed. Some of these instruments provide temporary closures, and some include zoning approaches that regulate activities like research and fishing. Overall, marine spatial protection schemes apply across a range of spatial and temporal scales, target species, and activities. Aside from inherent scientific complexities, the adoption and implementation of further protection measures (such as MPAs) has proven to be increasingly difficult due to political and economic considerations. In this presentation, we attempt to present this complex arrangement in black and white. We address basic questions concerning the application of these tools in the Southern Ocean. What activities are covered by these instruments, and when? What are the gaps in marine spatial protection? We provide an overview of the current status of Southern Ocean area protections, and make recommendations for improvements.
Providing the Antarctic policy community the tools and knowledge to support environmental management is critical for both the health of the Antarctic environment but also the Antarctic Treaty itself. This paper will introduce a tool that has been designed to provide context to, and assist, the Antarctic Policy community in the planning, permitting, and implementation of Antarctic activities. The tool, which has been developed with input from the Antarctic Policy community, leverages new and existing insights into the environmental pressures facing the Antarctic continent through a range of climate, biological, human activity, geological and soil perspectives.

The resulting tool is based on the established principle of a 'spatial decision support system', an interactive approach that provides knowledge to support management using analysis of spatially explicit data. We expect that this tool would be utilised to enable the conservation of the Antarctic continent through activities such as: investigating a NNS incursion and the likelihood of continued incursions in areas based on current and future climate as well as current and predicted future human activity; the comparison of multiple sites for future activities or to provide a set of baseline environmental data to support area protection; and supporting a CEP Member to undertake Environmental Impact Assessment of activities in context with regional scale environmental patterns.
Arctic marine resources overlap is increasing (in space and time) as climate change narrows the availability of appropriate habitat ranges for existing species to survive, and new species enter and compete. This challenges the management of both commercial and ecosystem-valued species. Two invasive crab species (snow crab and red king crab) offer a platform to explore adaptive conservation challenges for Arctic countries facing dynamic and spatial changes in new (crab) and existing (benthic and commercial) resource productivity. Shifting supply (US, CAN, NOR, RUS) and increasing demand (esp. Asia) add economic uncertainty to the ecological changes. Ongoing sovereign and international policy interests matter, as they evolve in ongoing legal cases. The crabs differ in their uncertainty, biology, economic, climatic and political factors. We exploit these differences using quantitative and qualitative data in a bioeconomic framework that spans time and space dimensions. The crab invasions in the Barents Sea region serve as a building block for broader pan Arctic conservation issues in the Year of Polar Prediction and beyond. Optimal decision-making regarding commercial species such as crab in ecosystems must incorporate how strategic institutional shifts, occurring in response to the economic incentives, asymmetrically affect local and global stakeholders in addition to standard concerns over ecological and economic damages amidst climate change.
Ex-situ Conservation of Polar Cyanobacteria in the BCCM/ULC Collection

Annick Wilmotte¹ (awilmotte@ulg.ac.be), Kim Beets¹, Veronique Simons², Yannick Lara¹,³,⁴, Benoit Durieu¹, Luc Cornet¹,⁵, Denis Baurain⁵, H Dail Laughinghouse⁶
¹University of Liège, InBios-Centre for Protein Engineering, Liège, Belgium, ²Université catholique de Louvain (UCL), BCCM/MUCL, Louvain la Neuve, Belgium, ³University of Liège, UR-Geology—Paleo-Biogeology-Botany-Palynology, Liège, Belgium, ⁴University of Liège, Microbial Processes and Interactions - GemblouxAgroBioTech, Gembloux, Belgium, ⁵University of Liège, InBioS—PhytoSYSTEMS, Eukaryotic Phylogenomics, Liège, Belgium, ⁶University of Florida/IFAS, Fort Lauderdale Research and Education Center, Fort Lauderdale, United States

The BCCM/ULC public collection is funded by the Belgian Science Policy Office (BELSPO) and aims to gather a representative portion of Polar cyanobacterial diversity from different ecological origins (limnetic microbial mats, soil crusts, cryoconites, endoliths, etc.) and ensure their ex-situ conservation in a context of global change. These strains are available for researchers to study the biodiversity, taxonomy, evolution, adaptations to harsh environmental conditions, and genomic make-up of Polar cyanobacteria. Currently, there are 120 cyanobacterial strains of Polar origin in the collection (catalogue: http://bccm.belspo.be/catalogues/ulc-catalogue-search). The strains are kept living and their cryopreservation is currently tested. The collection is ISO 9001 certified for depositing and distributing strains, as part of the multi-site certification of the Belgian Coordinated Collections of Microorganisms (BCCM) consortium.

Morphological and molecular identification (based on 16S rRNA sequences) indicate that the strains belong to the orders Chroococcales, Chroococcidiopsidales, Nostocales, Oscillatoriales, Pleurocapsales, and Synechococcales. This broad genotypic distribution makes the BCCM/ULC collection particularly interesting for phylogenomic studies. The genomes of several strains are currently being sequenced and the first genome of an Antarctic cyanobacterial strain, Phormidesmis priestleyi ULC007 was recently published.
Krill for All: What the Antarctic Krill Fishery Can Learn from Other Systems

Nicole Bransome¹ (nbransome@pewtrusts.org), Rodolfo Werner²,³

The notion that marine predators (seabirds and mammals) and fisheries compete for the same resources (i.e., small pelagic fish) has been of interest to the marine conservation community for decades. In the Southern Ocean, fishing grounds for Antarctic krill (Euphausia superba) overlap with foraging ranges of krill-dependent predators. Combined with the impacts of climate change, competition for resources in the Southern Ocean could compromise conditions for Southern Ocean species, particularly as the fishery grows. To address these challenges, the Scientific Committee of the Commission for the Conservation of Antarctic Marine Living Resources has agreed to advance ecosystem-based management for the krill fishery in its 2017-2021 work plan. Here, we provide an overview of Antarctic krill fisheries management. Next, we review practices for detecting and managing for competition between marine predators and fisheries, focusing on two recent synthesis workshops. These workshops evaluated three approaches to understand fisheries impacts on seabirds and other predators:
1) models including food web models that parameterize biomass
2) Experimental manipulation of fisheries (e.g., time-area closures) in the vicinity of seabird colonies or marine mammal rookeries and
3) observational studies.
We share best practices including data requirements and method variations, and hope to initiate a dialogue where practitioners from Antarctica and other systems can share lessons learned.
Fildes Peninsula, King George Island, South Shetland Islands, Antarctic, is characterized by a high biodiversity and hosts six permanent stations and an airport turning the region into a major logistic hub for the Antarctic Peninsula. It is the scene of a multitude of human activities including scientific research, station operations, transport logistics and tourism. Consequently, the human pressure on the local ecosystem affects natural and historical values. Numerous provisions and guidelines, in particular the Madrid Protocol, have been developed in order to reduce negative impacts of human activities on fauna and flora. Most of the legally binding and non-binding provisions have relevance on Fildes Peninsula due to the unique concentration of different human activities.

Human activities and environmental impacts on Fildes Peninsula have been documented and quantified since 2003/04 and have repeatedly revealed substantial shortcomings in the implementation of some aspects of the Madrid Protocol by resident national Antarctic programmes. Various improvements are in opposition with current observations of persistent breaches of the legal requirements for environmental protection. Sadly, the lack of consensus of the local stakeholders hampers the immediate implementation of effective management measures along with an accompanying monitoring scheme, which is required to prevent a further degradation of the habitat and to safeguard scientific and environmental values in the area.
The waters around South Georgia and the South Sandwich Islands are home to some of the highest levels of marine biodiversity in the Southern Ocean. In 2012 the regional government established a large IUCN category IV marine protected area for the conservation of this diversity. With the MPA currently in a period of review, a detailed assessment of the benthic biogeography of the region is paramount, if the importance of its benthic habitats are to be reflected in spatial planning policy for the region. There is however a mismatch between the size of this very large MPA and the biological data available to underpin its establishment and inform on its zonation.

Here we present the findings of a three-year project to map benthic habitats around South Georgia from coastal waters to deep-sea. Habitat mapping has increasingly been adopted as a means of addressing paucity in biological data, through use of environmental proxies and biological surrogates. We integrated biological, geophysical and oceanographic data to evaluate the application of landscape mapping and an ensemble approach to predictive distribution modelling, in assessing the benthic community structure of the region. This ambitious synthesis of multi-disciplinary information enabled, for the first time in the Southern Ocean, a biotopic characterisation of an entire archipelago's benthic habitats and provided a framework for policy makers to set priorities for its future management.
Conserving Terrestrial Antarctic Biodiversity in the Face of Multiple Threats

Jasmine Lee¹ (jasmine.lee1@uqconnect.edu.au)
²University of Queensland, Centre for Biodiversity and Conservation Science, Brisbane, Australia

Like many corners of the globe, Antarctica is subject to multiple threatening processes, including climate change, invasive species and an expanding human footprint. Prioritising management actions in the face of these multiple threats is a challenging, yet essential goal for progressing biodiversity conservation in the region. One method of prioritising management actions for taxonomic groups or regions is using a Priority Threat Management (PTM) approach, which relies on expert elicitation to derive a cost-efficient outcome. We applied the PTM approach to terrestrial Antarctic biodiversity in an international workshop that brought together over twenty-five biodiversity experts, logistics managers and policymakers in Belgium, in July 2017. Here I will present the results from this workshop, including the identification of management strategies and priority actions to be employed across the Antarctic region. This work represents a substantial leap for conservation planning in the region and will be of great use to future management decisions.
The problem of invasive species in ships' ballast water is getting large over the last few decades due to the expanded trade and traffic volume. Quantitative data show an alarming rate of increasing bio-invasions in new areas. The International Convention for the Control and Management of Ships' Ballast Water and Sediments (BWM Convention) is a new international convention to prevent the potentially devastating effects of the spread of harmful aquatic organisms carried by ship ballast water has been adopted by the International Maritime Organization (IMO). IMO has also adopted the International Code for Ships Operating in Polar Waters (Polar Code). The Polar Code is intended to cover the full range of shipping-related matters relevant to navigation in waters surrounding the two poles - ship design, construction, and equipment; operational and training concerns; search and rescue; and, equally important, the protection of the unique environment and Eco-systems of the polar regions.

Considering that the shipping traffic already increased in Arctic because of the new routes, operations in the Arctic and even Antarctic environments are exposed to a number of unique risks. In this work, authors analyze and compare Polar Code and BWM, also evaluates the new requirements for marine environmental protection and safety of ships for these remote and sensitive areas.
While Arctic and Antarctic have some similar geographic aspects, they exhibit differences such as administration and legal status conditional to their location. On the basis of scientific predictions, Arctic is warming faster than the global average. The annual minimum Arctic sea ice extent has declined by 50% since late 1970’s. On the other hand the giant iceberg broke free from Antarctica’s Larsen C ice shelf which was the largest ever recorded. According to sea ice modeling scenarios; Arctic region, is under risk to have larger openings in the future, might provide a wider area for shipping operations. Unfortunately, several collisions occurred in the Arctic already during such operations. Those incidents have been caused through the special conditions which underlines the special need for appropriate ship safety infrastructure in form of ports of distress, maritime salvage stations and bases for search and rescue operations. Arctic is surrounded by land however Antarctica surrounded by the Southern Ocean which means search and rescue operation standards cannot be same. IMO has adopted the Polar Code which includes existing regulations on ship safety and pollution prevention of Polar Regions. However, there is still a debate if it provides significant additional protection for Antarctic waters. In this study we will discuss the lack of any significant new provisions in Polar Code.
Establishing the Sea Ice Proxy IPSO\textsubscript{25} at the Western Antarctic Peninsula

Maria-Elena Vorrath\textsuperscript{1} (maria-elena.vorrath@awi.de), Juliane Müller\textsuperscript{1}, Oliver Esper\textsuperscript{1}, Gesine Mollenhauer\textsuperscript{1}, Christian Haas\textsuperscript{1}, Jens Hefter\textsuperscript{1}, Frank Lamy\textsuperscript{1}

\textsuperscript{1}Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

Sea ice proxies are important and useful tools to reconstruct the climate and environmental history in polar regions. In the Southern Ocean, the biomarker IPSO\textsubscript{25}, a highly branched isoprenoid (HBI) diene produced by sea ice diatoms (Belt et al., 2016), is not well established yet. To evaluate the advantages and limitations of IPSO\textsubscript{25}, recent ocean surface sediments from the southern Drake Passage and the Western Antarctic Peninsula (WAP) were used for an analysis of several biomarkers (HBIs, sterols, alkenones, GDGTs) and diatom assemblages.

The concentrations of IPSO\textsubscript{25} are significantly high along the WAP and on the shelf, pointing to a spring sea ice cover. In contrast, IPSO\textsubscript{25} is absent in Drake Passage sediments. Similarly, the distribution of open marine and sea ice diatoms suggests a seasonal sea ice coverage at the shelf, along the Bransfield Strait and a reduced sea ice extent towards the continental slope up to 61° S. These proxy-based sea ice estimates are in good agreement with satellite-derived sea ice data. The further consideration of e.g. higher unsaturated HBIs alongside IPSO\textsubscript{25} proves helpful and supports the application of IPSO\textsubscript{25} as a suitable tool for sea ice and environmental studies of the past in the Southern Ocean and Antarctica.

Sediment Trap Particles (2014 - 2016) in the Terra Nova Bay of the Ross Sea

Boo-Keun Khim¹ (bkkhim@pusan.ac.kr), Hyeong Jeek Kim², Kyu-Cheul Yoo³, Hyun Cheol Kim³, Sunghan Kim³, Sangbeom Ha¹, Ho Il Yoon³

¹Pusan National University, Busan, Korea, Republic of, ²Korea Advanced Institute of Science and Technology, Ansan, Korea, Republic of, ³Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of

KOPRI mooring system has been operated at Site X1 (74°50.27’S, 166°15.89’E, 1,050 m) during March 2014 to Dec. 2016 and at Site X2 (74°33.13’S, 167°38.92’E, 850 m) during Feb. 2015 to Jan. 2017, respectively, in the trough of Drygalski Basin adjacent to Jangbogo Station of the Terra Nova Bay in the southwestern Ross Sea. The bottom-tethered mooring system was deployed at 550 m below sea level (mbsl) at Site X1 and 350 mbsl at Site X2, consisting of a Seaguard RCM current meter, a SBE Micro CAT conductivity/temperature recorder, and a 13-cup time-series sediment trap. However, sediment trap system was not operated at Site X1 during a year of 2015. All flux data (total mass, CaCO₃, organic carbon, and biogenic opal) of sediment trap particles show the distinct seasonal and inter-annual variations. Biogenic opal flux occupies more than half of total mass flux, indicating that the seasonal diatom bloom is a key process to contribute to the biogenic opal composition. Higher flux occurred seasonally during a short time of March to May at both sites, but a peculiar high total flux continued from Feb. to June 2015 at Site X2. During this period, the abnormally high CaCO₃ flux was observed. Inter-annual variation is also distinct, showing that the total flux in April 2016 was remarkably high particularly at Site X1. These preliminary analytical results will be discussed in terms of physical and sea ice data which have been organized.
Analysis of Synoptic Variability of the Antarctic MIZ with in Situ Observations

Ehlke de Jong¹ (djnehl001@myuct.ac.za), Marcello Vichi¹, Carolin Mehlmann², Piotr Minakowski², Thomas Richter²
¹University of Cape Town, Oceanography and Marine Research Institute, Cape Town, South Africa, ²University of Magdeburg, Institute of Analysis and Numerics, Magdeburg, Germany

Our knowledge of sea ice variability, which contributes to the detection of climate change trends, stems primarily from remotely sensed information. However, sea ice in the Southern Ocean is characterised by large variability that remains unresolved and limits our confidence in the remotely sensed products. Although one of the biggest seasonal changes on Earth is the annual advance and retreat of the Antarctic sea-ice cover, relatively little attention has been given to the processes by which the marginal ice zone (MIZ) edge forms and responds to synoptic events. The objective of this study was to compare sea-ice observations from the SA Agulhas II to high resolution satellite imagery when transecting the MIZ. The location of the ship was tracked, allowing a more quantitative description of spatial sea-ice characteristics, specifically focusing on the MIZ and its edge. SAR as well as ASI-AMSR2 data were used to retrieve sea-ice properties. Extent and concentration were investigated to evaluate the quality of satellite retrievals with respect to on-board observational estimates, based on the ASPeCt protocol. To maximize the retrieval of information from previous cruises not specifically dedicated to sea-ice observations, an algorithm was developed to automatically retrieve sea ice concentration from still images and videos. This method can be used to obtain quantitative sea-ice data from vessels of opportunity without the need to have trained personnel on-board.
Leads are elongated cracks within the pack ice more than 50 m in width and up to several hundreds of kilometers in length. Since sea-ice leads influence the lower atmosphere as well as the ocean it is crucial to specify their temporal and spatial patterns. They are caused by mechanical forcing such as ocean currents or wind stress and are therefore short-lived and fast moving objects. Sea-ice leads influence e.g. the fluxes of moisture and sensible heat from the ocean to the atmosphere as well as the ice production. The characteristics of leads require a temporally and spatially accurate monitoring. Satellite thermal imagery from the MODIS sensor is used to produce daily potential lead maps for the entire southern ocean at a spatial resolution of 1.5 km. Data are analyzed for the winter periods from 2002 to 2017. Digital image processing and advanced filtering techniques are used. In particular, fuzzy logic is applied to minimize errors induced by a misclassification of leads caused by clouds. A variety of lead characteristics e.g. the object eccentricity is taken into account to distinguish between leads and artifacts. Here we present improvements of the filtering algorithms and preliminary results of potential lead occurrences in the Southern Ocean.
Pancake and frazil ice represent an important component of the Arctic and Antarctic cryosphere, especially in the Marginal Ice Zones. The retrieval of its thickness by remote sensing is, in general, a very difficult task. A processing system has been developed and refined by these authors in the framework of the EU SPICES project; it is meant for routinely deriving ice thickness in frazil-pancake regions using the spectral changes in wave spectra from imagery provided by space-borne SAR systems. This methodology has been successfully tested in the Beaufort Sea through comparison with ground truth collected during fall 2015.

In the present study, this technique has been adapted and applied to Antarctic frazil/pancake icefields. Several case studies have been identified using different SAR products (CosmoSkyMed, Sentinel-1, TerraSAR-X). Our retrievals have been analyzed and validated through the comparison with co-located in situ observations collected by international research cruises realized in different sectors of the Antarctic region (i.e., Ross Sea, Weddell Sea). Particular attention has been addressed to in situ information collected in the framework of 2017 PIPERS cruise in the Terra Nova Bay and its polynya.

A broad agreement was found between measured thicknesses and those retrieved from the SAR imagery. Results and statistics are presented and discussed in details.
In the context of global warming, the question of why Antarctic sea ice extent (SIE) has increased is one of the most fundamental unsolved mysteries. Although many mechanisms have been proposed, it is still unclear whether the increasing trend is anthropogenically originated or only caused by internal natural variability. In this study, we employ a new method where the underlying natural persistence in the Antarctic SIE can be correctly accounted for. We find that the Antarctic SIE is not simply short-term persistent as assumed in the standard significance analysis, but actually characterized by a combination of both short- and long-term persistence. By generating surrogate data with the same persistence properties, the SIE trends over Antarctica (as well as five sub-regions) are evaluated using Monte-Carlo simulations. It is found that the SIE trends over most sub-regions of Antarctica are not statistically significant. Only the SIE over Ross Sea has experienced a highly significant increasing trend ($p = 0.008$) which cannot be explained by natural variability. Influenced by the positive SIE trend over Ross Sea, the SIE over the entire Antarctica also increased over the past decades, but the trend is only at the edge of being significant ($p = 0.034$).
Ross Sea ice thickness is an important indicator of Antarctic climate change but needs to be evaluated over several seasons to define any trends. In November (20, 21, 27 and 28) 2013, NASA’s IceBridge mission flew over the Ross Sea, Antarctica and collected important surface sea ice data with airborne lidar (ATM) and digital camera imagery (DMS) for the first time. An automatic lead-classification method based on DMS images is developed in this paper. Using the leads only, we were able to derive the sea surface height anomaly by subtracting geoidal mean sea surface height product DTU15 from ATM L1B (~1m resolution) retrieved surface elevations. We then computed total freeboard (over the sea ice) by subtracting the derived sea surface anomaly from the difference between ATM L2 retrieved surface elevation (80 m sample width 40 m spacing along track) and mean sea surface height product DTU15. Preliminary results are, apparent reflectivity values of leads in Ross Sea are mostly less than 0.15; Track 1 and 4 (the two most near the coast) shows the thickest ice thickness, which can be as great as three meters. For all tracks (except one) mode thicknesses vary between 0.35-0.45 meter. Track 3 (east-west) shows the thinnest mode ice thickness (0.35 m) and mean ice thickness (0.48 m). An ATM and DMS mission using the NSF C-130 with the Icepod system was flown in 2016 and will be repeated in 2017. Using the 2013 mission shown here as a baseline will assist in defining any trends.
Valeria Selyuzhenok¹ (valeria.selyuzhenok@niersc.spb.ru), Thomas Krumpen², Matti Leppäranta³, Rüdiger Gerdes²

By using operational sea ice charts (Arctic and Antarctic Research Institute, Russia) we analyzed seasonal and interannual variability of fast ice extent in the East Siberian Sea between 1999 and 2015. We identified key events in each annual fast ice cycle and linked the occurrence of these events to freezeup and melt onset and air temperature (FDDs and TDDs). The analysis reveals that fast ice in the region is sensitive to the thermodynamic processes throughout a season. On the interannual time scale we found a tendency towards shorter fast ice season. The duration of fast ice season reduces by 1.5 d/y which is in agreement with Arctic-wide trend. Analyzing fast ice annual cycle in the East Siberian Sea we describe two modes of fast regime characterized by small (S-mode) and large (L-mode) extent. By liking the occurrence of the modes to thermodynamic and dynamic factors we suggest the large fast ice extent forms during seasons with atmospheric circulating favoring sea ice import to the East Siberian Sea. This likely results in a higher rate of sea ice deformation and formation of grounded sea ice ridges which stabilize extensive fast ice cover. To confirm this hypotheses, the processes of ice ridging in the East Siberian Sea further investigated.
Sea Ice Leads Detection using High-resolution SAR Imagery

Yu Zhang¹ (yuzhang_spl@whu.whu.cn), Fei Li¹, Shengkai Zhang¹, Tingting Zhu²
¹Wuhan University, Chinese Antarctic Center of Surveying and Mapping, Wuhan, China, ²Wuhan University, Collaborative Innovation Center for Territorial Sovereignty and Maritime Rights, Wuhan, China

From sea ice monitoring, the line feature like sea ice leads due to winds and ocean currents not only influences the exchange of heat between ocean and atmosphere, and it is of great significance for ship navigation. SAR is sensitive to surface roughness of sea ice with different dielectric properties and polarization feature, and it can be utilized for detecting leads from SAR imagery. A line operator based edge detection method is proposed for leads detection in high-resolution SAR imagery. Co-polarization of different polarization channels and frequencies is investigate to measure the energy distribution of leads from different orientation and wavelength. Histogram of gradient is calculated, and the linear feature of leads can be extracted after a segmentation procedure, where the bounding line of leads has the largest gradient with lowest energy. Spatial smoothing procedure is carried out to connect the segmentation of leads into a curvilinear line. Algorithm is validated on Sentinel-1 SAR imagery with a pixel spacing of 40 meters and GF-3 SAR imagery in Beaufort Sea. Main work is listed: 1) A line segmentation based edge detection method is proposed for high-resolution SAR imagery. 2) The assessment of the proposed segmentation based method and classification based algorithm has been presented. 3) The preferable parameters sets including incident angle correction, the polarization ratio threshold and spatial smoothing window size have been discussed.
Arctic sea ice area has been decreasing over the last decades and increased area of open waters releases new possibilities for navigation along the Northern Sea Route (NSR). Model simulations indicate an accelerated Arctic climate change in the next decades with a potential total loss of Arctic sea ice in summer season around the middle of this century. Increased area of open water will cause generation of larger waves in the marginal seas that can make an area dangerous to navigation. Here, we analyze changes in sea ice and wave conditions in the NSR over the period of satellite observations. The study is done for several standard navigation routes suggested by NSR Advisory. The decline in the Arctic sea ice extent at the end of melt season has been estimated at about 10% per decade over the period of satellite observations. In the seas of the Russian Arctic the similar trend was from -9% per decade in the East-Siberian Sea to -25% per decade in the Kara Sea over the same period. Satellite data demonstrate almost complete NSR opening in September for the period from 2008 and 2012 and from 2014 to 2017. In 2013 the passage was blocked by the ice in the Vilkitsky Strait, which is known to be a bottleneck of the whole NSR. Ice conditions in the Kara Gates, Long Strait and Vilkitsky Strait has been studies separately. In the Vilkitsky Strait, where ice conditions were the heaviest and most changeable, the average ice concentration has decreased at about 10% per decade.
Surface sea-ice area fraction (sea-ice concentration or SIC) data sets derived from satellite microwave radiometry have been among the backbones to quantify amplification of global climate change in the Arctic with its remarkable sea-ice cover reduction contrasted by a yet to be understood Antarctic sea-ice cover variability. For this purpose SIC data sets require the accuracy level of a climate data record (CDR). They should be insensitive to sensor drift or change. They should include retrieval uncertainties to ease usage for climate applications. Retrieval limitations should be understood well. We present the maturity of the joint EUMETSAT OSI SAF and ESA CCI CDRs of daily global SIC at 25 km grid resolution. We find the SIC, its retrieval uncertainty, and the filters applied to be consistent across sensors. Open water (SIC=0%) is retrieved with a bias < 0.1%. Pack ice (SIC=100%) is retrieved with a bias < 2% during winter. Associated precisions fall into the retrieval uncertainty range of 2 - 4%. Retrieval uncertainties reflect seasonal variations of atmospheric and surface properties. CDR SIC agrees within 3% with SIC derived from ~ 400 Landsat optical images. Over < 0.2 m thick ice SIC is biased low by up to 20%. Pan-Arctic (regional) SIC differences to 1 minus open-water fraction derived from nine summers of MODIS data are < 5% (< 20%) but CDR SIC exceeds MODIS net ice surface fraction by up to 30% during peak melt. Grid resolution 25 km vs. 50 km will be discussed.
Evaluation of Passive Microwave Sea-ice Concentration Products with Landsat Data

Stefan Kern¹ (stefan.kern@uni-hamburg.de), Louisa Bell², Thomas Lavergne¹, Maybritt Meyer²

¹University of Hamburg, Center for Climate System Research and Sustainability (CEN), Hamburg, Germany, ²University of Hamburg, Hamburg, Germany, ³Norwegian Meteorological Institute, Oslo, Norway

Evaluation of a sea-ice area fraction (sea-ice concentration or SIC) climate data record (CDR) obtained from satellite microwave (MW) radiometry - like the joint EUMETSAT OSISAF - ESA CCI SIC CDRs - against independent data is one of the key activities required to quantify its maturity. Optical imagery acquired by the Landsat satellites provides an independent, high-resolution SIC estimate under clear-sky conditions with daylight.

In this contribution, we use Landsat optical imagery in bands 2, 3 and 4 of Landsat 5 TM, Landsat 7 ETM, and Landsat 8 OLI. We compute the broadband surface albedo and classify the scenes into surface types (open water, thin sea ice, and thick >~ 0.3m sea ice). The resulting Landsat ice maps (with 30 m resolution) are co-located with the CDR SIC, having grid resolutions between 12.5 km and 50.0 km depending on the MW frequencies used for the SIC retrieval.

We compare CDR SIC and Landsat SIC of more than 400 clear-sky Landsat images, from both hemispheres, from years 2002 to 2015. We document a bias between Landsat SIC and the CDR SIC of about 2% to 4%. We discuss this bias in relation to the type of ice in the scene (thin vs thick), the MW frequencies used in the SIC CDR, and the Landsat SIC estimation accuracy.
Laminated diatom oozes collected from Antarctic coastal basins provide an opportunity to create high-resolution paleoclimate records of ocean-atmosphere variability. The relationship between sediment geochemistry, diatom assemblages, and related environmental conditions can be utilised to reconstruct a range of climatic conditions at a particular site through time.

We present results from a unique marine sediment core, LC-62 (4.82m long), collected from Moubray Bay, Ross Sea, Antarctica. The upper portion of LC-62 comprises a laminated diatomaceous ooze with the horizontal layering differentiated by changes in colour, texture and density. The lower half of the core is composed of ooze of the same colours and textures but in undulating and interweaving layers. Overall, $\delta^{13}C$ values in LC-62 are more negative than typical Antarctic values (-24-25‰). At the base of the core $\delta^{13}C$ is very negative (-33‰) but becomes more positive up core (-27 to -30‰). Core top samples contain diverse and well-preserved diatom assemblages characterized by sea-ice associated species. Section break samples are dominated by assemblages associated with a shallow mixed layer and rapid export and burial, and by variable abundances of sea-ice associated species. This record will provide a new point of comparison to high-resolution ice and sediment cores from Antarctica and sediment cores from the mid-latitudes of the Southern Hemisphere.
In this study we investigated suspended particulate matter (SPM) collected along a transect from the East Sea of Korea to the Bering Sea from 18 to 28 July in 2015, a multicore (ARA01B-3MUC) retrieved from the Chukchi shelf region, and a piston core (MD95-2009) taken from the Nordic Seas. We analyzed the samples for the Arctic sea ice proxy IP$_{25}$ together with a tri-unsaturated highly branched isoprenoid (HBI triene) and two sterols (epi-brassicasterol and dinosterol) to assess the suitability of these compounds for the so-called PIP$_{25}$ index in the Arctic region as a proxy for sea ice change in the past. Our results highlight that the use of HBI triene, epi-brassicasterol, and dinosterol, as strict phytoplankton markers for the PIP$_{25}$ index (i.e. PrIP$_{25}$, PaIP$_{25}$ and PeIP$_{25}$, respectively), might result in misleading outcomes. Accordingly, our study highlights that more work is needed to better constrain the use of HBI triene, epi-brassicasterol, and dinosterol, as strict ice-free, open ocean phytoplankton biomarkers when applying the PIP$_{25}$ index for reconstructing past sea ice changes.
Application of IPSO25 for Reconstructing Sea Ice Conditions in the Amundsen Sea

Nele Lamping¹ (nele.lamping@awi.de), Juliane Müller¹, Oliver Esper¹, Jens Hefter¹, Gesine Mollenhauer¹, Gerhard Kuhn¹
¹Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany

A continuous decline in sea ice extent has recently been observed in the Amundsen Sea, standing in stark contrast to observations of an increasing trend in other regions around Antarctica. Polar sea ice plays a key role in Earth’s global climate system as it has a strong influence on atmospheric and oceanic processes. Reconstructions of sea ice extent and the understanding of sea ice-induced mechanisms are therefore of crucial importance.

Here, we apply organic geochemical proxies in order to reconstruct the paleoenvironment in the Amundsen Sea. Several samples from the Amundsen Sea Shelf will be investigated with a main focus on the reconstruction of sea ice conditions via a specific organic biomarker, a highly branched isoprenoid (HBI), called IPSO25, which is produced by sea ice diatoms and well preserved in marine sediments (Belt et al., 2016). For surveying IPSO25 as a sea ice proxy, surface sediment samples will be investigated, while the analysis of two sediment cores (PS104/014-3 and PS69/274-1) give insight into the environmental and climatic conditions across the last deglaciation.

First measurements show highly variable concentrations of IPSO25 at both core sites. Further biomarkers, such as HBI trienes, GDGTs (TEX86) and sterols will be investigated for reconstructions of SSTs and primary productivity. Comparisons to diatom assemblages and diatom-derived sea ice concentrations are intended for an evaluation of both approaches to reconstruct sea ice conditions.

Record Low Antarctic Sea Ice Area in Springtime of 2016: Forcing and Responses

Zhaomin Wang¹ (zhaomin.wang@hhu.edu.cn)
¹Hohai University, College of Oceanography, Nanjing, China

Antarctic sea ice area reached record lows for the season in the springtime of 2016. The analysis of sea level pressure from two reanalysis datasets revealed that the atmospheric forcing at southern high latitudes appeared to be extremely strong during the first three months of 2016, and in June and September 2016, characterized by record low daily and monthly mean sea level pressure at southern high latitudes. Satellite sea ice concentration data, winds from ERA-Interim, and results from a global high resolution ocean-sea ice model, were analyzed to investigate the responses of sea ice and near-surface ocean to such atmospheric forcing. It was found that the patterns of sea ice anomalies in June and September 2016 were controlled by both the thermal and dynamical effects of atmospheric anomalies. The anomalously strong cyclonic wind forcing at southern high latitudes associated with extreme atmospheric conditions generated warmer near-surface oceanic states from April 2016 onwards than in previous years.
Reconstruction of past changes to sea ice extent is central to understanding the factors that control its distribution and informs how changes in sea ice might occur in the future. Such reconstructions are often hindered, however, by poor age control (or resolution) in marine archives, or the absence of robust proxy signatures. Here, we show preliminary results from a 14.6 m long piston-core collected in the Edisto inlet (Cape Hallett, Ross Sea, Antarctica). The aim of the project was to obtain a continuous and highly resolved record of sea ice dynamics and other environmental parameters during the late Holocene. With this goal in mind, the coring site was chosen in the inner bay where the Holocene unit is particularly expanded (up to 60 m thick). Bottom core AMS $^{14}$C dating of the acid insoluble organic fraction (2820 cal. aBP after reservoir correction) indicates an average annual sedimentation rate of ca. 0.5 cm/y. X-ray radiographs show well-preserved laminated sediments dominated by diatom oozes alternating with dark-like sediments likely supplied from the inner bay. In this abstract, we present high resolution bulk organic carbon geochemistry (δ$^{13}$C and carbon content), XRF core scanning data, diatom assemblages and lipid biomarker results. Specific focus will be placed on the di-unsaturated highly branched isoprenoid biomarker IPSO25, which has been recently proposed as a proxy of Antarctic landfast sea ice.
Here we present the Southern Ocean (SO) past sea ice (SI) duration and summer SST estimates utilizing sediment cores. SSTs and SI reconstruction is based on diatom transfer function and is compared with other climatic records from SO and Arabian Sea. SI records reconstructed here reveal that the SI presence at the core sites was discontinuous during the past. SI was largely absent at the core sites during the interglacial stages. Nonetheless, the winter SI presence of 1 month/year at the core sites was evident during glacial periods. The advance phases of SI coverage which occurred during the glacial periods (MIS 2, 3 and 4) apparently coincided with the drop in summer SSTs. On comparing our records of SSTs and SI with ISM reconstruction, it was seen that the weakening of ISM during glacial period was in phase with the equatorward shift of Antarctic SI. In addition to the SI, the SO fronts were also likely to have shifted equatorward during the glacial period, this in turn is in compliance with the equatorward shift of the southern hemisphere westerly winds. Such latitudinal changes in the westerly wind belt during glacial-interglacial period was recorded to have been in phase with the north-south shift of Intertropical Convergence Zone, thereby hinting at a possible mode for SO and ISM linkages in the past. Hence there is a need to understand how such modes impacted the variation of the thermal gradient developed between the Indian landmass and southern tropical ocean.
Modelling the Annual Cycle of Antarctic Sea Ice Extent

Marilyn Raphael¹ (raphael@geog.ucla.edu), Mark Handcock²

¹UCLA, Geography, Los Angeles, United States, ²UCLA, Statistics, Los Angeles, United States

Satellite-observed, total Antarctic sea ice extent (SIE) experiences a distinct annual cycle, peaking in September and troughing in March on average. The amplitude and phase of the annual cycle also varies regionally. What forces the observed annual cycle and its variations is not completely understood. The average annual cycle may be calculated by simply taking the average SIE for each day of the year. However, while simple and transparent, this method produces a value that is subject to substantial variation since it is based on fewer than 40 numbers, one for each year of observed data. It also disguises the fact that the annual cycle might be slowly changing phase and that the amplitude as well as shape of the daily extent might vary. Here, we present a model that allows the mathematical and stochastic representation of the proximate forces that lead to the observed annual cycle of sea ice extent. Our methods allow amplitude and phase dilation and contraction. Thus, the annual cycle is not constrained to be a fixed cyclical pattern rather, it is a pattern that allows both temporal dilation and contraction as well as amplitude modulation. We use this model in an ensemble interpolation to reconstruct missing daily data in the early part of the satellite-observed sea ice data set. Results are presented and discussed.
Comparing Pre-industrial and Late Pleistocene Antarctic Sea Ice Trends

Juliane Müller1,2 (juliane.mueller@awi.de), Gesine Mollenhauer1, Oliver Esper1, Gerhard Kuhn1, Frank Lamy1
1Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, 2University of Bremen, Bremen, Germany

The Antarctic sea ice proxy IPSO25, a highly branched isoprenoid (HBI) alkene (Belt et al., 2016; Massé et al., 2011), constitutes a promising palaeoceanographic tool for the community of Antarctic polar marine geologists. In particular, where (or when) the application of diatoms is limited due to silica dissolution, this biomarker approach seems highly valuable to gain insight into sea ice-ocean-atmosphere interactions. Here, we target at HBI-based sea ice reconstructions covering the pre-industrial time interval and the last interglacial. Pursuing a multi-proxy approach, sediment cores obtained during RV Polarstern cruises PS97, PS104 and PS111 in the southern Drake Passage, the Amundsen and Weddell Sea, respectively, will be investigated for, amongst others, their biomarker inventory and diatom assemblages to reconstruct sea ice and ocean temperature changes and associated fluctuations in primary productivity. These records will provide the base for an assessment of how sea ice variability may have been linked to shifts in atmospheric circulation (ENSO, SAM) and ocean warming - two of the main drivers of recent environmental changes in the Southern Ocean.

Comparison of Ice/Water Classification from C- and L-band SAR Imagery

Wiebke Aldenhoff¹ (wiebke.aldenhoff@chalmers.se), Céline Heuzé², Leif E.B. Eriksson¹
¹Chalmers University of Technology, Department of Space, Earth and Environment, Gothenburg, Sweden,
²University of Gothenburg, Department of Marine Sciences, Gothenburg, Sweden

In this article an algorithm for ice/water classification of C- and L-band dual polarization synthetic aperture radar data is presented. A comparison of the two different frequencies is made in order to investigate the potential to improve classification results with multi frequency data. The algorithm is based on backscatter intensities in co- and cross-polarization and autocorrelation as a texture feature. The mapping between image features and ice/water classification is made with a neural network.

Accurate ice/water maps for both frequencies are produced by the algorithm and the results of the different frequencies generally agree very well. Differences are found in the marginal ice zone, where the time difference between acquisitions causes motion of the ice pack.

C-band reliably reproduces the outline of the ice edge, while L-band has its strengths for thin ice/calm water areas within the icepack.

The classification shows good agreement with ice/water maps derived from met.no ice-charts and radiometer data from AMSR-2. Variations are found in the marginal ice zone where the generalization of the ice charts and underestimation of ice concentration from radiometer data limit accuracy. Usage of high resolution dual frequency data increases timeliness and resolution of sea ice cover information for navigation and modelling.
Environmental Sensitivity of Diatom Biomarker Lipids Linked to Ice Edge Dynamics

Lukas Smik (lukas.smik@plymouth.ac.uk), Camille Visinand, Simon Belt, Katrine Husum, Phillip Assmy, Anette Wold, Claire Widdicombe, James Fishwick, Claire Allen

1University of Plymouth, Plymouth, United Kingdom, 2Norwegian Polar Institute, Tromsø, Norway, 3Plymouth Marine Laboratory, Plymouth, United Kingdom, 4British Antarctic Survey, Cambridge, United Kingdom

In recent years, the source or environmental specificity of certain C25 Highly Branched Isoprenoid (HBI) alkenes has led to their use as organic geochemical proxies for seasonal sea ice reconstruction. Thus, a mono-unsaturated C25 HBI termed IP25 provides a useful proxy measure of the past occurrence of Arctic sea ice, a di-unsaturated HBI (IPSO25) has been proposed as an equivalent proxy for Antarctic sea ice, while a tri-unsaturated C25 HBI counterpart (HBI III) has been suggested as a possible proxy indicator of the retreating ice edge during spring in both the Arctic and the Antarctic. Here, the environmental sensitivity of one of these diatom lipids, HBI III, to ice edge dynamics has been investigated further, through analysis of water column samples collected from two consecutive annual sampling events north of Svalbard, corresponding to a transect that tracks the retreating ice margin. Preliminary results show that, within this study area at least, biosynthesis of HBI III is indeed favoured in locations close to the retreating ice edge, consistent with the sedimentary distribution of this biomarker in the nearby region. To provide further context to the findings, we also measured the occurrence of HBI III from a temperate location in the English Channel (www.westernchannelobservatory.org) spanning three contrasting seasons (spring-autumn). Some new sedimentary HBI III data from the Antarctic will also be presented.
Extraction Method of Arctic Sea Ice and its Multiscale Change Characteristics

Tiantian Feng¹ (fengtiantian@tongji.edu.cn), Xiaomin Liu¹, Huizi Chen¹
¹Tongji University, Shanghai, China

The extent of polar sea ice is one of the key parameters of cryosphere and polar environmental change, which plays an important role in the study of global climate change. According to the recently research results from NASA, the extent of Arctic sea ice showed obvious decreasing trend with the average loss of 13.3% per decade, and decreased significantly since 2007. In this study, a new extraction method of Arctic sea ice is proposed based on multi-source remote sensing data. The accuracy of extraction results is validated using sea ice concentration products estimated by microwave data, such as SMMR. On the other hand, the temporal change analysis results of Arctic sea ice extent are also included. The change characteristics in various time scales, such as decade, annual, seasonal, are presented by using the extent products from 1979 to 2017, downloaded from the website of the National Snow and Ice Data Center (NSIDC). Moreover, this study would present the seasonal changes in the recent 20 years, and the correlation of sea ice changes in long-term and medium-term is revealed. In the further, we would like to improve the accuracy of extraction results and strive to the reasonable prediction of the future tendency of Arctic sea ice according to the sequential analysis. These results could provide important support for the research on global climate change.
Deep convection in the Greenland, the Irminger and the Labrador Seas is an inherent part of the Atlantic Meridional Overturning Circulation (AMOC), which modulates its intensity. Interannual variations in the intensity of deep convection, among other factors, are thought to be controlled by variations in the intensity of freshwater fluxes to these regions and the overall sea-ice extent in winter. In this study we investigate the role of sea ice transport and melting in the freshwater balance of the Greenland, the Irminger and the Labrador Seas between 1978 and 2016. The study is based on time series of sea ice volume and velocity from Pan-Arctic Ice Ocean Modeling and Assimilation System (PIOMAS). The analysis revealed variation of the sea ice volume with periods of 3 and 6-8 years in the Greenland Sea and 8-10 years in the Irminger and Labrador Seas. The 6-8 years cycle in the Greenland Sea lags between a quarter and a half of the period the corresponding variations in the Irminger and Labrador Seas. The links to the corresponding cycles in oceanic and atmospheric regional indexes (NAO, AO, AOO, etc.) are analyzed.

The research was supported by RSF project 17-17-01151
In a warming climate, observations indicate that sea ice surrounding Antarctica has been slowly expanding since 1979. Changes in the melt rates of Antarctic ice shelves and in atmospheric dynamics are both considered key drivers of sea ice variability. We present a sensitivity study with a global eddy-permitting ocean-sea ice model, which aims to investigate how modifications of regional/local climate conditions (freshwater discharge and wind fields) can affect sea ice properties around Antarctica. Numerical exercises with modified surface runoff shows that enhanced freshwater supply can increase the sea ice extent. However, a very strong increase of freshwater will eventually invert the trend. In our runs, the freshwater spatial distribution largely affects sea ice dynamics and regional sea ice concentration and thickness. Numerical runs with idealised changes of ERA-Interim wind velocities show that both zonal and meridional wind modifications do only slightly impact regional properties of sea ice.
Interannual Dynamics of the Ice Regime of the Sea of Azov in the XX-XXI Century

Natalia Yaitskaya1,2 (yaitskayan@gmail.com), Anastasia Magaeva1
1Southern Scientific Centre of the Russian Academy of Sciences, Rostov-on-Don, Russian Federation, 2Sochi Research Centre, Laboratory of Mathematical Modeling of Natural Processes, Sochi, Russian Federation

Ice regime of the Sea of Azov over the period XX-XXI centuries on the basis of the author’s GIS "Ice regime of the Southern Seas of the Russia" was investigated. The long-term dynamics of the ice cover, the duration, the beginning and the end of the ice period was considered. The analysis of the data showed that the average long-term value of the ice cover of the Sea of Azov is 33% for the period 1950-2015. The average area of fast ice is 6.3% of the total sea area. The duration of ice cover in the coastal weather stations was reduced by 5 to 9 days. Typification of winters in terms of severity was carried out for three coastal weather stations: the Taganrog, the Genichesk, the Kerch. Typification showed that the winters with moderate characteristics are prevail in the Azov region. A total allocated of 15 severe winters, 70 moderate and 40 soft winters. New classification of winter periods, which combined all the ice regime parameters and typification winters in terms of severity, was developed. It is shown that the moderate winter periods are prevalence. A total allocated of 9 severe winter period, 36 moderate and 21 soft winter periods for GMS «Taganrog» and 8 severe winter period, 41 moderate and 17 soft winter periods for GMS «Kerch».
The Role of Northern Sea Ice Variability during Abrupt Glacial Climate Changes

Henrik Sadatzki1 (henrik.sadatzki@uib.no), Trond Dokken2, Sarah Berben1, Francesco Muschitiello2,3, Ruediger Stein4,5, Kirsten Fahl6, Eystein Jansen1,2
1University of Bergen & Bjerknes Centre for Climate Research, Bergen, Norway, 2Uni Research Climate, Bergen, Norway, 3Lamont-Doherty Earth Observatory of Columbia University, Palisades, United States, 4Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, 5University of Bremen, Bremen, Germany, 6Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

Changes in sea ice cover in the Nordic Seas likely played a crucial role in amplifying ocean circulation and climate changes of the Dansgaard-Oeschger (D-O) cycles during the last glacial. We investigate the role of sea ice for abrupt Greenland climate changes, using high-resolution sea ice records from two Norwegian Sea cores covering four D-O cycles at 32-40 ka. These records are based on the sea ice diatom biomarker IP25, open-water phytoplankton biomarkers (sterols and alkenones) and semi-quantitative phytoplankton-IP25 (PIP25) sea ice estimates. Our biomarker records indicate that the Norwegian Sea was characterized by a near-perennial sea ice cover during cold stadials and enhanced open-ocean conditions during warmer interstadials. These changes in sea ice likely facilitated shifts in atmospheric circulation, potentially contributing to far reaching atmospheric teleconnections transmitting the D-O climate signals. Moreover, we find that initiation of sea ice retreat systematically preceded Greenland warming and major deep mixing in the Nordic Seas, acting as a precursor of oceanic reorganizations that likely generated much of the atmospheric warming of the Greenland D-O events. We thus conclude that the glacial sea ice variability acted as positive feedback mechanism for abrupt ocean circulation and Greenland climate change during D-O cycles.
Multivariate Biomarker Methods for Reconstructing Arctic Sea Ice Conditions

Deniz Can Koseoglu¹ (deniz.koseoglu@plymouth.ac.uk), Simon Belt¹, Jochen Knies²,³, Katrine Husum⁴

¹University of Plymouth, Petroleum and Environmental Geochemistry Group, Plymouth, United Kingdom, ²CAGE – Centre for Arctic Gas Hydrate, Environment and Climate, Department of Geology, UiT the Arctic University of Norway, Tromsø, Norway, ³Geological Survey of Norway, Trondheim, Norway, ⁴Norwegian Polar Institute, Fram Centre, Tromsø, Norway

The discovery of the C₂₅ Highly-Branched Isoprenoid (HBI) termed IP₂₅ provided a direct geochemical biomarker approach for reconstructing Arctic sea ice. Subsequent introduction of the PIP₂₅ index, based on the ratio of the sympagic IP₂₅ and certain pelagic biomarkers (e.g. sterols) facilitated semi-quantitative reconstructions of paleo spring sea ice concentration (SpSIC).

Despite these developments, the objective selection of appropriate marine open-water biomarkers as pelagic counterparts to IP₂₅ is challenging, and the same biomarkers may not be applicable in different Arctic regions. Further, the PIP₂₅ threshold values previously used to classify different sea ice conditions, ranging from open water (PIP₂₅ < 0.1) to extensive sea ice cover (PIP₂₅ > 0.75) were not based on a reproducible classification procedure, but arbitrarily estimated using linear regression.

To address these limitations, we constructed a classification tree (CT) model based on a multivariate set of sympagic and pelagic HBI biomarkers, including IP₂₅, in ca. 200 surface sediments encompassing the Barents Sea. The CT model was used to classify sea ice conditions as marginal (< 10% SpSIC), intermediate (10-50% SpSIC), or extensive (>50% SpSIC) in sediment cores from the Barents Sea spanning the last ca. 13 cal. ka BP. Comparison of CT model results to PIP₂₅-based SpSIC estimates showed consistent results, supporting the application of multivariate statistical methods for reconstructing paleo sea ice.
Hans Gazert (1870-1961), physician of the German South-Polar Expedition (1901-1903), evaluated various types of clothes, headgear, gloves, shoes as well as sleeping bags, tents, ice and snow huts and their use during the exploration of Antarctica around 1900. To demonstrate the historical value of Gazert’s manuscript that contains his findings I will present his thoughts about the best means of protection against harsh weather conditions in polar regions during sledging excursions.

Particularly interesting is his review of pros and cons of European tents made from canvas or silk of dark or light colors, ones differing both in size and shape from tents commonly constructed for summer use in the Arctic by Inuit people. Gazert describes contemporary types of tents developed by Fridjtof Nansen for the Arctic, or Frederick Cook and Roald Amundsen, as well as Robert Falcon Scott for Antarctic use. Arctic igloos, Gazert found are very warm, and therefore seem to be very useful for overwintering or to establish a secondary observing station. He recommended a simpler version to be built each day during sledging trips. Ice houses were more stable and lasted longer than igloos and were, he said, very good for observatories, but too cold as accommodation. Apart from Gazert’s findings the present paper will also illustrate and discuss further developments of tents designed by Nansen and Alfred Wegener for use as stations around the year 1929.
In Institutions play a central role in the production of knowledge, and in the maintenance of cultures that facilitate that production. We argue that the study of research institutes can be used as a window into the changing nature of science and politics. We study the evolution of four distinct but comparable Arctic research institutes during the early Cold War: the bi-national Arctic Institute of North America (AINA, US-Canadian), the Scott Polar Research Institute (SPRI, UK), the Norwegian Polar Institute (NP) (Norway) and the Arctic Research Institute (ARI, USSR). Using these institutional histories, we show how research in Antarctica - particularly in connection to the International Geophysical Year (IGY) of 1957/58 - had repercussions for Arctic research. We demonstrate how this bipolarity can be seen as part of the interplay between logistical and geopolitical frameworks and choices in polar research agendas. Moreover, focusing on these institutes can reveal how the relationship between the state, the individual scientists and these institutions as nodes in an international network were negotiated during the early Cold War.
This paper explores the research on polar history that shapes my “Unknown Explorer” series. Structured around objects from the archives of a fictitious, female explorer, Anna Schwartz, this project builds on my collaboration with scientists and my experience in Antarctica as a recipient of the NSF Antarctic Artists and Writers Grant. It intersects with the history of both Arctic and Antarctic exploration and science. The archival structure allows for a layered narrative that explores the bipolar research on climate change as well as the contrasting histories of exploration at the two poles, with the presence of native populations in the north and their absence in the south. While the character of Schwarz is fictitious, the archives contain factual materials from the past and the present. For example, Schwartz who has family ties to the 19th century Austro-Hungarian North Pole expedition is a photographer and a naturalist who grows obsessed with the microscopic planktonic snail, the Limacina helicina, through a chance meeting with the son of Admiral Scott in 1935. Her quest to find this organism in its habitat connects her with Vilhjalmur Stefansson, the Arctic explorer who helps her join admiral Byrd’s Antarctic Expedition in 1939. The archives also incorporate materials pertaining to Schwartz daughter who follows in her mother’s footsteps and finds that her mother’s beloved planktonic snail functions as the canary in the coalmine when it comes to ocean acidification.
Whaling has been a business in the Arctic and Antarctic. Over time, it has also become a political issue, especially amongst Britain, Norway and Germany. The Northern Sea was mainly controlled by the British (economy) and the Norwegians (whaling in the North and also in the South). The inter-war period brought great hardship for Germany because of failed industrial and agricultural developments, the political and financial pressure from the allied countries and the global financial crises. The so called “fat gap” (lack of providing enough food for the population) became a political issue for Germany. The attempts of the German “Schwabenland Expedition” 1938/39 to secure whaling grounds in the South failed. In 1940, a PhD candidate, Hans-Georg Baare-Schmidt researched the whaling business, science and claims in the Antarctic, mainly by the British. This thesis shows the political background, economic pressure and national ambitions in the Antarctic. This paper will explore the complexity of whaling, science and claiming sectors of the Antarctic, as outlined in the 1940 doctoral research and how the thesis unintentionally provided a vision for, then future, developments in economic, political and scientific terms, which followed the decades after the Second World War.
Probing Antarctic Ice in the Arctic: Connections in Radioglaciology’s History

Simone Turchetti¹ (simone.turchetti@manchester.ac.uk)
¹University of Manchester, Centre for the History of Science, Technology and Medicine, Manchester, United Kingdom

In the 1960s polar explorers started using airborne radar to measure the depth of the Antarctic ice. There are several studies (e.g. Turchetti, Dean, Naylor and Siegert, 2008) showing how the development of radio-echo sounding (RES) was pivotal to establishing morphological profiles of its ice-sheet. RES is still widely used today to further refine ice depth maps and charts.

Yet the set of crucial experiments catering for the adoption of RES in Antarctica took place at Camp Century, one of the heavily militarized U.S. bases north of the Arctic Circle. Promoted by the SCAR, two “international experiments” were completed in the spring of 1962 and 1963. Crews of engineers from several countries tested a variety of airborne (and land-based) instruments thus gaining a novel understanding of their merits in penetrating Greenland’s ice-sheet and paving the way to their adoption in Antarctica.

In this presentation I re-appraise the history of these landmarking trials in light of a fresh analysis of unpublished diaries and reports of one of the protagonists: the US Army Signal Corps radio engineer Amory H. (Bud) White. These papers are revealing of the tests’ utility in perfecting the instruments utilized. But also of their progeny in the context of surveillance-driven Cold War research...

The main goal of this paper is to show the analytical power that material culture studies have for understanding the sealers' presence in the history of Antarctica. This paper poses the following general question: What has the study of material remains meant to our knowledge of the historical sealing industry in Antarctica? The sealers' presence in Antarctica represents the process of exploration and of the incorporation of an unknown and remote place. From this perspective, I am interested in learning about the particularities of this process by posing specific questions that help characterize the strategies used by sealers.

This paper presents a summary and meta-analysis of the data produced during three decades of archaeological research on the topic, addressing specific questions regarding the decisions involved in the uses of space, the selection of the economic activities developed, the organization of onshore activities and possible temporal changes in these choices. More specifically, this paper examines whether the sealer strategies were expansive or focalized in terms of their use of space, were opportunistic or specialized in terms of the resources exploited and were flexible or rigid in terms of their organization as well as to what degree they changed through time during the nineteenth century. The data to answer these questions were gathered through a deep review of all the currently published information.
Isla Observatorio and its Significance for Antarctic Expeditions in 1900s

Gabriela Roldan¹ (gabriela.roldan@pg.canterbury.ac.nz)
¹University of Canterbury, Gateway Antarctica, Christchurch, New Zealand

Following the conclusions of the International Geographical Congresses of 1885 and 1899, Argentina built in 1902 a magnetic observatory, a meteorological station and lighthouse at Isla Observatorio, Tierra del Fuego, to cooperate with international Antarctic expeditions. Although its use only spans a few decades, it was the required stop for calibrations, meteorological information and even sledge dogs training for polar expeditions heading South. Its past significance was marked by the visits from well-known polar explorers, such as Nordenskjold and Charcot, who spent time on the island before and after their Antarctic expeditions. This paper analyses the international significance of Isla Observatorio in the support for science expeditions at the beginning of the 20th century, and examines the reasons for the state of disrepair and abandonment of this National Historic Monument, and the newly discovered interest by the regional and national governments of Argentina.

History of French Polar Shuttles

Emmanuelle Sultan¹ (emmanuelle.sultan@mnhn.fr), Daphné Buiron², Stephane Degast³, Elisa Dupuis⁴
¹MNHN, DGD REVE, Dinard, France, ²Collectif CryoSalide, Paris, France, ³Degast Reporter, Paris, France,
⁴Sorbonne Universités (Université 4), Paris, France

Focus on the French polar fleet from the "Pourquoi Pas? " of Charcot early 1900’s to the brand new Astrolabe, this paper will demonstrate how those vessels are tools to connect poles, oceans and people using corpus of memories. To illustrate that point the Astrolabe is used as a case study. The initial corpus is based on the one used in the book «L’Astrolabe , le passeur de l’Antarctique 1988-2018 » (Buiron and Degast Oct 2017, E/P/A) build from a collaborative gathering of memories in the framework of the retirement of the « old Astrolabe ». This corpus points out the evolution of this ship from a simple supply to a platform for research, heritage and creative solution to logistic issues that concern different polar countries and initiatives. More than a shuttle this boat is also a bridge between French Polar activities and Tasmanian one as discovered through a pilot study conducted in Hobart in July 2017 by collecting some memories about this ship which is a second corpus in the framework of this ongoing work.
The Surface Ocean-Lower Atmosphere Study (SOLAS) is an international science coordination and capacity-building body established “to achieve quantitative understanding of the key biogeochemical-physical interactions and feedbacks between the ocean and the atmosphere, and of how this coupled system affects and is affected by climate and environmental change.” The new SOLAS science plan places particular emphasis on air-sea exchange in the polar oceans, including the roles of sea ice and fresh water. Specific high-latitude activities sponsored by SOLAS include the Biogeochemical Exchange Processes at Sea-Ice Interfaces (BEPSII) and Cryosphere and Atmospheric Chemistry (CATCH) research communities, and other workshops and working groups. These polar initiatives integrate research on all five core SOLAS themes: Greenhouse gases and the oceans; Air-sea interface and fluxes of mass and energy; Atmospheric deposition and ocean biogeochemistry; Interconnections between aerosols, clouds, and marine ecosystems; and Ocean biogeochemical control on atmospheric chemistry. The SOLAS Science & Society task team also explores topics such as impacts of increasing ship-plume emissions on Arctic Ocean biogeochemistry, blue carbon, open-ocean stewardship, and implications of proposed geoengineering strategies. As a grass-roots science organization, SOLAS encourages involvement of new people with new ideas for studying air-sea exchange processes and their implications for the global system.
Antarctic Sun Lines: Connecting Antarctic Gateway Cities through Art

Adele Jackson1 (adele.jackson@pg.canterbury.ac.nz)
1University of Canterbury, Gateway Antarctica, Christchurch, New Zealand

The cities of Cape Town, Christchurch, Hobart, Punta Arenas and Ushuaia can be described as Antarctic Gateway Cities. Although supporting international Antarctic operations is something these cities have in common, each city has its own diverse history, culture and political concerns. The significance of the sun is one unifying factor: the austral summer season is the narrow window of time when Antarctic activity is at its peak. In October 2017, I established Antarctic Sun Lines working with the Antarctic Gateway Cities research network, COMNAP, Gateway Antarctica researchers, and the UK and NZ Antarctic Heritage Trusts. Each gateway city and several Antarctic research and heritage sites hosted a 'Solar Collector' pinhole camera throughout the summer season. Up to 4 months of sunlight and the ebbing of the summer sun were captured in a single image at each site. Founded on international collaboration and requiring the active participation of key stakeholders, the work bridged cultural and political boundaries and created connections.

In this paper I examine the role art can have in supporting international Antarctic relationships. I argue that this project contributed to shaping a sense of shared identity and offers opportunities for further shared gains: inspiring new research and continuing creative collaborations; shared international cultural events such as exhibitions; and opportunities for public engagement.
The recent changes and the increased economic activity in the Arctic region have triggered a societal demand for accurate sea-ice and weather predictions, information on the status of the Arctic Ocean (AO) and its marine life, and complex predictions of future scenarios. To address these issues and to develop policy recommendations for a sustainable usage of the AO and its resources, the international Arctic science community must have access to world-class research icebreakers (RIs) to access the ice-covered AO. The new EU infrastructure project ARICE joins the efforts of 14 partners from 12 different countries to provide Europe with better capacities for marine-based research in the AO. ARICE will develop strategies to ensure the optimal use of the existing polar research vessels and will work towards an International Arctic Research Icebreaker Consortium which shares and jointly funds operational ship time on the available RIs.

ARICE will also provide transnational access to six key European and international RIs for European scientists, based on scientific excellence of submitted proposals. Amongst others, it will give access to the winter experiment MOSAiC on board the PRV Polarstern.

ARICE is partnering with the maritime industry on a “ships and platforms of opportunity” programme and will improve the research icebreakers' services by exploring into new key technologies which could lead to an improvement of ship-based and autonomous measurements in the AO.
International Collaboration at Ny-Ålesund Research Station in Svalbard, Norway

Christina A. Pedersen1 (christina.pedersen@npolar.no), Kai Bischof2, Jack Kohler1, Maarten J. J. E. Loonen3, Roland Neuber4
1Norwegian Polar Institute, Fram Centre, Tromsø, Norway, 2University of Bremen, Bremen, Germany, 3University of Groningen, Groningen, Netherlands, 4Alfred Wegener Institute, Potsdam, Germany

The Ny-Ålesund Arctic Research Station in Svalbard, Norway, is a location for true international research collaboration. Ny-Ålesund is located at the northernmost point of the warm Atlantic Ocean inflow, and hosts a sophisticated infrastructure enabling observations of relevant parameters in the ocean, on land, and in the atmosphere. The site is thus, among other, ideally positioned for research and monitoring of contemporary environmental changes related to climate change issues. With its long-term data series, the station represents one of the most important environmental monitoring site in the Arctic, and hosts numerous international multidisciplinary collaborative science projects from institutions from more than ten nations. With so many actors and initiatives, it is essential creating coordination tools for increased and enhanced collaboration. The Ny-Ålesund Science Managers Committee (NySMAC) was established some twenty years ago to enhance cooperation and coordination between institutions, and includes representatives from all parties with major vested interests in Ny-Ålesund.

The research in Ny-Ålesund is coordinated through four flagship programs: Atmosphere, Marine System, Terrestrial Ecosystem and Glaciology. The flagship's chair and science committees are working on establishing meeting-places for scientific discussions and collaboration, coordinating field-activities, and generally increasing information flow between the individual research groups.
Remote polar research stations and field camps may embody a long-term combination of extreme weather, physical boundedness, and blurred boundaries among work, play, and sleep as personnel necessarily work, live, and socialize within the same, fairly-restricted space. Many of those personnel document and share their experiences through creative work including writing, visual and performing arts, and craft. This creative documentation appears to be a common practice in remote research settings and a significant, yet overlooked, form of knowledge production. In addition to these creative documentation practices, there seems also to be a more pragmatic type of creativity operating as scientists, engineers, and support staff manipulate station infrastructure and use limited materials to facilitate their work and domesticate an austere living environment. Thus, it appears that in these remote research settings, science, creativity, and infrastructure function together in unexpected and exciting ways; yet, despite the critical implications of polar science, the creative processes at work in polar research settings have received little scholarly attention. The proposed work uses archival research and semi-structured interviews to expand scholarly understanding of the roles of creativity in knowledge production and to advance infrastructure studies by exploring how science and creativity interact through material, technical, and social infrastructures in remote research settings.
Efficacy of Outreach Efforts: An Insight from Stakeholders

Swati Nagar¹ (swati23n@gmail.com), Rahul Mohan²
¹National Centre for Antarctic and Ocean Research (ESSO-NCAOR), Antarctic Science Division, Vasco da Gama, India, ²National Centre for Antarctic & Ocean Research (ESSO-NCAOR), Antarctic Science Division, Vasco da Gama, India

The role of science in sound decision making is vital. Scientific awareness helps people to see the socio-scientific problems in different way and try to find their solution or how they can contribute in solving the problem.

Outreach efforts at NCAOR have been made to link the science with its stakeholders. The pervasiveness of science is well explained by organizing public lectures and events like Open Day, Antarctic Day, educational tours, etc for students and/or community. The main aim of such efforts is to make students/community aware about the polar sciences with respect to Indian endeavors in Polar Regions and also global socio-scientific issues like climate change etc. Moreover, the engagement of community creates a sense of appreciation for the scientist which is a source of motivation and encouragement for scientists.

Although the increased response received from schools and colleges indicates its success. However, a survey has been conducted to understand and assess the efficacy of outreach activities. The survey included the opinions and suggestions of school and college teachers, school and college students etc. based on their experiences either in events or educational tours to NCAOR. The survey indicated increasing interest of audiences in Polar sciences, which is also a motivation for the team to further improve the outreach activities so that more and more number of audiences can be approached. This is an attempt to inculcate a scientific outlook in them.
The State of Environmental Science in Svalbard - The SIOS Optimisation Report

Vito Vitale¹,², Sebastian Mernild³,⁴, Roland Neuber²,⁴, Piotr Glowacki⁵,⁶, Pascal Morin⁵,⁶, Ole Jørgen Lønne²,⁷, Kim Holmén²,⁸, Jens Debernard²,⁹, Øystein Godøy²,⁹ (data@sios-svalbard.org)

¹Institute of Atmospheric Sciences and Climate (ISAC) Italian National Research Council (CNR), Bologna, Italy, ²Svalbard Integrated Arctic Earth Observing System (SIOS), Longyearbyen, Norway, ³Nansen Environmental and Remote Sensing Centre, Bergen, Norway, ⁴Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Potsdam, Germany, ⁵Institute for Geophysics, Polish Academy of Sciences, Warsaw, Poland, ⁶French Polar Institute, Paul-Emile Victor, Brest, France, ⁷University Centre in Svalbard, Longyearbyen, Norway, ⁸Norwegian Polar Institute, Longyearbyen, Norway, ⁹Norwegian Meteorological Institute, Oslo, Norway

The State of Environmental Science in Svalbard (SESS) is an annual report produced by the Svalbard Integrated Arctic Earth Observing System (SIOS). It summarises the state of current knowledge of key Earth System Science parameters in and around the Norwegian High Arctic archipelago of Svalbard. The SESS report outlines the work that has been done in the previous years within the SIOS cooperation to optimise the observing system and recommends research priorities for the following year(s).

The report contains information about the long-term monitoring data that form the core of the SIOS observing system. It will also cover new, innovative monitoring and research that has been carried out through SIOS. The focus is on integrating datasets, encouraging new thinking about connections between measured parameters and pursuing quantitative links. In addition to evaluating the state of current knowledge, the SESS report highlights the questions that remain unanswered and recommends solutions.

SIOS promotes scientific innovation and sees cooperation across nations and disciplines as an important means to this end. By improving access to new and existing monitoring data, prioritising investment in new research infrastructure and strengthening collaboration, SIOS will use the SESS report to promote innovative solutions to answering the big questions in Earth System Science.

The preliminary findings of the first SESS report are presented here. It will be published in autumn 2018.
Disaster Diplomacy in the Arctic: Advancing Research and Bridging Boundaries

Katia Kontar1,2 (yekaterina.kontar@tufts.edu), Paul Berkman1,2, Patrizia Duda3, Tuyara Gavrilyeva4,5, Alik Ismail-Zadeh6,7, Ilan Kelman8,9, Ester Sztein10, Yulia Zaika11
1Tufts University, Fletcher School of Law and Diplomacy, Medford, United States, 2Science Diplomacy Center, Boston, United States, 3University College London, Institute for Risk & Disaster Reduction, London, United Kingdom, 4North-Eastern Federal University, Institute of Engineering & Technology, Yakutsk, Russian Federation, 5Yakutian Scientific Center of the Russian Academy of Sciences, Department of Regional Economic and Social Studies, Yakutsk, Russian Federation, 6Karlsruhe Institute of Technology, Karlsruhe, Germany, 7Russian Academy of Science, Moscow, Russian Federation, 8University College London, Institute for Risk & Disaster Reduction and Institute for Global Health, London, United Kingdom, 9University of Agder, Kristiansand, Norway, 10National Academies of Sciences, Engineering, and Medicine, Board on International Scientific Organizations (BISO), Washington, D.C., United States, 11Lomonosov Moscow State University, Department of Geography, Moscow, Russian Federation

Disasters are destructive anywhere, but in the Arctic, the disruption is further intensified by the region’s unique features. Lack of preparation for the weather, vast distances, limited physical and communication infrastructure, and seasonal lack of daylight pose significant obstacles to emergency response in the region. Collaboration between disaster scholars and practitioners across the Arctic countries could significantly reduce the adverse impacts of disasters. Examples of collaborative initiatives include search and rescue exercises, and exchange of best practices in disaster risk and crisis management among emergency managers and Arctic populations. Benefits of international and interdisciplinary research and practice collaborations include advancement in risk assessment and monitoring, and disaster risk reduction. Faced with shared risk, opposing parties are often eager to collaborate to find solutions. Fostering disaster diplomacy in the Arctic would help to bridge the boundaries between diverse communities with shared risk, and advance scientific understanding of disasters. The effectiveness of disaster diplomacy was evident in the 2015-2016 collaboration between US and Russian scientists, emergency managers, regional administration, and communities’ leaders to reduce adverse impacts of spring floods in Alaska and the Sakha Republic (Siberia). This and other examples of effective disaster diplomacy in the Arctic will be discussed.
Young Researchers Develop Lists of Sustainable Practice in Arctic Communities

Josefine Lenz1,2 (josefine.lenz@awi.de), Emily Choy3, Elena Kutnetzowa4, Kristina Brown5, Louis-Philippe Roy6, Robert Way7

1Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Periglacial Research Section, Potsdam, Germany, 2University of Alaska - Fairbanks, Water and Environmental Research Center, Fairbanks, United States, 3University of Manitoba, Winnipeg, Canada, 4Norwegian Institute of Science and Technology, Trondheim, Norway, 5Woods Hole Oceanographic Institution, Woods Hole, United States, 6Yukon College, Yukon Research Centre, Whitehorse, Canada, 7University of Ottawa, Ottawa, Canada

Pairing scientific and traditional knowledge approaches is crucial to understanding the fate of environmental systems under ongoing climate change; however creating a bridge between non-local, non-indigenous research scientists and traditional knowledge holders in northern communities brings its own challenges. In an IASC cross-cutting initiative, Fellows of the Terrestrial, Cryosphere and Marine Working Groups organized a workshop on “Community-based Research: Do’s and Don’ts of Arctic Research” bringing together young researchers with resident Arctic representatives and experts to discuss best practices in the exchange of traditional and scientific knowledge and in conducting research in northern communities.

The format and organization of the workshop allowed an interactive and fruitful discussion, generating a diverse list of Arctic Research considerations and sustainable practices. An extensive list of positive (Do’s) and few negative recommendations (Don’ts) was generated together with the young researchers and Arctic representatives, including considerations of:

1. the research design and early planning,
2. the contribution of science to northern communities,
3. the relationship of researchers and indigenous people,
4. the communication and overall impression of visiting scientists and
5. ways to get involved with local people.

This study is a good example of bottom-up strategy development to enhance knowledge transfer between scientists and indigenous communities.
Finnish research vessel Aranda has undergone a major conversion and refit during 2017-2018. In this update the vessel’s ability and capacity for polar work has been significantly improved and enhanced. Since commissioning in 1989, Aranda has completed two expeditions to the Antarctic, and several to Arctic Seas. Aranda was originally designed as a polar r/v, and these properties have been further enhanced in the conversion/refit. Aranda is oceanic class research vessel, and has very good capacity for 3 season ice edge work in the Arctic Seas. Aranda is one of very few mid-size polar capacity research vessels, with a very good capacity/cost ratio, especially in ICES/European Arctic area. Presentation will give a full description of Aranda’s conversion/refit, and describe her capacity for polar work in different disciplines, most important of which is arctic biological oceanography, environmental research and food web studies. Aranda is also very environmentally friendly r/v, with very low noise emission to sea, high fuel efficiency, and capacity for using biofuels.
The Year of Polar Prediction (YOPP) has been initiated by the World Meteorological Organization’s World Weather Research Programme resulting from the ongoing changes in polar regions and increasing new opportunities such as raising economic, touristic, transportation, and scientific activities. Scheduled from mid-2017 to mid-2019, YOPP is a major international activity to significantly advance our environmental prediction capabilities for the polar regions and beyond on a wide range of time scales from hours to seasons. Supporting improved weather and climate services, various international stakeholders such as the interdisciplinary polar science community, the operational centres providing but also those using polar forecast products are involved when it comes to the various YOPP activities such as intensive observing, modelling, prediction, verification, user-engagement and education. The International Coordination Office for Polar Prediction hosted by the Alfred Wegener Institute for Polar and Marine Research in Bremerhaven, Germany, not only oversees everyday activities and fosters communication and outreach but also coordinates, plans and prepares details of the different work packages together with the YOPP steering group and several task teams. Engaging such a wide range of interdisciplinary and international stakeholder groups, YOPP will contribute to the knowledge base needed to managing the opportunities and risks that come with polar climate change.
Towards the Marine Arctic Component of the Pan-Eurasian Experiment (PEEX)

Timo Vihma¹ (timo.vihma@fmi.fi), Petteri Uotila², Stein Sandven³, Dmitry Pozdnyakov⁴, Alexander Makshtas⁵, Vladimir Ivanov⁵, Alexander Pelyasov⁶, Finn Danielsen⁷, Roberta Pirazzini¹, Hanna Lappalainen², Anna Albin⁷, Bin Cheng³, Tuukka Petajä², Ivan Frolov⁵, Markku Kulmala²
¹Finnish Meteorological Institute, Helsinki, Finland, ²University of Helsinki, Department of Physics, INAR - Institute for Atmospheric and Earth System Research, Helsinki, Finland, ³Nansen Environmental and Remote Sensing Centre, Bergen, Norway, ⁴Nansen International Environmental and Remote Sensing Centre, St. Petersburg, Russian Federation, ⁵Arctic and Antarctic Research Institute, St. Petersburg, Russian Federation, ⁶Center for the Arctic and Northern Economies, Council for Research for Productive Forces, Moscow, Russian Federation, ⁷Nordic Foundation for Development and Ecology, Copenhagen, Denmark

The recent rapid climate change in the marine Arctic has strong environmental and socio-economic impacts, which calls for enhancement of cross-disciplinary research. We present a plan for a marine Arctic component of PEEX. The plan is based on
(a) evaluation of the state and change of the marine Arctic climate and environmental system,
(b) identification of the actual research needs and the state of existing observations in relation to the needs,
(c) evaluation of the information available on the basis of atmospheric and ocean reanalyses,
(d) and evaluation of the relevant socio-economic and cultural aspects that both affect and are affected by the climate and environmental changes.

Among the first practical steps is establishment of a coherent, coordinated, comprehensive observation system. It is a pronounced technological and logistical challenge, but advance is possible via international collaboration, new observation technology, community-based coastal observations respectful for knowledge holders, better data management, and better reanalyses supporting observations. The marine Arctic component of PEEX is aimed to be integrated with the well-established structure and activities of the terrestrial and atmospheric components of PEEX. This requires particular attention to the linkage and feedback processes between the marine Arctic and Eurasian continent. These include atmospheric transports in and out of the Arctic, river discharge, and various other coastal processes.
Rapid Response to Environmental Emergency Alerts. An INTERACT Initiative

Alexandra Bernardová¹ (alex.bernardova@gmail.com), Marie Sabacka¹, Josef Elster¹, Terry Callaghan²,³
¹University of South Bohemia in Ceske Budejovice, Faculty of Science, Centre for Polar Ecology, Ceske Budejovice, Czech Republic, ²University of Sheffield, Sheffield, United Kingdom, ³Tomsk State University, Tomsk, Russian Federation

INTERACT - International Network for Terrestrial Research and Monitoring in the Arctic is an infrastructure project funded by the EU. Its main objective is to build capacity for identifying, understanding, predicting and responding to diverse environmental changes throughout the wide environmental and land-use envelopes of the Arctic. It encompasses a circum Arctic network of 82 terrestrial field bases in Europe, Russia, US, Canada and stations in northern Alpine regions.

Rapid response to environmental emergency alerts, the “Red Phone”, is a work package within INTERACT with a main goal to help protect Arctic and global residents from the hazards of potential future environmental emergencies by identifying and responding to any upcoming environmental hazards and disasters. Relevant agencies and organisations (such as GEO, Arctic council, SAON, COOPEUS, CLINF, etc) are planned to be contacted to help with rapid response actions.

The Red Phone’s main output will be the development of protocols for monitoring of any potential environmental risks and hazards and a subsequent implementation of an alert system for Arctic research stations and adjoining territories.

The whole project is dependent on efficient networking throughout the Arctic, for which INTERACT provides a great platform with its comprehensive net of research stations where sampling and observations can be carried out simultaneously and comparatively across a wide range of territories, often in remote regions.
Polar Research Center - Together Conducting Research in Svalbard

Ireneusz Sobota\(^1\) (irso@umk.pl)
\(^2\text{Nicolaus Copernicus University, Faculty of Earth Sciences, Polar Research Center, Toruń, Poland}\)

Polar Research Center is an independent unit of the university’s Faculty of Earth Sciences of Nicolaus Copernicus University in Torun.
Main tasks of Polar Research Center are:
- Initiating and leading interdisciplinary research in polar regions and other glaciated areas,
- Encouraging interdisciplinary research projects,
- Supporting Polish Nicolaus University Polar Station. Kafføyra, Spitsbergen,
- Cooperation with Polish and foreign polar research institutions,
- Cooperation with non-academic partners interested in polar research and exploration,
- Promoting knowledge about polar regions and their important role in our life and global processes.

Our research in Svalbard has essentially covered all components of the geographic environment, however with a particular focus on glaciology, glacial geomorphology, permafrost and periglacial processes, as well as climatological and biological studies. The glaciology studies cover: mass balance of glaciers, glaciers geometry change processes, glacier dynamics, glacier surge, glacier-climate interactions, polar hydrology, subaqual extent change records in the forefields of marine-type glaciers and others.

For us Svalbard is a unique natural research laboratory. It is a place where we can witness processes which once shaped the surface features of Poland. As such, it provides a perfect educational base for research fellows, academic staff, and doctoral, postgraduate and undergraduate students.
The presentation considers opportunities of communication, coordination, and collaboration to help span disciplinary, institutional, international, and sector boundaries at the example of snow remote sensing. The NASA snow algorithms are capable to provide daily global snow output including subpixel snow fraction at 500 m resolution. Snow fraction information improves downstream remote sensing products: vertical atmosphere profiles, soil moisture, heat fluxes, etc. The global snow observation is an important component of land surface and hydrologic models estimating water storage and runoff from melting snow for agricultural and other activities. Snow cover influences not only the terrestrial water cycle but climate change too.

Recent developments show increasing interest to fractional snow cover, confirmed by the decisions made by European Space Agency and Japan Aerospace Exploration Agency to derive snow fraction using visible observations from Sentinel-3 and GCOM-C respectively. The collaboration between several parties tackling the same problem can be very promising and successful.

After the SCAR Working Group, SnowAnt, made its first successful action - organizing Snow Science Winter School, it is recommended that the group contributes efforts aimed at the key goal - improve the knowledge on processes in Antarctic snow and its feedbacks to the climate system; develop a snow classification for Antarctica - the tasks impossible without implementing snow remote sensing.
The interdisciplinary project “Comparative analysis of the sources of incomes and the problem of poverty in traditional communities of northern regions of Russia, the USA and Canada” is running with funding of the Russian Foundation for Basic Research in 2017-2019. It aims at a comprehensive study of the phenomenon of poverty among native communities of the northern regions and the development of effective mechanisms to overcome it.

The first stage of 2017 consists in the analysis of the structure and size of incomes, poverty level as well, retrospective analysis of the spatial transformation, accessibility to lands and natural resources for the local people and the evolution of the social policies in designated northern countries. Regional factors that affect poverty and its long-term retention are studied in conjunction with other factors (institutional, demographic, and economic). Surveys in selected settlements were implemented on this basis.

Thereby, subjects of presentation and discussion are:
- common issues and national features of poverty including inefficient and redundant mechanisms of social protection;
- cases of industrial projects affecting the sustainability of the traditional economy and communities of the indigenous peoples of the Russian North;
- benefits and risks of the local communities under implementation of the model Guaranteed Annual Income or Basic Income;
- cross-country studies and surveys.
The INTERACT Fieldwork Guidebook - A Brief Introduction

Fiona Tummon¹ (fiona.tummon@apecs.is), Gerlis Fugmann², Elmer Topp-Jørgensen³, Morten Rasch⁴, Ruth Vingerhagen⁵, Morgan Seag⁶, Gwenaelle Gremion⁶
¹University of Tromsø, Tromsø, Norway, ²APECS Directorate/Alfred Wegner Institute, Potsdam, Germany, ³Aarhus University, Aarhus, Denmark, ⁴University of Copenhagen, Copenhagen, Denmark, ⁵University of Cambridge, Cambridge, United Kingdom, ⁶Université de Québec à Rimouski, Rimouski, Canada

The Horizon-2020 INTERACT (International Network for Terrestrial Research and Monitoring in the Arctic) aims for a geographically comprehensive and excellent state-of-the-art terrestrial research infrastructure throughout the Arctic and in adjoining forest and alpine regions. The project will help to identify environmental change, to facilitate understanding and prediction of future change, and to inform decision makers about societally-relevant impacts. INTERACT uniquely unites 83 research stations offering access to the Arctic and surrounding regions and stimulating new collaborations and information flow.

Effectively carrying out research in the field means being well-prepared in relation to planning and safe execution of the field activities. Together with the Association of Polar Early Career Scientists (APECS), INTERACT is developing a fieldwork planning handbook and a general practical field guide. The handbook will include recommendations for preparing for fieldwork, covering a wide range of topics such as health and safety, environmental issues, outreach, and country-specific sections on obtaining relevant permits. The field guide will be a practical guide to be carried into the field, providing recommendations on practical issues related to conducting field work at research stations. The handbook and field guide will be developed in cooperation with INTERACT station managers to make use of their wealth of expertise.
Early Career Engagement Bridges Polar Boundaries: A Case Study from Horizon 2020

Jilda Alicia Caccavo¹ (jildaalicia.caccavo@studenti.unipd.it), Alexander E. Thornton², Jean Holloway³, Alice Bradley⁴, Ruth Hindshaw⁵, Fiona Tummon⁶, Gerlis Fugmann⁷

¹Università degli Studi di Padova, Dipartimento di Biologia, Padova, Italy, ²University of Alaska Fairbanks, Fairbanks, United States, ³University of Ottawa, Ottawa, Canada, ⁴Dartmouth College, Hanover, United States, ⁵University of Cambridge, Cambridge, United Kingdom, ⁶University of Tromsø, APECS International Directorate, Tromsø, Norway, ⁷APECS Directorate/Alfred Wegner Institute, Potsdam, Germany

Early Career Researchers (ECRs) comprise a significant portion of the workforce in the Arctic and Antarctic communities, yet remain an underutilized resource in many large polar research projects. A key goal of the Association for Early Career Polar Scientists (APECS) is to develop opportunities for ECRs, and part of that is achieved by integrating ECRs into polar research and coordination activities from the outset. Benefits to projects who welcome ECRs include gaining unique perspectives from passionate, skilled minds as well as having an active role in training future leaders of these groups. APECS also serves as an institutional partner to support early career involvement to reduce a project’s organizational risk of working with ECRs given, for example, inherent and relatively unpredictable career transitions. This poster will describe opportunities available to ECRs through APECS’ engagement in large consortia like the EU Horizon 2020 funded projects APPLICATE, INTERACT, ARICE, and NUNATARYUK. APECS is uniquely qualified to plan digital and in-person training experiences, as evidenced through our long-term webinar series and the Polar Prediction School 2018 as part of APPLICATE. Successful collaborations have depended on early engagement with APECS as a partner in order to integrate education, outreach, and training activities within these projects. APECS looks forward to working with other polar research groups to include ECRs through every phase of development.
RoSES - Role of the Southern Ocean in the Earth System: A NERC Funded Programme

Elaina Ford 1 (eakf@bas.ac.uk)
1 British Antarctic Survey, Cambridge, United Kingdom

The Role of the Southern Ocean in the Earth System - RoSES - is a programme funded by the UK’s Natural Environment Research Council (NERC) and aims to substantially reduce uncertainty in 21st century global climate change projections through improved assessment of the Southern Ocean carbon sink. It is a five-year programme, funded from 2017 to 2022. RoSES (@RoSES_ocean, www.roses.ac.uk) currently consists of three projects (with a fourth to be funded in due course):
- CUSTARD: Carbon Uptake and Seasonal Traits in Antarctic Remineralisation Depth. Principal Investigator: Dr Adrian Martin, National Oceanography Centre. #RoSES_CUSTARD
- PICCOLO: Processes Influencing Carbon Cycling: Observations of the Lower limb of the Antarctic Overturning. Principal Investigator: Prof Karen Heywood, University of East Anglia coPI Tom Bell, Plymouth Marine Laboratory. #RoSES_PICCOLO
- SONATA: Southern OceaN optimal Approach to Assess the carbon state, variability and climatic drivers. Principal Investigator: Prof. Corrine Le Quere, University of East Anglia. #RoSES_SONATA

Here we present the aims and objectives of these three projects, and their links to the ORCHESTRA programme:
- Ocean Regulation of Climate by Heat and Carbon Sequestration and Transports. @ORCHESTRAProj, www.bas.ac.uk/projects/orchestra.
Thu_395_SH-6_2525
Arctic Pedagogic Landscape Inquiry Bridging the Polar to the Peak

Bin Li$^{1,2}$ (bin.li@aho.no)
$^1$Oslo School of Architecture and Design, Urbanism and Landscape, Oslo, Norway, $^2$The Arctic University of Norway, Tromso, Norway

Synthesis of high latitude and high altitude, territories of high peaks expand from Arctic polar regions to the Third Pole Hindu Kush-Himalayan regions, storing snow and ice and facing climate change, industrial challenge, infrastructure development, resource management, traveler pressure and indigenous need. Landscape researchers situated in Tromso been inquiring into Arctic challenges, are expeditioners to Mount Gongga of the third pole region, observing and mapping similar social and ecological challenges, referencing Arctic cases, providing alternatives to the high altitude. Perceptual and motional mapping from ground into both the polar and the peak, high walking routes and high ecological lines, and representational images of both start to bridge the high polar to the high peak. The paper is a critical reflection on the bridging value of Arctic pedagogic landscape inquiry to Third Pole high peaks.
The biggest questions in Arctic research need the best partnerships and the most joined-up research communities. The UK Arctic Office, funded by the Natural Environment Research Council, exists to:
- support UK-based researchers in the High North;
- provide advice to policy makers; and
- develop new international research initiatives across the Arctic
Since 2010 the UK Arctic Office has supported a wide range of initiatives and is ambitious to do even more. This Abstract provides attendees with the opportunity to hear about the role of the Office; to discover new international initiatives, such as the UK-Canada Bursaries Programme (2017 & 2018); and see how a small team can add value in building new collaboration.
The United Kingdom has always been a key player in Antarctic politics. Almost all studies regarding the politics of the white continent on the period previous to the Antarctic Treaty have taken into consideration the British policy on those latitudes. Much of those studies have centered their attention into the geopolitical variables that influenced the British imperial ambitions, and when considering the role of ‘science’, they usually have ascribed it a merely ‘instrumental’—when not absolutely accessory—role. Based on the idea that scientists and scientific institutions have played a significant role in shaping the Antarctic politics, we contend that ‘science’ could not be reduced to being instrumental to the imperialist policy, and that exerted important influences on the political agenda setting and further structuring of southern polar politics, particularly in determining the shape of the final arrangement of the 1959 Antarctic Treaty. In order to contrast those ideas and adopting a pluralistic approach informed on the Historical Sociology, we will apply a process tracing of the British Antarctic history through archival material, paying special attention to the involvement of scientist and scientific institutions, alongside other geopolitical, economic and ideational variables.
The Policy Relevancy of Arctic Marine Scientific Research: A PRS Case Study

Akiho Shibata1 (akihos@kobe-u.ac.jp), Naomi Harada2, Hajime Kimura2
1Kobe University, Polar Cooperation Research Centre (PCRC), Kobe, Japan, 2Japan Agency for Marine Science and Technology, Yokohama, Japan

Many of the challenges facing modern societies today like climate change cannot be adequately addressed without the input from science and scientific advice. At the same time, the science necessary to solve societal problems and the expensive scientific activities to support it, more often than not, need to be prioritized and selected because of, for example, budgetary reasons. The Policy-Relevant-Science (PRS) study, embarked upon by Kobe University PCRC and JAMSTEC under the Japanese ArCS project, tries to explore academically the ways in which to support such decision making by public entities regarding the prioritization and selection of scientific activities.

In our examination, we utilize the Value Tree Analysis (VTA) as a methodological tool for identifying the degree of policy relevancy of Arctic marine observation activities. In applying the VAT, we analyze the Arctic strategies of major Arctic marine research countries so as to clarify the key policy objectives in each of the major international Arctic policy areas. The policy relevancy is the subjective value to be achieved in our PRS Study. We then examine the key scientific outcomes that would support and realize the key policy objectives. The degree of policy relevancy of a particular Arctic marine observation activity would be evaluated by examining how much such activity supports the multiple key scientific outcomes that in turn support to achieve the key policy objectives of the international community.
Importance and Interest on Arctic and Svalbard Treaty

Y. Barbaros Buyuksagnak1 (ybbuyuksagnak@pirireis.edu.tr), Burcu Ozsoy2
1Piri Reis University, Istanbul, Turkey, 2ITU, Istanbul, Turkey

As the Arctic is increasingly becoming one of the focus points of international community, Svalbard Islands, with its location, rich wildlife, arctic nature, and old mining towns also draw attention of the states which are interested in the region. The 1920 Svalbard Treaty confers full and absolute sovereignty on Norway. Nevertheless, under the Treaty, Norway is obliged to give the citizens and companies of the signatory nations equal rights in certain areas, such as; entrance to and residence in Svalbard; fishing, hunting and trapping; maritime, industrial, scientific research, mining and commercial activities; acquisition and utilization of property and mineral rights.

More than 40 states have signed the treaty since 1920. Turkey, a maritime country surrounded by sea on three sides, with its 80-million population as having seventeenth largest economy and being close interest to global affairs is not among signatory states. Besides, Turkey has signed the Antarctic Treaty in 1996. In a very short period, launching the initiatives to become a party of the Svalbard Treaty will be evaluated.

This study aims to reveal the position of Turkey in Arctic related issues within the concept of Svalbard Treaty. Keywords: Arctic, Svalbard Treaty, Turkey
The Diplomacy of Science in Antarctica

Annebelle Davis\textsuperscript{1} (annebelle.davis@anu.edu.au)
\textsuperscript{1}Australian National University, Asia-Pacific College of Diplomacy, Deakin, Australia

Antarctic diplomacy seen through the lens of States negotiating The Antarctic Treaty after World War II and the environmental protections of the 1990s has to date emphasised traditional diplomatic practices and approaches. Much of what is known outside Ministries for Foreign Affairs about the dynamics of Antarctic diplomacy behind the scenes comes to us via the recollections of diplomats in conference papers, and the personal insights of Antarctic decision-makers published after they left office. No matter their starting point, or whether these negotiations were about State interests exclusively or preserving the continent untouched in keeping with collective interests, many of these decision-makers took opportunities inside and outside diplomatic tracks to reiterate that Antarctica and its management constitute a special case in international engagement. 'Specialness' is prominent in the diplomatic lexicon of Antarctica. This presentation is responding to the challenge that this specialness poses by exploring what is unique, different, replicable or generalisable about Antarctic diplomacy. It focuses on whether Antarctic diplomacy has a signature that sets it apart from mainstream diplomacy, and what this means for managing Antarctica seen through the lens of science diplomacy as an evolving and necessary adjunct to international engagement on Antarctica and Antarctic issues.
How Can My Research Data Be Useful for Conservation and Policy-making?

Kevin Hughes¹ (kehu@bas.ac.uk), José C Xavier¹,², Daniela Liggett³, Gabriela Roldan³, Annick Wilmotte⁴
¹British Antarctic Survey, Cambridge, United Kingdom, ²University of Coimbra, Marine and Environmental Sciences Centre (MARE-UC), Department of Life Sciences, Coimbra, Portugal, ³University of Canterbury, Gateway Antarctica, Christchurch, New Zealand, ⁴University of Liège, InBios-Centre for Protein Engineering, Liège, Belgium

Biodiversity conservation is a main goal of the Protocol on Environmental Protection to the Antarctic Treaty. Policy should be based on the best scientific data available, and policy-makers are eager to have access to up-to-date and high quality information. Scientists are on the frontline to gather relevant data, though their primary aim is to publish in international refereed journals. However, once the data, and resulting information, have been scrutinized and quality-checked during the review process, their usefulness for policy-making should be also considered as they may have the potential to inform conservation measures or document processes affecting biodiversity.

However, it is not always simple to find out how to convey this information to policy-makers. In this poster, three main pathways are presented, through (a) the Scientific Committee on Antarctic Research (SCAR) and its Standing Committee on the Antarctic Treaty System (SCATS: see www.scar.org/policy/scats/); (b) your National Delegates to the Committee on Environmental Protection (see: www.ats.aq/devAS/cep_authorities.aspx); or (c) writing a summary for the Antarctic Environments Portal (www.environments.aq). The latter publishes short articles presenting state-of-the-art research findings after a thorough review process.

Hopefully, this description will encourage scientists to consider the value of their research data for conservation of Antarctic biodiversity.
An Assessment of South Korean-New Zealand Cooperation in Antarctica

Patrick Flamm\textsuperscript{1} (p.flamm@auckland.ac.nz)
\textsuperscript{1}University of Auckland, Auckland, New Zealand

While the Antarctic Treaty System intended to keep Antarctica an area of international cooperation and science free from politics and militarization, it is not protected from global and regional power transformations today. Among the emerging players from Asia, South Korea has already been identified as likely key challenger to the status-quo polar order. This raises questions about what South Korea wants from its presence in Antarctica and how challenging Seoul's demands are perceived to be for the existing Antarctic order. This paper is an role theoretical assessment of Antarctic cooperation between South Korea and its main partner, New Zealand. This cooperation is crucial for South Korea not only for the politics and logistics in relation to the newly established Jang Bogo research station in Terra Nova Bay, but also scientifically between the Antarctic agencies Antarctica New Zealand and the Korean Polar Research Institute (KOPRI). How was this cooperation experienced so far and how is it valued especially with regard to an increasingly less engaged US Antarctic program and an growing Chinese polar presence? How do especially the NZ government and Antarctica New Zealand perceive South Korea in the role of a 'challenger'? Does Wellington see any chance in socializing Seoul through engagement into something else than a challenger to the Antarctic order?
Morning Plenary III  
22.06.2018 07:50-09:00, A Davos

Keynote Lecture V  
The Emerging Importance of the Humanities and Social Sciences in Polar Research

Peder Roberts (Peder.roberts@abe.kth.se)  
Division of History of Science, Technology and Environment, KTH Royal Institute of Technology, Stockholm, Sweden

The humanities and social sciences are increasingly recognized as central components of Antarctic as well as Arctic research. This presentation provides an overview of emerging trends with a particular focus on critical heritage studies, human relationships to physical geographical environments, and the construction of governance structures. Specific examples discussed include 1) processes for identifying, managing, and in some cases re-using the material legacies of human presence; 2) how the construction and implementation of fauna management regimes reflect particular conceptions of how humans should interact with the natural world; and 3) how changing social expectations can be accommodated within polar governance structures. In each case, emphasis is placed upon exploring the assumptions that underpin human activity in the polar regions and how these can (and indeed) have changed through time. The presentation concludes with brief reflections on how the significant differences between the Arctic and Antarctic have shaped research agendas, while nevertheless including substantial opportunities for bi-polar comparisons.
West Antarctica has been identified as one of the fastest warming places on the planet. Large parts of the West Antarctic Ice Sheet (WAIS) are predicted to melt as a result of climate change. Reducing uncertainties over the rate of that melt has been identified as a key research priority in the 5th IPCC Assessment Report. It is well understood from geological reconstructions that there are times in the past when average temperatures were only ~2-3°C warmer than today, but global sea levels may have been up to 20 m higher. Determining which of these times may have been accompanied by a widespread collapse of the WAIS is needed to provide critical insights into the potential rate and magnitude of sea-level rise over the coming decades and centuries. It is unknown whether there was a collapse of the WAIS during the Last Interglacial, 125,000 years ago – the last time Earth was +1°C warmer than the pre-industrial period. A recent ice sheet model implies Antarctica may have contributed up to 5m of the 6-9m of global sea-level rise known from geological evidence. Confirming this is particularly important for constraining future sea level projections. The complete collapse of the WAIS would lead to the existence of trans-west Antarctic seaways linking the present day Ross, Weddell and Amundsen Seas. Such seaways would allow marine animal migration across newly opened straits, and a genetic signature of that historical connectivity will persist in the genomes of benthic animals present in Antarctica today. I will describe how we are using this information to distinguish between hypotheses to determine when the WAIS last collapsed.
The Influence of Abiotic Factors on the Plant Growth in the High Arctic

Krzysztof Migala¹ (krzysztof.migala@uwr.edu.pl), Magdalena Opała-Owczarek², Piotr Owczarek¹, Bartek Luks⁴, Daniel Kepski³, Wojciech Szymanski⁵, Mariusz Szymanowski⁶, Bronisław Wojtun⁶
¹University of Wrocław, Institute of Geography and Regional Development, Wrocław, Poland, ²University of Silesia, Faculty of Earth Sciences, Sosnowiec, Poland, ³University of Wrocław, Institute of Geography and Regional Development, Wrocław, Poland, ⁴Institute of Geophysics, Pol. Acad. of Sciences, Warszawa, Poland, ⁵Jagiellonian University, Institute of Geography and Spatial Management, Krakow, Poland, ⁶University of Wrocław, Wrocław, Poland

The aim of our studies was to comprehensively evaluate the abiotic factors that influence changes in the annual growth rates of selected species of tundra plant. The study was conducted on Wedel Jarlsberg Land, SW Spitsbergen.

It is argued that the spatial and seasonal variability of annual growth is determined by the rate at which snow cover disappears, and also by soil moisture, which determines the plants' access to water. Soil moisture depends on soil particle size distribution and weather; it is regulated by the supply of snowmelt water and rainfall and also the depth at which the top layer of permafrost is situated (thaw depth), which determines the level of groundwater during the growing season. The spatial characteristics of the process of seasonal snow cover disappearance are co-determined by the morphology of the substrate and the physical properties of the soil. An important but also destructive role is played by thawing episodes, which are increasingly frequent in the winter season. The observed trend towards warming in polar areas does not inevitably lead to an increase in biomass production. An increase in temperature during the growing season does not necessarily promote plant growth, but rather is an indicator of drought stress caused by the lowering of groundwater levels related to the increase in the depth to which the active permafrost layer thaws.
Remote Sensing of Spatial Structure of the Circumpolar Tundra-taiga Transition

Wenkai Guo¹ (wg241@cam.ac.uk), Gareth Rees¹
¹Scott Polar Research Institute, University of Cambridge, Cambridge, United Kingdom

The tundra-taiga ecotone (TTE) or the arctic treeline is the world’s longest vegetation transition zone, the configuration, composition and dynamics of which vary greatly across the circumarctic region. Overall, the TTE responds positively to global temperature changes with a net global treeline advance, although showing significant regional diversities in movement patterns, which are linked to different controlling factors of tree growth. Despite its high ecological significance, currently available derivation of the TTE suffers from low spatial resolution and high dependence on arbitrary vegetation coverage thresholds. This study uses texture analysis of Landsat Vegetation Continuous Field data to separate the TTE from other land cover types trained using a collection of ground truth sites with known types. We also further explore the detailed texture differences within the treeline class which greatly influences treeline response to climate change. Using the FOurier-based Textural Ordination (FOTO) technique, treeline areas are separated into abrupt, diffuse and islands forms which correspond to different levels of treeline vulnerability to climate change. Thus, this study identifies the TTE and further divides it into ecologically significant categories, which may serve as a global map of treeline vulnerability and provide the basis for future studies into the detailed correlation between treeline processes and spatial characteristics.
Marginal Population Hotspots of Cold-adapted Species in a Warmer World

Simone Orsenigo¹, Milena Cere², Thomas Abeli² (thomas.abeli@unipv.it)
¹University of Milan, Department of Agricultural and Environmental Sciences - Production, Landscape, Agroenergy, Milano, Italy, ²University of Pavia, Department of Earth and Environmental Sciences, Pavia, Italy

We know little about factors shaping geographical location of margin ranges in plant species. However, understanding factors and processes allowing populations to survive at the range edge or migrate is crucial to trace the effect of past climate changes and to predict future species distribution and evolution. This is particularly important for cold-adapted species that are predicted to be affected by global warming more than other species, especially at the southern range edge. Consequently, identification of areas where arctic-alpine, circumpolar and circumboreal species reach their southernmost ends of their distribution and group together (marginal hotspots) will present a unique opportunity to highlight uncover processes that shaped current biogeographical patterns, as well as prepare for future scenarios and set conservation management.

We identify areas where southernmost populations of 183 cold-adapted taxa, are clustered in north America and Europe, based on the number of species reaching their southern range edge in each cell of a 50×50 km grid. Marginality hotspot partially correspond to known refugia, in other cases high latitude areas are extremely important.

From an applied conservation perspective, we detected areas where studies and monitoring of cold-adapted species are best performed to maximize the knowledge gain and where conservation efforts should be directed to allow marginality hotspots to continue their function of refugia in a warmer world.
Micodiversity across Altitudinal Gradient and Solar Exposure in Antarctic Rocks

Laura Selbmann¹ (selbmann@unitus.it), Claudia Coleine¹, Silvano Onofri¹, Laura Zucconi¹
¹University of Tuscia, Dept of Ecological and Biological Sciences (DEB), Viterbo, Italy

Rocky outcrops support the highest standing biomass in the Antarctic ice-free areas; along the Victoria Land, the largest ice-free area of the McMurdo Dry Valleys, together with mountain tops and nunataks hanging from the ice sheet, represent significant examples. In some of these locations, conditions approach the limits of tolerability for most organisms and endolithic communities are the predominant life-forms. This study focused on sandstone, the best substratum for endolithic colonization, collected in 3 locations over an altitudinal gradient from 800 to 3100 m asl; both north/south sun expositions were considered. Rock samples were analyzed with a meta-barcoding approach on Illumina MiSeq platform, targeting the Internal Transcribed Sequence 1 (ITS1) region for fungi. Taxonomic results, alpha-diversity and statistical analysis were performed to investigate microbial diversity and community structure related to environmental changes. Preliminary results show a large predominance of Ascomycota in all the sites studied, the classes Lecanoromycetes and Dothideomycetes prevailed. Among the localities considered, species richness varied between 80 and 106. All the biodiversity indexes (Shannon, Pielou and Simpson) clearly showed that the number of predominating species decreases with the environmental pressure, indicating a higher specialization of the community, and that sun exposition is the parameter that influences fungal community composition most.
Physiological Responses and DNA Repair in *Pseudogymnoascus* spp. Fungi toward UV

Hao Jie Wong\(^1,2\) (maccus92_1@hotmail.my), Nuradilla Mohamad-Fauzi\(^1,3\), Mohammed Rizman-Idid\(^1\), Peter Convey\(^4,5\), Siti Alias\(^1,5\)

\(^1\)University of Malaya, Institute of Ocean and Earth Sciences, Kuala Lumpur, Malaysia, \(^2\)University of Malaya, Institute of Graduate Studies, Kuala Lumpur, Malaysia, \(^3\)University of Malaya, Institute of Biological Sciences, Kuala Lumpur, Malaysia, \(^4\)British Antarctic Survey/NERC, Cambridge, United Kingdom, \(^5\)University of Malaya, National Antarctic Research Centre, Kuala Lumpur, Malaysia

Solar radiation drives almost all biological activities on Earth and regulates morphological, biochemical and developmental processes in many organisms. Soil microorganisms such as fungi within the polar regions can be continuously exposed to considerable solar UV radiation in the summer. This could negatively impact their key functions, for instance in regulating nitrogen and carbon cycles. We examined the responses of four polar strains of *Pseudogymnoascus* spp. (isolated from Hornsund, Svalbard, and King George Island, Antarctic), assessing growth, pigmentation, conidia production, post-UV DNA lesion changes and expression of DNA repair genes. Cultures were irradiated with 6.1 kJm\(^{-2}\)d\(^{-1}\) UV-B dosage and 12 h of PAR at 15°C for 10 d in the laboratory. All strains showed growth rate reduction of between 21.74 and 35.52%. Coloured pigment production was not induced by exposure to UV-B, suggesting no dependence on pigments for protection. UV-B exposure also reduced conidia production. We are now targeting genes involved in photoreactivation and nucleotide excision repair, primary DNA repair pathways responsible for maintaining DNA integrity under UV. The expression levels of genes will be determined after UV exposure in dark and light conditions, and UV-induced DNA lesions, CPDs and 6-4PPs will be quantified. Preliminary ELISA results suggest that *Pseudogymnoascus* HND16 R4-1 sp.1 is able to reduce UV-B induced CPDs significantly after 2 h in both dark and light conditions.
Similar to abiotic particles, microorganisms from marine and terrestrial environments are transported via the atmosphere to glaciers all over the world through dry or wet (snowfall or rain events) deposition, sometimes carried over thousands of kilometers. Once deposited, these organisms can survive in the snow and interact with their environment even at sub-zero temperatures. However, in order to colonize some of these new niches, microorganisms must either already be equipped with, or rapidly acquire, the necessary functions. Since cryosphere environments are undergoing rapid change, they are ideally suited for understanding the dynamic and rapid adaptation of microbial communities. Based on our cold environment metagenomic research performed over the last ten years, different drivers of adaptation lead to dynamic shifts in microbial community structure and function in Arctic environments and strategies used to acquire genes critical for ecosystem functioning. This field and laboratory-based research in snow and ice ecosystems, including sea-ice and terrestrial snow packs, has examined multiple habitats that present steep environmental gradients. As climate change continues, we need to improve our knowledge about the biotic system in order to predict its response to environmental forcing. Microorganisms are both sentinels and bioindicators of change, but the information they encode is rapidly being lost as habitats disappear.
Iron (Fe) is a critical micronutrient that controls phytoplankton growth in the Southern Ocean. As part of the Heard Earth-Ocean-Biosphere Interactions (HEOBI) voyage in January/February 2016, we surveyed suspended particles in the water column and underlying sediments at 11 stations over the southern Kerguelen plateau close to Heard and McDonald Islands (HIMI) to assess the sources of natural phytoplankton iron fertilisation in the region. Heard is glaciated, while McDonald is ice-free. These characteristics should, we hypothesise, ensure unique fertilisation in the downstream waters of these highly productive island hotspots. Glacial erosion and fluvial outflow into surrounding waters near Heard proved to be an important source of highly labile nanoparticulate Fe oxides. In contrast, proximal to diffuse gasohydrothermal sites near McDonald, only highly refractory titanium and iron bearing minerals (Ilmenite) were found. We conclude that glacial erosion of Heard Island is an important mechanism of Fe supply to downstream waters and therefore critical to the productivity of the area near-shore and downstream of the Kerguelen plateau. Conversely, shallow gasohydrothermal sources seem less efficient at delivering labile Fe. As our climate warms and our glaciers retreat, this source of labile Fe may temporarily increase and then dramatically decrease into the future.
Sources and Transport of Iron and Organic Carbon in the Lena River

Per Andersson\(^1\) (per.andersson@nrm.se), Don Porcelli\(^2\), Liselott Kutscher\(^3\), Catherine Hirst\(^4\), Carl-Magnus Mörth\(^3\), Trofim Maximov\(^5\)

\(^1\)Swedish Museum of Natural History, Stockholm, Department of Geosciences, Stockholm, Sweden, \(^2\)University of Oxford, Department of Earth Sciences, Oxford, United Kingdom, \(^3\)Stockholm University, Department of Geological Sciences, Stockholm, Sweden, \(^4\)Swedish Museum of Natural History, Department of Geosciences, Stockholm, Sweden, \(^5\)North-Eastern Federal University, International Center for BioGeoScience Education and Scientific Training (BEST), Yakutsk, Russian Federation

The Lena River basin, which is one of the largest contributors of organic carbon (OC) and Fe to the Arctic Ocean, is mainly underlain by continuous permafrost. This area is vulnerable to climate driven permafrost thawing, with possible future changes in OC and element fluxes. Filtered water (< 0.22 \(\mu\)m) with colloids and particle fraction (>0.22 \(\mu\)m) have been separated in samples from the Lena River main channel and major tributaries collected during 2012 to 2017. The particles in river water are dominated by authigenic Fe primarily in the form of chemically reactive ferrihydrite with a wide size range, between 20 to 1 \(\mu\)m. The ferrihydrate constitute about 70\% of the particulate Fe transported in the Lena River and tributaries, and thus is an important carrier for trace elements and adsorbed carbon. The annual export and fluxes of organic carbon, based on concentration data of DOC (dissolved organic C) and POC (particulate organic C) and long term discharge data, showed large geographical variations related to differences in precipitation and catchment topography. The $\delta^{13}$C and C/N ratios showed that the primary sources of DOC were terrestrial plant debris and soil organic matter (SOM), while POC was a mixture between SOM and aquatic primary production. These results, from a large area, show that the contribution to the river water concentrations and composition primarily depend on the water flow pathways in a permafrost dominated region.
Incipient warming of peatlands at high latitudes is expected to modify soil drainage and hence the redox conditions, which has implications for Fe export from soils. To disentangle the complex biogeochemical interactions in soils controlling the sources and processes which govern this vital function, understanding the controls on stable isotope fractionation of Fe in peat soils is essential. This study uses Fe isotopes to assess the processes controlling Fe export in a range of Icelandic soils including peat soils derived from the same parent basalt, where Fe isotope variations principally reflect differences in weathering and drainage. An additional constraint on soil weathering is provided by Si stable isotopes. Si supersaturation in solution with respect to amorphous silica is reached upon freezing when Al availability to form aluminosilicates is limited by the affinity of Al for metal-organic complexes. Therefore, the precipitation of amorphous silica in peat soils indirectly supports the formation of metal-organic complexes in poorly drained soils. The influence of organic matter on metals is confirmed using Zn stable isotopes. These observations highlight that in a scenario of decreasing soil drainage with warming high latitude peatlands, Fe export from soils as Fe-organic complexes will increase, which in turn has implications for Fe transport in rivers, and ultimately the delivery of Fe to the oceans.
Iron and Nutrient Flux to the Southern Ocean from McMurdo Dry Valleys Antarctica

Sydney Olund1, Susan Welch1, Anthony Lutton2, Wm Berry Lyons1 (lyons.142@osu.edu)
1Ohio State University, School of Earth Sciences and Byrd Polar and Climate Research Center, Columbus, United States, 2Ohio State University, School of Earth Sciences, Columbus, United States

Primary production in the Southern Ocean is thought to be limited by the micro-nutrient iron (Fe). Numerous investigations over the past decade have attempted to quantify the major sources and chemical speciation of Fe into the Southern Ocean. The potential sources include icebergs, atmospheric deposition, deep-water upwelling, melting glacier and sea ice, and groundwater/subglacial inflow. Our initial work demonstrated that as glaciers retreat and ice-free areas in Antarctica expand, streams could also be a major source of Fe into the coastal ocean. We have expanded our work, and have examined streams flowing directly into the ocean from the McMurdo Dry Valleys (MDV). In addition to the filterable Fe (passing 0.4 µm filter), we have analyzed a number of these samples for biologically important metals such as Mo and V. We have also compared the stoichiometry of the stream waters (N:P:Si:Fe) to that of phytoplankton, and conclude that these streams provide excess Fe and P, relative to fixed N and Si, needed by plants. Our results support the idea that increased cryospheric loss should increase the flux of Fe and other macro and micro-nutrients into the coastal Southern Ocean.
Impact of Ice-ocean Interactions on Nutrient Fluxes in Barilari Bay, Antarctica

The West Antarctic Peninsula (WAP) is home to a thriving marine ecosystem whose dynamics are closely linked to the physical environment. Recent studies along the WAP continental shelf have suggested that the seasonal input of iron-rich glacial melt from the continent may serve to regulate primary production. Export of glacial meltwater occurs primarily through coastal bays and fjords, which serve as the link between the large-scale ocean and the ice sheet. Limited observational datasets have identified these systems as hotspots of primary and secondary productivity, suggesting that input of meltwater may have important consequences for both local and regional carbon cycling. In this study, we provide insight into glacier-ocean interactions along the AP by examining physical, chemical and biological properties of Barilari Bay, a coastal embayment where glacier fronts have experienced net retreat since the 1960s. We show that warm, Upper Circumpolar Deep Water, thought as the primary source of heat for submarine melting of the ice sheet, reaches and interacts with the glacier front in this system. In turn, delivery of meltwater affects local ocean circulation, enriching the fjord with macro-nutrients by entraining deep nutrient-rich water through upwelling at the glacier front. Linking these observations to phytoplankton community composition, biomass and productivity provides insight into glacial contributions to local and regional carbon cycling.
Scales of Southern Ocean Productivity Responses to Iron Inputs

Thomas William Trull\textsuperscript{1,2} (tom.trull@csiro.au), Alice Della Penna\textsuperscript{3}, Bozena Wojtasiewicz\textsuperscript{4}, Melanie Grenier\textsuperscript{5}
\textsuperscript{1}CSIRO Oceans and Atmosphere, Hobart, Australia, \textsuperscript{2}ACE CRC, Hobart, Australia, \textsuperscript{3}University of Washington, Air-Sea Interaction and Remote Sensing, Applied Physics Laboratory, Seattle, United States, \textsuperscript{4}CSIRO Oceans and Atmosphere, Perth, Australia, \textsuperscript{5}University of British Columbia, Vancouver, Canada

Inputs of iron, the nutrient limiting Southern Ocean photosynthesis, are expected to increase in future. To assess possible productivity responses, we examined biomass dynamics (using satellite ocean colour, autonomous profiling floats, and shipboard bio-optics) near the Kerguelen plateau, which has elevated iron inputs from volcanism, glaciers, sediment resuspension, and deep water upwelling. Low iron loss rates (1-2\% per day) during downstream transport in the Antarctic Circumpolar Current in winter can explain the overall length scale (1000 km) of the elevated biomass plume. Mesoscale (10-100 km) biomass variations close to the plateau are also reasonably described by Lagrangian transport, provided Fe loss rates are higher in spring (3-5\% per day), and recycling or resupply processes modulate Fe influence offshore. Surprisingly, at small scale (1-10 km) close to the Heard and MacDonald islands, phytoplankton biomass is low despite elevated iron and high photosynthetic competency. Multiple processes may contribute, including short residence times and removal by grazing and/or settling induced by lithogenic particle inputs. These varying responses emphasize the difficulty of assessing future Southern Ocean productivity changes from local studies, the importance of considering iron removal processes (noting that first-order removal implies the scope of responses will scale with the logarithm of supply), and the usefulness of comparisons across scales.
Sea Ice Retreat and Cold European Winter Revisited

Ida Margrethe Ringgaard\textsuperscript{1,2} (iri@dmi.dk), Shuting Yang\textsuperscript{2}, Jens Hesselbjerg Christensen\textsuperscript{1}, Eigil Kaas\textsuperscript{1}
\textsuperscript{1}University of Copenhagen, Copenhagen, Denmark, \textsuperscript{2}Danish Meteorological Institute, Copenhagen, Denmark

Arctic sea ice has been retreating during most of the satellite era. In recent years, Arctic sea ice experienced a dramatic reduction: the summer extent in 2012 and 2016 was only half of the 1979-2000 average. With such dramatic changes in the current sea ice coverage as a point of departure, several studies have linked reduction in wintertime sea ice in the Barents-Kara Seas to cold weather anomalies over Europe and through large scale tele-connections to regional warming elsewhere. Here we aim to investigate the interaction between sea ice changes in the Barents-Kara Seas and mid-latitude dynamics. Particular focus will be if, and how, Arctic sea ice impacts European winter weather, i.e. if the Arctic sea ice works as the ‘cold heart’ of European weather. Additionally, the potential for the atmosphere to precondition the sea ice conditions in the Barents-Kara Seas is also investigated. To understand the effects of the sea ice reduction on the full climate system, a fully-coupled atmosphere-ocean-sea ice global climate model, EC-Earth, is used. A new method for assimilating sea ice using the sensible heat flux is implemented in the coupled climate model. Using this method, experiments are performed with reduced sea ice cover in the Barents-Kara seas. Results indicate an increase in extreme cold winters over Europe as a response to this reduction in sea ice cover. Here we present some preliminary analysis of the chain of processes responsible for this apparent teleconnection.
Cold Winters in Midlatitudes Coincident with, Not Caused by, Low Arctic Sea Ice

Russell Blackport1, James Screen1 (j.screen@exeter.ac.uk)
1University of Exeter, Exeter, United Kingdom

Rapid Arctic warming has coincided with a spate of cold winters over midlatitude continents. Previous work has proposed two distinct influences of Arctic warming: warm conditions over the Barents-Kara Sea are associated with cold winters across East Asia, whereas severe winters over North America are related with anomalous warmth in the East Siberian-Chukchi Sea. However, this work is based upon correlation and causality has not been established. Here we use physical arguments based on the direction of the surface heat flux over the Arctic regions to elucidate whether low Arctic sea ice is a cause of cold midlatitude winters. We make use of large ensemble simulations with two coupled ocean-atmosphere models under present day conditions. The models are able to accurately capture the two observed modes of interannual variability between low sea ice and cold midlatitude winters, and the anomalous large-scale circulation patterns in which they are embedded. However, these associations are only present during winters when low sea ice coincides with a downward turbulent heat flux, implying the atmosphere is driving the ocean-ice. No midlatitude cooling is found during winters where low sea ice coincides with an upward turbulent heat flux anomaly. This strongly suggests that low sea ice loss is not a cause of severe midlatitude winters, but instead that anomalous large-scale atmospheric circulation simultaneously drives cold midlatitude winters and contributes to Arctic warmth.
The 'Warm Arctic Cold Continents' Pattern during 1901 - 2010

Linling Chen\textsuperscript{1,2} (linling.chen@nersc.no), Edward Hanna\textsuperscript{3}, Jennifer Francis\textsuperscript{4}
\textsuperscript{1}Nansen Environmental and Remote Sensing Centre, Bergen, Norway, \textsuperscript{2}Bjerknes Centre for Climate Research, Bergen, Norway, \textsuperscript{3}University of Lincoln, Lincoln, United Kingdom, \textsuperscript{4}Rutgers University, New Jersey, United States

The 'Warm-Arctic Cold-Continents' (WACC) winter weather pattern is investigated using the European Centre for Medium-Range Weather Forecasts 20th Century reanalysis data (ERA20C) spanning 1901-2010. Both the 1920-1940 and 1990-2010 periods are characterized by Arctic Amplification (AA) and mid-latitude cooling, although the Arctic warming signal for 1990-2010 is almost twice as strong as that for 1920-1940. Compared to the reference period of 1951-1980, significant weakening in mid-latitude poleward temperature gradient and zonal wind, wavier upper level flow character, and strong regional blocking frequency/intensity changes are detected during both AA periods. These results based on statistical analyses highlight the possible role of AA in affecting mid-latitude weather patterns, but further work is needed to quantify the influence of AA on particular mid-latitude dynamical features.
Significant Contribution of Stratospheric Pathway to “Warm Arctic Cold Siberia”

Yutian Wu1 (yutianwu@ldeo.columbia.edu), Pengfei Zhang2
1Lamont-Doherty Earth Observatory of Columbia University, Palisades, United States, 2Purdue University, West Lafayette, United States

Previous studies have extensively documented the impact of Arctic sea ice melting on the midlatitude circulation in winter. However, whether and how sea ice retreat affects the adjacent continent cooling is still unclear and controversial among the scientific community. Here we use a state-of-the-art atmospheric general circulation model, that has been extended into the stratosphere and above, to provide evidence of “Warm Arctic Cold Siberia” pattern. In particular, we explicitly show that an active stratosphere plays a key role in the cold conditions in northern Asia in the subsequent winter following sea ice loss over the BKS. The mechanism involves two-way stratosphere-troposphere coupling and the downward effect from the stratosphere significantly enhances the ridge over East Europe and trough over East Asia, which causes cold air advection and increased frequency of extreme cold air outbreaks over Siberia. The results suggest that it is necessary to use a well-resolved stratosphere model to understand the full impact of Arctic sea ice retreat.
Mechanisms for the Influence of Arctic Sea-ice Loss on Mid-latitudes

Christine McKenna\textsuperscript{1,2} (christine.mckenna@bas.ac.uk), Tom Bracegirdle\textsuperscript{1}, Emily Shuckburgh\textsuperscript{1}, Peter Haynes\textsuperscript{2}, Manoj Joshi\textsuperscript{3,4}
\textsuperscript{1}British Antarctic Survey, Cambridge, United Kingdom, \textsuperscript{2}University of Cambridge, Department of Applied Mathematics and Theoretical Physics, Cambridge, United Kingdom, \textsuperscript{3}University of East Anglia, Centre for Ocean and Atmospheric Sciences, Norwich, United Kingdom, \textsuperscript{4}University of East Anglia, Climatic Research Unit, Norwich, United Kingdom

To explore the mechanisms linking Arctic sea-ice loss to changes in mid-latitude surface temperatures, we conduct idealised modelling experiments. In these, we use an intermediate general circulation model and confine sea-ice loss of two different magnitudes to the Atlantic or Pacific sectors of the Arctic (respectively the Barents-Kara or Chukchi-Bering Seas). Extending previous findings, in the Atlantic and Pacific experiments there are opposite effects on the winter stratospheric polar vortex, for both large-magnitude (end of twenty-first century) and moderate-magnitude sea-ice loss. Accordingly, there are opposite tropospheric Arctic Oscillation (AO) responses for moderate-magnitude sea-ice loss. However, there are similar strength negative tropospheric AO responses for large-magnitude sea-ice loss, suggesting that tropospheric mechanisms become relatively more important than stratospheric mechanisms as the sea-ice loss magnitude increases. The mid-latitude surface temperature response for each loss region and magnitude can be understood as the combination of an 'indirect' part induced by the large-scale circulation (AO) response, and a residual 'direct' part that is local to the loss region. Additional experiments designed to definitively quantify the relative role played by stratospheric and tropospheric mechanisms in the tropospheric AO responses will also be discussed.
How Does Arctic Change Affect European Weather and Climate?

Timo Vihma1 (timo.vihma@fmi.fi), Halldor Björnsson2, Linling Chen3, Klaus Dethloff4, Jennifer Francis5, Rune Graversen6, Edward Hanna7, Dörthe Handorf4, Richard Hall2, Alexey Karpechko1, James E Overland8, Nicholas Tyrell1, Petteri Uotila9

1Finnish Meteorological Institute, Helsinki, Finland, 2Icelandic Meteorological Office, Reykjavik, Iceland, 3Nansen Environmental and Remote Sensing Centre, Bergen, Norway, 4Alfred Wegener Institute, Helmholtz Center for Polar and Marine Research, Potsdam, Germany, 5Rutgers University, Department of Marine and Coastal Sciences, New York, United States, 6University of Tromsø, Department of Physics and Technology, Tromsø, Norway, 7University of Lincoln, School of Geography, Lincoln, United Kingdom, 8NOAA, Pacific Marine Environmental Laboratory, Seattle, United States, 9University of Helsinki, Department of Physics, INAR - Institute for Atmospheric and Earth System Research, Helsinki, Finland

During the period of Arctic amplification since the mid-1990s, air masses originating from the Arctic have become warmer, but the direct advective effects from the marine Arctic to Europe are limited. However, changes in the Arctic affect large-scale circulation regimes that further affect European weather. Important circulation regimes include the positive and negative NAO patterns, a circulation pattern resembling the East-Atlantic West-Russia pattern, and a high-pressure system over Scandinavia with a tongue towards northern Siberia (SCA). During the Arctic amplification period, based on daily data, the frequency of occurrence of SCA has increased in December and January, and the negative NAO pattern has become more common in February and March. Sea ice decline in the Barents and Kara seas has favoured intensification of SCA, which interferes with the Atlantic wave train in autumn. The wave train contributes to strengthening of the Siberian High, generating increased vertical wave flux up to the stratosphere, and further to weakening of the Polar vortex in December - February. Downward feedback to the troposphere perpetuates strong Siberian High, favouring cold-air advection to eastern Europe. In addition, Arctic amplification affects the jet-stream latitude and speed, the occurrence of split jets, and the persistency of weather. Greenland Blocking affects European weather both directly and indirectly via forcing on the jet stream.
Chinese Deep Ice Core Drilling at Dome A, Antarctica: Progress and Problems

Nan Zhang¹, Guitao Shi², Xiaopeng Fan¹, Chunlei An², Zhengyi Hu², Chuanjin Li³, Pavel Talalay¹, Yuansheng Li²
¹Jilin University, Polar Research Center, Construction Engineering College, Changchun, China, ²Polar Research Institute of China, Shanghai, China, ³Northwest Institute of Eco-environment and Resources, Chinese Academy of Sciences, Lanzhou, China

During last six years, five seasons were realized at Dome A, East Antarctica within the Chinese Deep Ice Core Drilling Project DK-1. The tasks of the first two seasons were to construct pilot-hole and to install drilling system. From the very end of the second season (January 2013), the deep ice core drilling was commenced from ~120 m to 800.73 m recorded in January 2017. As the hole became deeper, more drilling data were obtained which allows to analyze the drilling process with depth and gives useful reference to improve the drilling technology. At the same time, drilling team gained more experience. Nevertheless, drilling problems often occurred due to technological reasons and human factor. In general, drilling parameters’ variation exhibits some certain regular pattern, however, unusual service condition often came across because of the indeterminacy of ice structure and complicated situation at the bottom. Even the drilling system was always operated according with certain regulations, the rig, ice and operations form a complicated time varying system. Some key drilling parameters collected in the last three seasons, problems met in the field, experience of drilling system repairing and drilling accident treatment are analyzed and discussed.
Lightweight Ice Coring Systems

Victor Zagorodnov¹ (victor.zagorodnov@gmail.com)
¹Cryosphere Research Solutions LLC, Columbus, United States

In mid-1970th a few portable shallow ice core drills were designed and successfully used for study of polar ice sheets. Later, shallow ice core drills were employed for mountain glaciers research. Depending on ice core diameter and depth capabilities of the drilling system its weight can be 200-300 kg, including power source. Considering personnel involved in an ice coring field operation, total depth of drilling and duration of stay of a drilling site, the total weight of drilling and camping equipment, including food and fuel, can reach 3 ton. This deployment weight is not a big burden for transportation by avionic or surface vehicles but is prolonged and expensive for high altitude coring operations.

Major goals of new ice coring and non-coring drills development are: reduction of its weight, increasing depth capabilities and production drilling rate. These modifications will reduce costs of field operations, as well as reduce environmental impact of thereof. All mentioned modifications are suitable and applicable to high altitude and Polar glacier research.
Evidence of sea level under paleoclimate conditions that were warmer than the present is important for prediction of sea level rise anticipated under current climate change. Cosmogenic nuclides in rock beneath ice sheets can reveal former ice sheet extent and the timing and duration of past exposure periods. Under ice less than 700m thick, nimble methods for reconnaissance recovery of small rock cores would be useful for use near outcrops and near the ice margins. This was previously not possible because a drill capable of drilling the core did not exist. A development project in the Ice Drilling Program Office - Ice Drilling Design and Operations (IDPO-IDDO) group has succeeded in developing such a drill. The Agile Sub-Ice Geological (ASIG) drill is capable of drilling through 700 meters of ice and then retrieving 8 meters of 39-mm diameter rock core. The drill was successful in the first field season of its use, when IDDO retrieved 8 meters of rock core from under 150 meters of ice at Pirrit Hills, Antarctica during the 2016-17 field season. This is the first time that a rock core more than a meter long has been retrieved from beneath glacial ice. In this presentation characteristics of the drill are described, along with a description of the drill performance in the field at Pirrit Hills.
Drilling to bedrock of ice sheets and glaciers offers unique opportunities to research processes acting at the ice sheets bed for paleo-environmental reconstructions, subglacial geology, tectonics, geophysics, microbiology. To drill through the ice and bedrock a novel movable drilling rig and cable-suspended electromechanical core drill are designed. All drilling equipment is installed inside a movable, sledge-mounted, temperature-controlled, and wind-protected drilling shelter and workshop connected by steel pathway. The drilling shelter (without the sledges and mast) has overall dimensions of 7.8×4.8×3.0m. The shelter is set on two transverse frames with four 3.05×0.8 m skis. Four hand screw jacks with a travel of 300 mm are located on the corners of the shelter. The mast can be folded during transportation. The workshop has the same basic design and dimensions as the drilling shelter. It is divided into two rooms: one room for generators and one that serves as a logging/glaciological laboratory and workshop. Drilling shelter and workshop are transported with crawler tractors and could be ready for drilling operations 2-3 days after arrival at the chosen site. Drilling is carried out with electromechanical drill that permits the accomplishment of three different tasks: a large-diameter auger for dry core drilling in the upper snow-firn layers; ice-core drilling with near-bottom fluid circulation; and bedrock core drilling.
Intermediate Depth Drill Design Innovations

Jay Johnson¹ (jay.johnson@ssec.wisc.edu), Tanner Kuhl¹, Chris Gibson¹, Grant Boeckmann¹, Zachary Meulemans¹, Josh Goetz¹, Kristina Slawny¹
¹University of Wisconsin - Madison, IDDO, Madison, United States

In response to a call from the International Partnership in Ice Core Sciences group (IPICS) for ice core records to contribute toward the 2k array and 40k network, the U.S. science community identified the retrieval of cores to depths of 1000-1500 meters as a high priority. In response, the Ice Drilling Program Office - Ice Drilling Design and Operations (IDPO-IDDO) group developed a new Intermediate Depth Drill (IDD) system that was successfully utilized for the South Pole Ice Core (SPICEcore) project from 2014-2017 to drill a 1750 meter core. The drill, which is based on the Danish Hans Tausen (HT) drill design, was paired with new IDDO component designs for the winch and surface systems that focused on improved core quality and ease of use. This presentation focuses on the new and innovative features of the IDD system and ever-important lessons learned from the SPICEcore project.
Direct Laser Ice Penetrators: A Breakthrough in Subglacial Access Technology

Victoria Siegel¹ (vickie.siegel@ston aerospace.com), William Stone¹, Bartholomew Hogan¹, John Harman¹, Alberto Lopez¹, Kristof Richmond¹
¹Stone Aerospace, Del Valle, United States

The exploration of sub-glacial lakes on Earth presently requires an extraordinary logistics footprint (up to 1,000 tonnes of equipment) to use either traditional drilling technology or hot water drilling approaches. Stone Aerospace has investigated alternative methods to make access to sub-glacial lakes both routine and, critically, allow for persistent science. An ideal access method should allow for any length of time for downhole instrumentation and vehicles to make temporal measurements, investigate areas far from the access hole, and be recoverable to the surface on demand at the conclusion of a mission. With NASA funding we have developed an entirely novel ice penetrating technology using focused laser light carried by an optical fiber and emitted from the nose of an ice penetrator. Photons are used to directly melt the ice in front of the descending vehicle at near 100% efficiency. Laboratory tests show that this approach could lead to unprecedented ice penetration rates and enable access to any Antarctic sub-glacial lake. The design is bi-directional and could melt its way to the surface at conclusion of a mission.
A New Volcanic Province: An Inventory of Subglacial Volcanoes in West Antarctica

Maximillian Van Wyk de Vries¹, Robert G. Bingham¹ (r.bingham@ed.ac.uk), Andrew S. Hein¹
¹University of Edinburgh, Edinburgh, United Kingdom

The West Antarctic Ice Sheet overlies the West Antarctic Rift System about which, due to the comprehensive ice cover, we have only limited and sporadic knowledge of volcanic activity and its extent. Improving our understanding of subglacial volcanic activity across the province is important both for helping to constrain how volcanism and rifting may have influenced ice-sheet growth and decay over previous glacial cycles, and in light of concerns over whether enhanced geothermal heat fluxes and subglacial melting may contribute to instability of the West Antarctic Ice Sheet. Here, we use ice-sheet bed-elevation data to locate individual conical edifices protruding upwards into the ice across West Antarctica, and we propose that these edifices represent subglacial volcanoes. We used aeromagnetic, aerogravity, satellite imagery and databases of confirmed volcanoes to support this interpretation. The overall result presented here constitutes a first inventory of West Antarctica’s subglacial volcanism. We identified 138 volcanoes, 91 of which have not previously been identified, and which are widely distributed throughout the deep basins of West Antarctica, but are especially concentrated and orientated along the >3000 km central axis of the West Antarctic Rift System.
Melting of the West Antarctic Ice Sheet (WAIS), Accelerates Subglacial Volcanism

John C Behrendt1,2 (john.behrendt@colorado.edu)

1University of Colorado at Boulder, Institute of Arctic and Alpine Research (INSTAAR), Boulder, United States,
2US Geological Survey, Boulder, United States

Melting of the West Antarctic Ice Sheet (WAIS) would raise global sea level \( \sim 3 \) m. WAIS flows through the volcanically active West Antarctic rift system (WARS), possibly associated with a mantle plume. Heat flow is high beneath WAIS. Satellite altimetry shows rapid retreat of ice shelves bordering WAIS resulting from the warming ocean resulting from climate change. GRACE satellite data indicate accelerating mass loss from WAIS, reducing basal pressure. Aeromagnetic and radar ice sounding surveys (5 by 5 km line spacing) over the central WAIS revealed >1000 high-amplitude magnetic anomalies having mostly < 200 m bed relief, indicative of the late Cenozoic-recent age subglacial volcanic rocks at its base. 17 anomalies have 600-2000 m edifices beneath the ice. Increased volcanic activity resulting from decompression mantle melting beneath a thinning WAIS may serve as a positive feedback mechanism that could further destabilize WAIS. In both Iceland, and on midocean ridges, dated volcanism suggests decompression mantle melting associated with reductions in either ice or water loads drives significant volcanism. Acceleration of volcanic activity as the WAIS thins, could enhance the rate of ice loss and accelerate global sea level rise.
Subglacial Water Flow Adjacent to Mt. Melbourne Volcano, Antarctica

Choon-Ki Lee1 (cklee@kopri.re.kr), Yong Cheol Park1, Won Sang Lee1, Joohan Lee1, Hyangsun Han1, Hyeon Tae Ju1, Seung Hyun Lee1, Mi Jung Lee1, Su Kyung Yun1
1Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of

The volcano-ice interaction is very important to understand the glacial process adjacent to volcanoes. In order to investigate the influence of volcano on glacier, we deployed three GPS stations on the Campbell Glacier nearby the Mt. Melbourne, Antarctica. From year-round GPS records, we observed a sudden elevation change probably caused by the draining of subglacial water reservoir. The elevation change propagated downstream in company with a phase change from draining to filling. Immediately after the draining, the velocity of ice flow was suddenly increased at downstream area, while it was significantly decreased at the reservoir. The sequential velocity change implies that the ice velocity of Campbell Glacier is partly controlled by the draining of subglacial water flow. Previous seismic records and InSAR velocity changes also indicate the presence of dynamic changes in this area, although they are not concurrent with the GPS events. Since there was no significant change in elevation and ice velocity at the GPS station upstream of Mt. Melbourne, the source of subglacial water seems to be the water melt by the geothermal heat from Mt. Melbourne. Further long-term monitoring of ice flow at the Campbell Glacier would give more valuable information on the activities of Mt. Melbourne volcano and subsequent volcano-ice interactions.
Melbourne and Rittmann Volcanoes: Results from ICE-VOLC Project

Andrea Cannata\textsuperscript{1,2}, Danilo Contrafatto\textsuperscript{2}, Paola Del Carlo\textsuperscript{3} (paola.delcarlo@ingv.it), Giuseppe Di Grazia\textsuperscript{2}, Angelo Ferro\textsuperscript{2}, Salvatore Gambino\textsuperscript{2}, Gaetano Giudice\textsuperscript{4}, Giovanni Giuffrida\textsuperscript{4}, Alessandro La Spina\textsuperscript{2}, Graziano Larocca\textsuperscript{2}, Marco Liuzzo\textsuperscript{4}, Giuseppe Salerno\textsuperscript{2}, Letizia Spampinato\textsuperscript{2}, Luciano Zuccarello\textsuperscript{2}
\textsuperscript{1}Università degli Studi di Perugia, Dipartimento di Fisica e Geologia, Perugia, Italy, \textsuperscript{2}Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Etneo, Catania, Italy, \textsuperscript{3}Istituto Nazionale di Geofisica e Vulcanologia, Pisa, Italy, \textsuperscript{4}Istituto Nazionale di Geofisica e Vulcanologia, Palermo, Italy

Melbourne and Rittmann volcanoes are located in the Victoria Land. While Rittmann's last eruption dates back probably to Pleistocene, those of Melbourne occurred between 1862 and 1922, thus suggesting that it is still active. At present, Melbourne and Rittmann show fumarolic fields. Despite the limited knowledge on both volcanoes (particularly for Mt. Rittmann), the Antarctic uncontaminated framework (characterised by absence of anthropic noise) and the proximity to the Italian Mario Zucchelli Station make them ideal sites for studying volcano seismic sources, geothermal emissions and volcanic gas impact on the environment.

In the framework of the ICE-VOLC project (www.icevolc-project.com), multiparametric investigations have been performed during the XXXII and XXXIII Italian expeditions in Antarctica (2016-2017). During the campaigns, different kinds of research activities were carried out, in particular: i) acquisition of seismic signals by two temporary stations on different sites of both volcanoes; ii) collection of rock samples from Mt. Rittmann and Melbourne; iii) sampling of ash layers within glaciers nearby Melbourne; iv) sampling of fumaroles gases on both volcanoes; v) remote sensing measurements of volcanic gases in atmosphere; and vi) prospection, exploration and mapping of ice-caves on both volcanoes. Results gathered in the first phase of the project allowed us to shed new light into the state of activity of these poorly-known volcanoes.
Tephra layers in Antarctic ice cores are valuable time planes and are useful for reconstructing the eruptive history of young volcanic centers. An ice core drilled at Talos Dome in northern Victoria Land contains many tephra layers and some have been attributed to eruptions from Mt. Melbourne. Three young englacial tephra layers are exposed on the flanks of Melbourne volcano. The youngest tephra is inferred from snow accumulation rates to be between 100 and 300 years old. The other two tephra are over 1 m thick and closely spaced to each other and probably represent two significant eruptions from the same vent. We geochemically analyzed the two older tephra and young lavas from the summit area of Melbourne to try and identify the source vent for the tephra. The tephra have a strong geochemical correlation with the Talos Dome tephra layer TD85, which suggests they are the same. This is an important finding as it indicates that significant eruptions of Melbourne occurred at 1280 CE. The youngest tephra on Melbourne is not found in the Talos Dome ice core, suggesting the eruption was smaller than that for the 1280 CE tephra or the wind direction did not disperse the tephra towards Talos Dome.
Petrogenesis of the Lithospheric Mantle Beneath the Erebus Volcanic Province

Adam Martin¹ (a.martin@gns.cri.nz), Alan Cooper², Richard Price³, Philip Kyle⁴, John Gamble⁵
¹GNS Science, Dunedin, New Zealand, ²University of Otago, Department of Geology, Dunedin, New Zealand, ³University of Waikato, Science and Engineering, Hamilton, New Zealand, ⁴New Mexico Institute of Mining and Technology, Department of Earth & Environmental Science, Socorro, United States, ⁵Victoria University of Wellington, School of Geography, Environment and Earth Sciences, Wellington, New Zealand

Cenozoic alkalic igneous rocks of the Erebus volcanic province (EVP) are extensive in the southwest Ross Sea and provide insight into the nature of the underlying upper mantle. Younger basanites also host numerous xenoliths of spinel lherzolites, harzburgites, crustal granulites, and rare dunites, glimmerites and plagioclase-bearing spinel lherzolites. The latter are thought to have formed via metamorphic reaction and refertilisation. Pyroxenite and crustal xenoliths show an atypically hot EVP geotherm of 50-100 °C/km with heat potentially from advective transfer from melt refertilisation over the past 24 Ma. A deca-kilometre-scale mantle H₂O, trace element and Sr-Nd-Pb isotopic heterogeneity is demonstrated and it has been variously suggested that the lithosphere has been refertilised and metasomatised by carbonatite, N-MORB or alkaline melts. Isotopic data for primitive basanites define trajectories between DMM and HIMU, with enriched EMI and EMII components also evident at White Island and Mount Morning. Erebus volcano samples also record a HIMU component on U/Th and ²³⁰Th/²³²Th versus Pb isotope plots. Some pyroxenites at Mount Morning share trace element and isotopic characteristics with eclogite. Despite this complex regional history, oxygen fugacity averaging -1 FMQ at Mount Morning (from Mössbauer spectroscopy), overlap with the global median in rifted settings (-0.9 FMQ).

Acting upon what we Know: Making Arctic Connections across Boundaries

Robert Rich¹ (bob@arcus.org), Helen Wiggins¹
¹Arctic Research Consortium of the United States, Fairbanks, United States

The Arctic Research Consortium of the United States (ARCUS) has been making connections across boundaries in support of Arctic research since 1988. There are many recent activities that have strengthened communication, coordination, and collaboration across disciplines, organizations, sectors, nations, and knowledge systems. This presentation will describe a process for planning and implementing collaborations and will highlight recent case studies.

Building cross-cutting connections requires a carefully planned and strategic approach. Examples of successes and failures will be drawn from ARCUS' portfolio of projects, including activities focused on co-production of knowledge with Arctic Indigenous communities and researchers, cross-disciplinary research collaborations, and education and outreach efforts.

As a real-time exercise in making connections and networking, attendees of this presentation will have the opportunity to use online polling technology to share their own efforts at brokering connections in support of Polar research.
NERC Changing Arctic Ocean: Implications for Marine biology and Biogeochemistry

Kirsty Crocket1 (kirsty.crocket@sams.ac.uk)
1Scottish Association for Marine Science, Dunstaffnage, United Kingdom

The Changing Arctic Ocean is a 5 year (2017-2022) research programme to investigate the effects of climate change on the marine biology and biogeochemistry of the Arctic Ocean. The programme has 4 large projects (Arctic PRIZE, ARISE, ChAOS, DIAPOD) that form the core of the programme, funded by the UK’s Natural Environment Research Council (NERC), and a further 10 smaller projects co-funded by NERC and the German Federal Ministry of Education and Research. An important aspect of the CAO programme is the strength of its international collaboration, reflected by the links established with over 60 international partner institutions. The topics covered by this international collaboration span the full scope of the science in the programme, as well as addressing societal challenges specific to the Arctic and the provision of evidence to feed into decision and policy making. The forms of this collaboration range from the level of communication between individual researchers, data sharing, exchange of staff on respective cruises, to representation of CAO investigators by collaborators at Arctic committees and other international bodies. Ultimately, the aspiration of the CAO programme is to forge lasting engagement with the international Arctic community beyond the funded lifetime of the programme. In this talk, I outline the scope of the programme and describe our activities in encouraging science-to-policy translation.
Early Career Involvement Prepares Workforce for the Future of Polar Research

Alexander Eliot Thornton1, Jean Holloway2, Alice Bradley3 (alice.chapman.bradley@dartmouth.edu), Gerlis Fugmann4

1University of Alaska Fairbanks, College of Fisheries & Ocean Sciences, Fairbanks, United States, 2University of Ottawa, Ottawa, Canada, 3Dartmouth College, Hanover, United States, 4Association of Polar Early Career Scientists, Alfred-Wegener Institute, Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

The Association of Polar Early Career Scientists (APECS) bridges disciplinary, institutional, national, and sector boundaries in the Arctic and Antarctic communities. APECS is an interdisciplinary organization for early career professionals (ECPs) interested in Earth’s polar regions and the wider cryosphere, with a global membership of nearly 3,000 actively-engaged ECPs from 67 countries. Our network creates opportunities for international collaborations and information exchange amongst both ECPs and established mentors from a range of disciplines. We aim to recruit, retain, increase cooperation amongst, and promote future polar experts. APECS facilitates the involvement of skilled ECPs in the working groups and committees of our partners, including those of the International Arctic Science Committee (IASC) and Scientific Committee on Antarctic Research (SCAR). This provides ECPs with an opportunity to practice career skills and to work with senior scientists to synthesize information and identify emerging research questions. In this presentation, we discuss how APECS contributes to training diverse, future leaders in the Arctic and Antarctic research and policy communities. Support of ECPs through APECS develops a workforce more adept in interdisciplinary, international, and collaborative work and is, therefore, an investment in the future of the Arctic and Antarctic science and policy.
Evaluation of Costs and Societal Benefits of Arctic Observing Systems

Srdjan Dobricic¹ (srdan.dobricic@ec.europa.eu), Luca Pozzoli¹, Fabio Monforti-Ferrario¹, Julian Wilson¹
¹European Commission, Joint Research Centre, Ispra, Italy

Observing the Arctic system is difficult due to the extremely harsh environmental conditions and long distance from the major research facilities. A number of past and existing EU research projects and international stakeholder initiatives have evaluated the present observational system in the Arctic, but still an overall picture on present and future observational requirements regarding the needs of stakeholders and costs for maintenance and investments has not been fully established. In order to support investments in observing the rapidly changing Arctic environment, taking also into consideration the expansion of a number of human activities in the area foreseen for the next decades, this study estimates costs and societal benefits of existing and future observational systems in the Arctic. The first part of the presentation gives an overview of investment and running costs of observational systems in the Arctic, the second shows the methodology based on the value tree analysis connecting observational systems and societal benefit areas and the third evaluates benefits for selected activities and societal benefit areas.
Recent developments in safe navigation, such as the passing of the Polar Code, have addressed important issues in marine transportation in Arctic waters. Yet contrary to a global downward trend, shipping losses have steadily increased in the past decade in this region due to expanded shipping operations and increasing spatial and temporal variability of Arctic weather patterns and sea ice hazards. The availability and quality of climate services in support of Arctic shipping operators therefore is an important factor in reducing hazards.

SALIENSEAS (Enhancing the saliency of climate services for marine mobility sectors in European Arctic seas) is an ERA4CS project that has undertaken the development of user-focused demonstration services based on an assessment of sector-specific user needs for climate services. Following an initial round of stakeholder interviews, the project’s first phase produced an integrated assessment model of mobilities, risks and vulnerabilities in the European maritime sectors. The model integrates spatial and temporal variables that impact stakeholder interests, and delineates the critical infrastructures and key resources that drive risk-informed decisions. We discuss the role of this model in an iterative, participatory research framework, and the model’s scalability in the assessment of other types of spatial data infrastructures.
Archival Processes of Water Stable Isotope Signal in East Antarctic Ice Cores

Mathieu Casado1,2 (mathieu.casado@gmail.com), Amaelle Landais2, Ghislain Picard2, Thomas Munch3, Thomas Laepple1, Barbara Stenni4, Giuliano Dreossi4, Alexey Ekaykin5, Laurent Arnaud3, Christophe Gentthon3, Alexandra Touzeau2, Valérie Masson-Delmotte2, Jean Jouzel2

1AWI, Potsdam, Germany, 2LSCE (UMR 8212 CEA-CNRS-UVSQ/IPSL), Université Paris Saclay, Gif sur Yvette, France, 3IGE, Université Grenoble Alpes, CNRS, IRD, Saint Martin d’Hères, France, 4Ca Foscari University of Venice, Venice, Italy, 5Arctic and Antarctic Research Institute, Saint Petersburg, Russian Federation

The oldest ice core records are obtained from the East Antarctic plateau. Water isotopes records are key to reconstructing past climates. The accuracy of climate reconstructions depends on knowledge of all the processes affecting water vapour, precipitation and snow isotopic compositions. However, a quantitative understanding of processes potentially altering the snow isotopic composition after the deposition is still missing. In low accumulation sites, such as those found in Antarctica, these poorly constrained processes are likely to play a significant role and limit the interpretation of isotopic composition.

Here, we combine observations of isotopic composition in the vapour, the precipitation, the surface snow and the buried snow from Dome C, a deep ice core site in Antarctica. At the seasonal scale, we suggest a significant impact of metamorphism on surface snow isotopic signal compared to the initial precipitation signal. Particularly, in summer, exchanges of water molecules between vapour and snow are driven by the sublimation/condensation cycles at the diurnal scale. Using snowpits in five Antarctic sites, we identify common patterns, despite different accumulation rates, which cannot be attributed to the seasonal variability of precipitation. Altogether, the difference in the signals observed in the precipitation, surface snow and buried snow isotopic composition constitute evidences of post-deposition processes affecting ice core records in low accumulation areas.
Reconstructions of atmospheric methane mixing ratios using ice cores have been available since decades. The large dynamic range, 350 to 800 ppb, and the abruptness of these CH₄ changes at DO events and during the final deglacial phases suggest that CH₄ is a powerful parameter to constrain past climate conditions, e.g. inferring the extend of wetlands. However, based on CH₄ concentrations alone, the methane source budget is notoriously underdetermined and allows numerous hypotheses to be accommodated with the CH₄ records. For example, catastrophic CH₄-clathrate releases have been suggested to cause CH₄ jumps, likewise, continuous geologic CH₄ emissions were thought to comprise a large fraction of the glacial CH₄ budget. Recent studies applying δ¹³C, δD and ¹⁴C of CH₄ were able to reject many hypotheses and concluded that low-latitude wetlands dominate the past budget and no additional source type is needed to explain CH₄ jumps. We provide an overview on the past CH₄ budget using δ¹³C and δD (Bock et al. 2017) and present a δ¹³C record extended by additional 120,000 years covering MIS7 to MIS10. As already visible in previous data, the δ¹³C evolution of our new interval shows a remarkable covariation with CO₂ for inceptions and glacials. By contrast, the δ¹³C trend departs from this covariation for deglaciations and interglacials, with the anomaly from the general δ¹³C-CO₂-covariation being proportional to the size of the interglacial CH₄ peak.
Constraining the Sources of Abrupt CH₄ Rise in the past with CH₄ Triple Isotopes

Michael Dyonisius¹ (mdyonisi@ur.rochester.edu), Vasilii Petrenko¹, Andrew Smith², Benjamin Hmiel¹, Jonas Beck³, Barbara Seth³, Quan Hua², Bin Yang², Christina Harth⁴, Ross Beaudette⁴, Jon Edwards⁵, James Lee⁵, Tobias Erhardt³, Edward Brook⁵, Ray Weiss⁴, Jeffrey Severinghaus⁴, Hubertus Fischer³
¹University of Rochester, Earth and Environmental Sciences, Rochester, United States, ²Australian Nuclear Science and Technology Organisation, Kirrawee DC, Australia, ³University of Bern, Physics Institute, Bern, Switzerland, ⁴Scripps Institution of Oceanography, UC San Diego, San Diego, United States, ⁵Oregon State University, College of Earth, Ocean and Atmospheric Sciences, Corvallis, United States

Methane (CH₄) is the third most important greenhouse gas in the atmosphere after water vapor and CO₂. Understanding how the natural CH₄ budget has changed in response to changing climate in the past can provide insights on the sensitivity of the natural CH₄ emissions to the current anthropogenic warming. CH₄ isotopes (Δ¹⁴CH₄, δ¹³C-CH₄, and δD-CH₄) from ice cores can be used to fingerprint the sources of CH₄ increases in the past. Here we present CH₄ triple isotopes data from Taylor Glacier horizontal ice cores, Antarctica spanning the Oldest Dryas-Bølling transition (~14.7ka) - the first abrupt warming and CH₄ rise since the LGM. Among the CH₄ isotopes, our Δ¹⁴CH₄ data during this transition are novel and unique in their ability to unambiguously distinguish between “old” CH₄ sources (e.g. marine clathrate, geologic sources) and “modern” CH₄ sources (e.g. tropical wetlands). The Δ¹⁴CH₄ data unambiguously rule out marine clathrate and old permafrost as the sources of the abrupt CH₄ rise. Our stable isotopes data (δ¹³C-CH₄ and δD-CH₄) agrees well with existing CH₄ stable isotopes dataset from other polar ice cores. Moreover, our CH₄ stable isotopes data provides the highest resolution paleoatmospheric CH₄ stable isotopes dataset that is currently available for this specific ~150 year timespan. Methane isotopes box modeling combined with interpolar CH₄ concentration gradient suggest that tropical wetlands were the dominant driver for the OD-BØ CH₄ rise.
Atmospheric CO₂ Variations on Millennial-scale during MIS 6

Jinhwa Shin¹ (jinhwa.shin@univ-grenoble-alpes.fr), Christoph Nehrbass-Ahles², Roberto Grilli¹, Jérôme Chappellaz², Grégory Teste¹, Loïc Schmidely², Jochen Schmitt², Thomas Stocker², Hubertus Fischer²
¹CNRS, Univ. Grenoble-Alpes, Institut des Géosciences de l’Environnement (IGE), Grenoble, France, ²Climate and Environmental Physics, Physics Institute, and Oeschger Center for Climate Change, University of Bern, Bern, Switzerland

Understanding natural carbon cycle / climate feedbacks on various time scales is highly important for predicting future climate changes. Paleoclimate records of Antarctic temperatures, relative sea level and foraminiferal isotope and pollen records in sediment cores from the Portuguese margin have shown climate variations on the millennial time scale over the Marine Isotope Stage 6 (MIS 6; from approximately 135 to 185 kyr BP). These proxy data suggested that an intensified hydrological cycle and iceberg calving in the North Atlantic may impact the Atlantic Meridional Overturning Circulation. This leads to cooling of the Northern hemisphere and warming of Antarctica, which is explained by the bipolar seesaw mechanism in the ocean (Margari et al., 2010). Atmospheric CO₂ reconstruction from Antarctic ice cores can provide key information on how atmospheric CO₂ concentrations are linked to millennial-scale climate changes. However, existing CO₂ records lack of suitable temporal resolution and precision. In this work, we present improved CO₂ data, obtained from the Dome C ice core (75°06’S, 123°24’E) spanning the MIS 6 period, using dry extraction methods. This new CO₂ data show variabilities which are similar with those of temperature in Dome C. Further investigations on those millennial-scale features will be conducted, with the aim of linking them to other possible atmospheric proxies.
The sub-Antarctic islands (SAI) are uniquely located to capture changes in the globally significant circumpolar westerly winds and the Antarctic circumpolar current, key to the mixing and ventilation of the world’s deep oceans. The glaciers on a number of these SAI’s potentially contain an inimitable record of past climate, atmospheric circulation, westerly winds and pollution from this data sparse region. Here we present the first results from seven new shallow (10-20 m) ice cores collected as part of the Antarctic Circumnavigation Expedition (ACE), including the first ever records from Bouvet Island, Peter 1st Island and the Balleny Islands.
China as a Polar Great Power

Anne-Marie Brady¹ (anne-marie.brady@canterbury.ac.nz)
¹University of Canterbury, Political Science and International Relations, Christchurch, New Zealand

In the last five years China has emerged as a member of the unique club of nations who are powerful at both poles. Polar states are global giants, strong in military, scientific, and economic terms. The concept of a polar great power is relatively unknown in international relations studies. Yet China, a rising power globally, is now widely using this term to sum up its aspirations and symbolise the significance of the polar regions to China’s national interests. Chinese Communist Party General Secretary Xi Jinping first referred to China as a polar great power when he visited Australia in November 2014. China’s focus on becoming a polar great power represents a fundamental re-orientation—a completely new way of imagining the world. In setting its sights on the polar regions now, China is looking to the mid to long term and planning for its future economic, political, and strategic needs. The Chinese government’s stated core national interests in the current era—to maintain China’s social system and state security, to preserve state sovereignty and territorial integrity, and the continued stable development of the economy and society—all require access and engagement in the polar regions. China has global interests and is well on the way to becoming a global great power. To succeed in this evolution it must be powerful in the polar regions.
The Arctic is the most important region that will ensure the future of Russia. Already, the largest Russian projects are being implemented there. For the last hundred years, Russia for the third time begins a large-scale industrial advancement to the Arctic. In addition, climate change is no longer scientific assumptions, but a reality. The ice is melting and new commercial opportunities are opening up in the Arctic, non-Arctic countries appear as investors and economic partners of Russia. Today the NSR is considered as the main Arctic shipping line in Russia and the government tries to make the NSR a competitive transport corridor of global importance as well as to strengthen geopolitical influence and Russia’s national security in the Arctic and a state program for the creation of stationary points for the development of the Arctic is proof of this. Industrial development in the Arctic is connected with preservation of the indigenous peoples, the traditional economy of nature. Also, the key priority remains the protection of the unique natural environment of the North, environmental security issues. Elimination of accumulated environmental damage throughout the Arctic zone, is a long-term process that requires considerable material and financial resources. In this regard, it can be argued that effective development of the Arctic can be achieved through an open, equitable and effective approach aimed at strengthening international political, economic, social dialogue.
Korea has started to conduct basic survey and research on the Arctic in 1993 and the full-scale Arctic researches after the Korea's Arctic Dasan Research Station was opened in 2012. Based on these scientific activities and outputs, Korea joined the Arctic Council Observer with Japan, China, India, etc. in 2013 and set the 5 years' Arctic Master plan (2013-2017) as an after-action on that year, which was a governmental platform for implementing the comprehensive Arctic Policy for the first time in history. The 2nd phase master plan (2018-2022) by the inter-ministerial work in 2017 is under way. Also, The Korean president offered Russia to cooperate on a range of projects, including NSR, shipbuilding, and others including the NSR at East Economic Forum in September of 2017: Arctic (Northern) policy of the new government is strengthened in various points.

This research will focus on change of Korea's Arctic policy through the comparison between the 1st and 2nd master plan and will do the policy-analysis on Arctic policy of Japan, a neighbor country on the Korean perspectives and draws implications for the improvement of Korea's Arctic policy.
While humanities and social sciences are increasingly represented, supported and well considered in Polar research and policy circles, the sub-discipline known as “geoconomics” remains largely underrepresented and overlooked. As an example, none of the EU H2020-funded projects do explicitly provide geoeconomics analyses as part of their research steps or their research objectives. Moreover, geoeconomists are often mistaken with economists, logistics or even geopolitics experts. This misunderstanding of geoeconomics studies applied to Arctic and Antarctic research has a direct impact on both the quality of the governance of the Polar regions and on the effective environmental stewardship of both Polar regions. The fact that policy-makers don’t have access to a wide number of Polar geoeconomics research prevents them from approaching Polar affairs in the most comprehensive way possible. This lack of capacity may lead them to overlook some foreseeable negative policy externalities, and even allow for socio-economic, diplomatic and/or future environmental so-called black swan events to happen. It is therefore important to raise the profile of geoeconomics as a useful research discipline in Polar policy-making. This presentation aims at laying down the foundations of a widespread discussion on the use of geoeconomics in Arctic and Antarctic policy; and to that aim, proposes a geographically-bounded framework for systemic analysis of both Arctic and Antarctic affairs: Polarnomics.
Geopolitical and Security Challenges in the Arctic

Barbora Padrtova\textsuperscript{1,2} (b.padrtova@gmail.com)
\textsuperscript{1}Masaryk University, Dept. of International Relations and European Studies, Brno, Czech Republic, \textsuperscript{2}Polar Research and Policy Initiative (PRPI), London, United Kingdom

The geopolitics in the Arctic has been influenced by the current international relations' developments and increasing tensions between Russia and the West. Additional drivers for geopolitical challenges are the availability and accessibility of energy resources (mainly oil and gas) and opening of new transportation routes for destination and transit shipping. The geopolitics of the Arctic is also influenced by the security developments. There are two major types of security issues facing the Arctic: issues related to military security of individual Arctic states and those relating to the common security of multiple regional states - including piracy, terrorism and environmental disasters. The aim of the presentation is to provide overview of geopolitical and security challenges which the Arctic faces in relation to climate change and current trends in international relations. The author will focus on how geopolitics transforms into policy and what are the key variables that influence the relations of cooperation/competition among states in the Arctic region.
Simplified Kamb Ice Stream Flowline Models with Differing Subglacial Conditions

Laurine Nathalie van Haastrecht\(^1\) (laurine.vanhaastrecht@vuw.ac.nz), Nicholas Golledge\(^1,2\), Huw Horgan\(^1\)
\(^1\)Antarctic Research Centre, Victoria University of Wellington, Wellington, New Zealand, \(^2\)GNS Science, Wellington, New Zealand

The subglacial environment exerts an important control on ice sheet velocity and on the volume of ice discharged across the grounding zone. Many subglacial processes and conditions, such as sediment porosity and the subglacial deformation profile, are still poorly constrained. For example, basal friction from ice-sediment contact can slow and thicken ice, whereas an increase in basal meltwater may accelerate flow. These processes are particularly important beneath ice streams, where deforming basal till allows fast ice motion in the absence of high driving stresses, ultimately controlling whether ice streams are flowing or stagnant. The importance of these processes means that there is still a need to focus on characterising the subglacial environment from observations.

Here we present flowline model results from PISM (a thermodynamic, coupled ice-sheet/shelf model) simulations that investigate variability using seismic estimates of basal conditions from the Kamb Ice Stream (KIS) as boundary values and tuned parameters. Seismic constraints are provided by an active-source seismic profile collected across the grounding zone of the KIS. Reflection coefficients along the seismic line signals a change in acoustic impedances, which can be used as a proxy for porosity and effective pressure. In our model experiments we varied subglacial conditions (deformation behaviour, basal roughness) and quantified the impact of each on ice stream velocity, discharge and grounding line location.
Grounding zone processes include the interaction of subglacial sediment and water with the overlying ice. These processes regulate accommodation space in the ice shelf cavity, supply and deform sediment, and determine the grounding zone’s location. Despite the importance of grounding zone sedimentation for ice sheet stability and ice sheet history, evidence for sedimentary deposits beneath West Antarctica’s modern grounding zone remains sparse. Recent seismic surveying shows that Kamb Ice Stream has no detectable grounding zone deposit. As grounding zone deposition relies strongly on ice flow, the absence of a deposit suggests that the transition from the ice stream to the ice shelf has moved after stagnation of Kamb Ice Stream. Further support for a recent grounding zone occupation comes from satellite imagery of sub-ice shelf channel features that likely originated at previous grounding-zone locations. These features begin 25 km seaward of the current grounding zone and cut across ice flow streak lines. We estimate that retreat to the modern grounding-zone position was abrupt at rates >0.2 km a\(^{-1}\).
Controls and Change of Enhanced Ice Flow in the Recovery Region, East Antarctica

Anja Diez¹, Kenichi Matsuoka¹ (kenichi.matsuoka@npolar.no), Fausto Ferraccioli², Tom Jordan², Hugh Corr², Jack Kohler¹, Arne Olesen³, René Forsberg³

¹Norwegian Polar Institute, Tromsø, Norway, ²British Antarctic Survey, Cambridge, United Kingdom, ³Technical University of Denmark, Copenhagen, Taiwan, Republic of China

The Recovery Region in East Antarctica has remained poorly explored, despite representing the largest potential contributor to future global sea level rise on a centennial to millennial timescale. The region, consisting of Recovery, Bailey and Slessor Glaciers, currently discharges 5% of the total fresh water outflow of Antarctica into the Filchner Ice Shelf, which is subject to extensive sub-shelf melting under ongoing climate change. No direct ice thickness data were available within 200 km in this region, which was identified as one of two 'poles of ignorance' by BEDMAP2. We use new airborne radar data to investigate the bed topography and controls of fast-ice flow in this region. We show that Recovery Glacier is underlain by an 800 km long trough. Its fast flow is strongly controlled by topography in its downstream region and the presence of subglacial water in its upstream region. Recovery Glacier is connected with the adjacent Slessor Glacier via the newly-discovered Recovery-Slessor Gate. Fast flow of Slessor Glacier occurs over a rougher bed and is controlled by an inferred channelized hydrological system. Englacial layer studies suggest changes in direction of past fast flow likely occurred within Slessor and Bailey glaciers. Similar changes could also reoccur here in future. Our findings refine the knowledge of the Recovery Region and provide a more precise understanding of past ice dynamics and potential of future change of this region.
Active Seismics at the Grounding Line of Support Force Glacier, Antarctica

Coen Hofstede¹ (coen.hofstede@awi.de), Daniel Steinhage¹, Hugh Corr², Emma Smith¹, Angelika Humbert¹,³, Olaf Eisen¹,³
¹Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, ²British Antarctic Survey, Cambridge, United Kingdom, ³University of Bremen, Department of Geosciences, Bremen, Germany

We report on a high-resolution seismic reflection survey, conducted across the grounding line and ice shelf of Support Force Glacier, an ice stream feeding into the Filchner Ice Shelf, Antarctica. Two longitudinal profiles were acquired in the ice-flow direction: a 43 km profile crossing the grounding line, parallel to a nearby ice shelf channel and a 10 km profile in the ice shelf channel. These are connected by three cross-profiles at 2, 8 and 33 km from the grounding line. The data indicate the grounded ice flows over a flat bed from which the top 20 m most likely are consolidated sediments. The ice becomes uncoupled from the bed 3 km upstream of the grounding line. Downstream of the grounding line we observe disturbed sedimentation at the seabed, increasing to a 300 m thick sequence at 6 km distance from the grounding line. At 10 km distance, the sedimentation sequence is undisturbed and stratified. We interpret the disturbed sedimentation as deposits from a possible subglacial water conduit upstream of the ice shelf channel although past changes at the grounding line position cannot be ruled out at this stage. The three cross-profiles show the ice shelf channel at 2 km and 8 km downstream of the grounding line. While the shape of the channel does not change, it widens 22% between 2 and 8 km and increases its height by 12% further downstream between 8 km and 33 km.
Ice-stream shear margins define highly localized transitions in ice-flow behavior. To reproduce these transitions, models typically impose lateral variability in either the substrate properties, the subglacial hydrologic system, or the thermally controlled rheology of the ice. Identifying the relative impact of these three mechanisms is critical to predicting shear-margin evolution, but attempts to identify the dominant process using ice penetrating radar suffer from unresolvable tradeoffs between ice temperature, bed roughness, and basal water availability. To improve our understanding of shear-margin dynamics and aid in radar-data interpretation collected over ice streams, we use Elmer/Ice to model the thermal state of ice-stream shear margins as a function of the shear-strain rate, the margin width, and the magnitude of cross-marginal ice flow. We show that lateral variability in ice temperature across shear margins is controlled by the balance of heat production and advection, making it possible to estimate temperature gradients across shear-margins using surface velocity observations alone. Finally, we compare temperature estimates derived from surface velocities with radar observations across the shear margin of the Northeast Greenland Ice Stream.
On-ice Vibroseis: Sediment Features below Ekström Ice Shelf, East Antarctica

Emma C Smith1 (emma.smith@awi.de), Reinhard Drews2, Todd Ehlers2, Dieter Franke3, Christoph Gaedicke3, Coen Hofstede1, Gerhard Kuhn1, Astrid Lambrecht4, Christoph Mayer4, Ralf Tiedemann1,5, Olaf Eisen1,5
1Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Glaciology, Bremerhaven, Germany,
2University of Tübingen, Geosciences, Tübingen, Germany, 3BGR, Federal Institute for Geosciences and Natural Resources, Hannover, Germany, 4Bavarian Academy of Sciences and Humanities, Geodesy and Glaciology, Munich, Germany, 5University of Bremen, Geosciences, Bremen, Germany

An extensive grid of seismic reflection data collected on Ekström Ice Shelf, East Antarctica, between 2010-2018, using an on-ice vibroseis source and snowstreamer, are used to reconstruct the glaciological and tectonic history of this region.

The data clearly image the outcrop and sub-ice extent of the volcanic Explora Wedge (generated through Jurassic rifting and seafloor spreading). The wedge is overlain by a sequence of truncated, dipping marine-sediment layers. The sediment were likely truncated by former ice advance and subsequent retreat; which has also left evidence in the form topographic over-deepening and glacial debris deposits at the sea floor. The debris deposits range from elongated bedforms in a topographic trough (indicating probable former ice-stream flow) to layered sediment wedges at the current ice-shelf front (indicating the likely former extent of grounded ice).

A series of sub-ice shelf geological drilling campaigns in the area will take place (2017-2019) to recover sediments from the sea floor. Combining the topography and material characteristics from vibroseis data with stratigraphic evidence from sediment cores allows a robust reconstruction in this area. Future integration of these results with numerical models will provide a better understanding of past and present interactions between the ice sheet and the solid Earth in Dronning Maud Land, which will in turn improve understanding of future contributions of this region to sea-level rise.
Arctic Sea Ice in a 1.5 °C Warmer World

Laura Niederdrenk¹ (laura.niederdrenk@mpimet.mpg.de), Dirk Notz¹
¹Max Planck Institute for Meteorology, Hamburg, Germany

We examine the seasonal cycle of Arctic sea ice for different levels of global warming and quantify the possible variations around this seasonal cycle caused by internal variability. To do so, we combine observations with simulated internal variability from a very large ensemble, the MPI-ESM Grand Ensemble. We use the observed sea ice sensitivity to global warming to recalibrate the sensitivity of the modelled sea-ice evolution. We show that for a global warming of 1.5 °C above pre-industrial levels, it is unlikely that September Arctic sea ice vanishes. The internal variability causes a range of about ±0.2 °C to the global warming magnitude at which September Arctic sea ice is lost. For a 2.0 °C warming, the Arctic Ocean becomes virtually certainly ice free in August and September. In March, for a 1.5 °C global warming, sea-ice area is reduced to about 85% and for a warming of 2.0°C to about 80% of pre-satellite levels.
For Arctic Summer Sea Ice, Staying Below 2.0°C Global Warming Matters

Alexandra Jahn¹ (alexandra.jahn@colorado.edu)
¹University of Colorado Boulder, Atmospheric and Oceanic Sciences and INSTAAR, Boulder, United States

What impact would the IPCC target of limiting global warming to 1.5°C to 2°C have on Arctic summer sea ice? To answer that question, we analyze five initial-condition Community Earth System Model (CESM) ensembles with global warming ranging from 1.5°C to 4°C by 2100. We find that if warming can be limited to 1.5°C, 45% of the time September sea ice extents will still be higher than the minimum observed to date by 2100, and there is a 30% probability for an ice-free September. If warming reaches 2°C, September sea ice extents will only be above the minimum to date 2% of the time, and we find a 100% probability of at least one occurrence of ice-free conditions. If warming exceeds 2.5°C, the sea ice extents will always be far below the minimum to date and ice-free conditions will occur frequently in the summer. Hence, for preserving Arctic summer sea ice, staying below 2.0°C global warming matters.
Polar Amplification and Sea Ice Changes in NorESM Low Warming Scenarios

Jens Boldingh Debernard¹ (jens.debernard@met.no), Øyvind Seland², Ingo Bethke³, Mats Bentsen³, Lise Seland Graff², Trond Iversen²

¹Norwegian Meteorological Institute, Research and Development, Oslo, Norway, ²Norwegian Meteorological Institute, Research and development, Oslo, Norway, ³Uni Research Climate, Bergen, Norway

The differences in polar amplification and consequences for sea ice were studied with the Norwegian Earth System Model (NorESM) during the multi-model project HAPPI, whose main focus was to evaluate differences in impacts between scenarios of 1.5- and 2.0-degree warming above pre-industrial. Simulations from an updated version of the fully coupled model (NorESM1-Happi) have been evaluated. Compared to earlier versions of the NorESM, the simulated Arctic sea ice is greatly improved. In addition, slab ocean (SO) versions of the model, specially designed to be comparable to the AMIP-style experiments used in the HAPPI-protocol, have been analysed to look at differences in polar amplification and sea ice properties. We find large differences in the polar amplification in the Northern and Southern Hemisphere depending on fully coupled, or slab ocean set-ups of the model. Ocean heat transport seems to be the main contributor to this difference between the hemispheres. Also, in the SO experiments designed to have similar ocean heat transport changes as the CMIP5 multi-model ensemble, we find very large changes in the September sea ice extent in the Arctic between the 1.5- and 2.0-degree warming scenarios. These large changes are sensitive to the simulated present-day sea ice cover in the model, and the sensitivity of this is discussed in light of model assumptions and uncertainties.
Sea-ice Cover Timing in the Pacific Arctic: The Present and Projections

Muyin Wang1,2 (muyin.wang@noaa.gov), Qiong Yang1,2, James Overland2, Phyllis Stabeno2
1University of Washington, JISAO, Seattle, United States, 2Pacific Marine Environmental Laboratory, Seattle, United States

With the sea-ice cover in the Arctic fast declining, changes to the timing of sea-ice break-up and freeze-up is an urgent economic, social, and scientific concern. Based on daily sea-ice concentration data we assess the dates of sea-ice break-up and freeze-up, and the annual sea-ice duration in the Pacific Arctic. The simulation results from the coupled climate models from the Coupled Model Intercomparison Project (CMIP5 and CMIP6) are the major source for this study. Based on CMIP5 results, the length of sea-ice duration is shrinking, with the strongest downward trend occurring for the period 1990-2014; this downward trend is projected to continue through mid-century. Comparisons made at eight Chukchi Sea mooring sites maintained by PMEL and eight Distributed Biological Observatory (DBO) regions show consistent results. The 30-year averaged trend for annual sea-ice duration in the southern Chukchi Sea is projected to be -0.68 (-0.74) days/year to -1.20 (-1.17) days/year for 2015-2044 under RCP8.5 (RCP4.5) emissions scenarios. This is equivalent to a reduction of 20 to 36 days in the annual sea-ice duration. Models project both earlier break-up dates and later freeze-up dates, and that a later freeze-up contributes more to the overall shortening of annual sea-ice duration. Up to a 60-day reduction of the annual sea-ice duration in the Chukchi, East Siberian, and Beaufort Seas, and less than 20 days in the Bering Strait area is projected near the middle of the 21st century.
Arctic Sea Ice Melt Season Length in the CESM Large Ensemble and CMIP Models

Abigail Ahlert\(^1\) (abigail.ahlert@colorado.edu), Alexandra Jahn\(^1\)
\(^1\)University of Colorado Boulder, Boulder, United States

Melt season length—the difference between the sea ice melt onset date and the sea ice freeze onset date—plays an important role in the radiation balance of the Arctic and the predictability of sea ice cover. Using the CESM Large Ensemble and CMIP5 model simulations, we explore three sources of uncertainty in the assessment of melt season length in climate models: definition choices, internal variability and model differences.

There are multiple possible definitions for sea ice melt and freeze onset in climate models, and none of them exactly correspond to the remote sensing definition. We first show how the mismatch between model and remote sensing definitions of melt and freeze onset limits the utility of melt season remote sensing data for bias detection in models. Then, by using the CESM Large Ensemble, we account for the role of internal variability, allowing us to assess the comparability of different melt and freeze onset definitions. Finally, we expand our analysis to CMIP5 models to study how model differences affect projections of melt and freeze onset. If possible, we will also include CMIP6 simulations in that analysis. Our study of CMIP5 models (and CMIP6 models when available) will explore the hypothesis that an underestimation of the melt season length trend is one factor contributing to the generally underestimated sea ice loss in climate models.
Arctic Sea Ice-free Season Projected to Extend into Fall

Marion Lebrun¹ (marion.lebrun@locean-ipsl.upmc.fr), Martin Vancoppenolle¹, Gurvan Madec¹, François Massonnet²,³
¹Sorbonne Universités (Université Pierre et Marie Curie Paris 6), LOCEAN-IPSL, CNRS/IRD/MNHN, Paris, France,
²Université Catholique de Louvain, Earth and Life Institute, Louvain-la-Neuve, Belgium, ³Barcelona Supercomputing Centre, Earth Sciences Department, Barcelona, Spain

The recent Arctic sea-ice reduction is associated with an increase in the ice-free season, with comparable contributions of earlier retreat and later freeze-up. Here we show that within the next decades, the trends towards earlier freeze-up should progressively exceed and ultimately double the trends in ice retreat date. Such asymmetry is due to the response of ice and ocean thermodynamics to warming: the extra solar heat reaching the ocean due to earlier ice retreat is absorbed at a higher rate than it is released until freeze-up. Based on climate change simulations, we envision an increase and a shift of the ice-free season towards fall, which will affect Arctic ecosystems and navigation.
The Local water Cycle Associated with Marine Cold Air Outbreaks

Lukas Papritz\textsuperscript{1,2} (lukas.papritz@uib.no), Harald Sodemann\textsuperscript{1,2}
\textsuperscript{1}Geophysical Institute, University of Bergen, Bergen, Norway, \textsuperscript{2}Bjerknes Centre for Climate Research, Bergen, Norway

At high latitudes marine cold air outbreaks (CAOs) are the dominant weather systems injecting moisture into the atmosphere - yet their role in the water cycle is not well understood and their representation in coarse resolution models is subject to substantial biases. We present a numerical process study of one of the most intense CAOs that occurred in the Nordic Seas in recent years. To that end we perform a set of simulations with the limited area weather prediction model COSMO at resolutions from coarse to convection resolving. Using tagged water tracers transported within a secondary water cycle built into the model, we follow the moisture that evaporates into the CAO air mass from evaporation to precipitation. Based on these simulations we characterize the water cycle associated with the CAO. Specifically, we quantify the amount of moisture injected into the atmosphere by the CAO and analyse the footprint of the CAO in surface evaporation and precipitation, as well as moisture pathways. Most importantly, we show that the CAO is associated with a local water cycle, where moisture origin and precipitation are close together and take place on a time scale of less than 3 days. This contrasts other weather systems that are associated with rather long-range moisture transport, such as frontal systems. This local nature of the water cycle associated with CAOs allows to study limitations of parameterised processes regarding evaporation and convection within a limited-area model.
Atmospheric Variability in the Subpolar North Atlantic: A Long-term Perspective

Erica Madonna¹,² (erica.madonna@uib.no), Camille Li¹,², Clio Michel¹,², Lukas Papritz¹,²
¹Geophysical Institute, University of Bergen, Bergen, Norway, ²Bjerknes Centre for Climate Research, Bergen, Norway

Understanding the interannual atmospheric variability in the polar and subpolar regions is essential for detecting and understanding future changes in these regions. Unfortunately, observations at high latitudes are sparse and the records are short, making it difficult to assess changes. The Arctic is dynamically linked to the mid-latitudes, for example via the poleward transport of heat and moisture in extratropical cyclones. Moreover, in the North Atlantic, the position of the eddy-driven jet stream is related to the occurrence of blocking, and accounts for a large portion of the internal (natural) variability in the region. The jet stream’s position also influences the occurrence of cold air outbreaks (CAOs), which contribute substantially to the oceanic heat loss in the Arctic due to air-sea heat exchanges.

The aim of the study is to investigate interannual variability and trends in the frequency of the jet configurations at mid-latitudes over the past century, and the implications for the conditions in the polar and subpolar regions. We use the long term (1900-2010) wintertime ECMWF ERA-20C reanalysis for the North Atlantic. First, we identify the North Atlantic jet configurations, which are closely related to the quasi-stationary states of the atmosphere, so called weather regimes. We then characterize each jet configuration with respect to cyclones, blocking and CAOs frequencies and study their long-term variability.
**Temporal and Spatial air Temperature Changes in the Arctic, 1951 - 2015**

Rajmund Przybylak¹ (rp11@umk.pl), Przemysław Wyszyński¹

¹Nicolaus Copernicus University, Department of Meteorology and Climatology, Toruń, Poland

Detailed research into air temperature tendencies in the Arctic based on instrumental data for the periods 1951-2015, 1976-2015 and 1996-2015 revealed the predominance of positive trends, statistically significant at the level of 0.05. In the two later periods the rate of warming was on average 2-3 times faster than in the entire study period. This is particularly true for mean annual values for the entire Arctic, and also for seasonal means (DJF, MAM, etc.) for the period 1976-2015. In the most recent 20-year period very large increases in both seasonal and annual means were observed in the Atlantic and Siberian climatic regions (after Atlas Arktiki 1985), while in the rest of the Arctic the rate of warming was usually weaker than trends for the period 1976-2015. In particular, there was a large fall in the rate of warming in spring, with near-zero trends (Baffin Bay and Canadian regions) and even a negative trend (-0.34°C/10 years, Pacific region). The scale of warming for the recent 20-year period relative to the reference period 1951-1990 ranges from 1.3°C (Baffin Bay region) to 1.7°C (Atlantic region). The average anomaly for the entire Arctic reached 1.6°C. The greatest warmings were for autumn (1.9°C) and winter (1.7°C), while the smallest was in summer (0.9°C).

The research work was supported by a grant entitled ‘Causes of the early 20th century Arctic warming’, funded by the National Science Centre, Poland (Grant No. 2015/1.9/B/ST10/02933).
Increasing Frequency and Duration of Arctic Winter Warming Events

Robert M. Graham¹, Lana Cohen¹, Alek A. Petty² (alek.a.petty@nasa.gov), Linette N. Boisvert¹, Annette Rinke³, Stephen R. Hudson¹, Marcel Nicolaus⁴, Mats A. Granskog¹

¹Norwegian Polar Institute, Tromso, Norway, ²Goddard Space Flight Center, National Aeronautics and Space Administration, Greenbelt, United States, ³Alfred Wegener Institute, Potsdam, Germany, ⁴Alfred Wegener Institute, Bremerhaven, Germany

Near-surface air temperatures close to 0°C were observed in situ over sea ice in the central Arctic during the last three winter seasons. Here we use in situ winter (December-March) temperature observations, such as those from Soviet North Pole drifting stations and ocean buoys, to determine how common Arctic winter warming events are. Observations of winter warming events exist over most of the Arctic Basin. Temperatures exceeding −5°C were observed during >30% of winters from 1954 to 2010 by North Pole drifting stations or ocean buoys. Using the ERA-Interim record (1979-2016), we show that the North Pole (NP) region typically experiences 10 warming events (T2m > −10°C) per winter, compared with only five in the Pacific Central Arctic (PCA). There is a positive trend in the overall duration of winter warming events for both the NP region (4.25 days/decade) and PCA (1.16 days/decade), due to an increased number of events of longer duration.
Modification of Polar Low Development by Sea Ice and Svalbard Orography

Denis Sergeev¹ (d.sergeev@uea.ac.uk), Ian Renfrew¹, Thomas Spengler²
¹University of East Anglia, School of Environmental Sciences, Norwich, United Kingdom, ²University of Bergen, Bergen, Norway

The life cycles of intense high-latitude mesoscale cyclones, polar lows, are uniquely shaped by their local geographical features. Our research focuses on the influence of Svalbard mountains and sea ice cover in the Norwegian and Barents Seas on polar low formation.

We present a modelling study of two typical polar lows that were in the Norwegian Sea during a northerly cold air outbreak. Each case is simulated using the UK Met Office Unified Model with grid spacing of 2.2 km. Compared to satellite cloud imagery and wind estimates, the model captures key features of the mesoscale vortices with reasonable accuracy. A series of sensitivity runs is conducted with artificially changed land mask, orography, and sea ice cover.

Besides its role in blocking stably stratified air from the ice-covered Arctic Ocean, Svalbard acts as an additional source of low-level cyclonic vorticity that helps polar lows to intensify. The change in the sea ice cover, especially west of Svalbard, results in larger changes in polar low intensity, particularly in the convectively-driven case.

The cases analysed in our study exemplify that polar mesoscale cyclones, originating from small vorticity clusters advected by synoptic-scale weather systems, often have stochastic nature.

To make broader conclusions about statistically significant influence of sea ice cover in the region, in the second part of our study we compile a climatology of mesocyclones in the vicinity of Svalbard using the ERA5 reanalysis.
Arctic CO₂ Variability Induced by the Madden-Julian Oscillation

King-Fai Li¹,² (king-fai.li@ucr.edu)  
¹University of California, Environmental Sciences, Riverside, United States, ²University of Washington, Applied Mathematics, Seattle, United States

Variability of atmospheric CO₂ must be well understood in order to better characterize the surface sources of anthropogenic CO₂ release. Previous studies have revealed the influence of the tropical Madden-Julian oscillation (MJO) to tropical mid-tropospheric CO₂ via convection. In this work, the observation by NASA’s Atmospheric Infrared Spectrometer (AIRS) is used to further study the MJO impact on the CO₂ concentration over the Arctic. A composite analysis shows that CO₂ north of 60°N varies with an amplitude of ±0.6 ppm over the MJO cycle. An empirical correlation analysis is applied to explore some possible mechanisms through which the MJO perturbs the Arctic CO₂ concentration remotely. The spatial pattern of the MJO-related Arctic CO₂ anomalies is found to resemble that of the isentropic potential vorticity (PV) anomalies at 475 K. A potential role of the lower stratospheric tropics-extratropics exchange is discussed.
Local Surface Mass and Energy Balance Processes in East Antarctica

Hendrik Huwald1 (hendrik.huwald@epfl.ch), Nander Wever1,2, Francesco Comola1, Michael Lehning1,2
1Ecole Polytechnique Federale de Lausanne (EPFL), School of Architecture, Civil and Environmental Engineering, Lausanne, Switzerland, 2WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland

In Antarctica, direct observations of key processes shaping the surface mass balance such as precipitation and snow deposition, wind transport of snow, and sublimation, are sparse due to the extreme environment and related difficulties in measuring the variables of interest. The ongoing project ‘Local Surface Mass Balance in East Antarctica’ (LOSUMEA) is designed to address these processes at the local scale with the objective of gaining insight on the dominant surface mass and energy balance components and their link to near-surface atmospheric dynamics and surface and sub-surface snow properties. To this end, two measurement stations have been installed near the Princess Elisabeth Station, Antarctica, in December 2016. Besides standard meteorological data the stations are equipped with snow particle counters and 3-D sonic anemometers relating wind, turbulence and mass flux. Pre- and post-storm Terrestrial Laser Scans (TLS) record the resulting surface morphological changes. While preliminary data is being analyzed, the full data set of the year 2017 is retrieved in early 2018. Addition of moisture sensors in 2018 is expected to provide valuable information on latent heat fluxes related to sublimation. This contribution presents an overview of the project experiments, the data obtained to date as well as their analysis and some first results.
Energy exchange between the ground and the atmosphere in the Arctic is of great interest to understand the amplification of global warming that is being experienced in that region. At very high latitudes the absence of sunlight in the prolonged Arctic night leads to conditions very different from most of the rest of the planet. In particular convection is suppressed though the presence of a very persistent inversion and this means that a major mechanism for energy exchange is turned off and other mechanisms (conduction, radiation, etc) are responsible for the exchange.

At the Polar Environment Atmospheric Research Laboratory (PEARL), Eureka, Nunavut, Canada, a research station at 80N latitude we have been studying this situation through the Polar night. We have used many in situ measurements including a microbarometer to watch small pressure fluctuations and a drone to measure the temperature gradient over a significant spatial area and through the lowest levels of the atmosphere. This talk will introduce some of the results from this work showing a strong spatial heterogeneity and significant variations in the conditions through the night. From these measurements we can begin to piece together a picture of the energy exchange in these unusual conditions.

PEARL is currently supported by the Natural Sciences and Engineering Research Council, Environment and Climate Change Canada and the Canadian Space Agency.
Cloud Role in Surface Radiation in Moisture and Sensible Heat Flux into Arctic

Yinghui Liu1 (yinghuil@ssec.wisc.edu)
1CIMSS, University of Wisconsin at Madison, Madison, United States

Previous studies show the impact of moisture and sensible heat into the Arctic on the surface energy budget, the Arctic sea ice concentration, and other atmospheric parameters. This study investigates how the moisture and sensible heat advection into the Arctic in the winter time affects the Arctic cloud. Composite analysis of radiation, cloud properties, air temperature, column integrated water vapor, and atmosphere circulation are performed using data from ECMWF Interim Re-Analysis (ERA-Interim), the Moderate Resolution Imaging Spectroradiometer (MODIS), and cloud profiling radar (CPR) onboard CloudSat. Results from ERA-Interim show greater downward longwave radiation (DLR), clear-sky downward longwave radiation (DLR_CLR), and cloud radiative forcing (CRF_LW), with CRF_LW accounting for approximately 40% of the total positive anomalies in the surface energy. Greater DLR_CLR can be attributed to higher air temperature, and higher column integrated water vapor; greater CRF_LW are results of greater cloud amount, and higher cloud ice and liquid water content. Changes in cloud properties are more obvious in the low-level clouds. Composite analysis from MODIS cloud shows similar spatial pattern as that from EAR-Interim. Composite analysis from CloudSat CPR shows moisture flux impact on the cloud vertical distribution stronger in the low-level, and stronger on the Atlantic side than that on the Pacific side of the Arctic Ocean.
Micrometeorology Controlling Snow and Ice Ablation Processes

Rebecca Mott-Grünewald\textsuperscript{1} \texttt{(rebecca.mott-gruenewald@partner.kit.edu)}, Michael Warscher\textsuperscript{1}, Sebastian Schlägl\textsuperscript{1,3}, Thomas Grünewald\textsuperscript{2}, Michael Lehning\textsuperscript{2,3}
\textsuperscript{1}Atmospheric Environmental Research, Institute of Meteorology and Climate Research, Karlsruhe Institute of Technology (KIT/IMK-IFU) KIT-Campus Alpin, Garmisch-Partenkirchen, Germany, \textsuperscript{2}WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland, \textsuperscript{3}Laboratory of Cryospheric Sciences, School of Architecture, Civil and Environmental Engineering, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Changing micrometeorology during an ablation season strongly affects melt dynamics of seasonal snow covers, perennial ice fields and small glaciers as complex boundary layer development over heterogeneous land-surfaces significantly alter the local air temperatures (and humidities). Micrometeorological processes such as advective heat transport, cold-air pooling or thermal wind systems are important meteorologic drivers for the mass balance of very small glaciers, by strongly affecting their sensitivity to an increase in the ambient air temperature.

In this study, we experimentally and numerically investigate the relative contribution of micrometeorological processes to the melt dynamics of seasonal snow-covers in alpine catchments and to the mass balance of the lowest perennial ice field of the Alps, the \textit{Eiskapelle}. Measurements indicate that the well-developed katabatic wind system significantly modifies the local air temperature field over the ice-field by decoupling the near-surface air from the warmer ambient air. For seasonal snow-covers we could evidence a high frequency of developing shallow stable internal boundary layers over snow patches, coinciding with atmospheric decoupling causing a shut-down of turbulence close to the snow surface. As a counteracting process, the advective transport of warm air is revealed to significantly increase the mean air temperature over snow resulting in 20-40\% larger catchments mean daily depletion rates.
The Role of Particle Cohesion in the Wind-driven Erosion of Snow Surfaces

Francesco Comola\textsuperscript{1} (francesco.comola@epfl.ch), Johan Gaume\textsuperscript{1,2}, Michael Lehning\textsuperscript{1,2}
\textsuperscript{1}Ecole Polytechnique Federale de Lausanne, Civil and Environmental Engineering, Lausanne, Switzerland, \textsuperscript{2}WSL Institute for Snow and and Avalanche Research SLF, Davos, Switzerland

Snow particles in a sintering snowpack develop cohesive bonds that significantly affect the predisposition of the snow surface to wind erosion. A better understanding of how cohesive bonds affect surface entrainment mechanisms is crucial to improve quantifications of the surface mass balance in polar regions. Given that particle cohesion is difficult to measure in experimental and field studies, this investigation relies on numerical models. Here, we use the discrete element method (DEM) to investigate the role of cohesive bonds in the granular splash process, which is the most efficient surface entrainment mechanism in wind-driven snow transport. Our granular splash simulations show a non-linear decrease of the number of ejected grains with increasing cohesion. The ejection speed, however, increases with increasing cohesion seemingly due to the smaller dissipation of elastic energy in frictional rearrangements. The interplay between number and velocity of ejected grains balances the cumulative kinetic energy of the splashed particles across a wide range of cohesion values. We further perform DEM simulations of wind-driven snow transport to show that the conservation of kinetic energy in the splash process can sustain the saltation mass flux over highly sintered snow beds. Our results may improve current surface parameterizations in larger scale models of snow transport and help us quantify, e.g., the amount of snow transported from the Antarctic ice sheet to the ocean.
Sublimation of drifting and blowing snow has been recognized as an important component of the mass budget of polar and alpine regions. The Thorpe and Mason (TM) model is the basis of all existing small and large-scale estimates of drifting snow sublimation. We revisit this model to test its validity for calculating sublimation from saltating snow grains.

Through simple numerical experiments, it is highlighted that the TM model is a steady-state model that reconciles well with the solution of the unsteady mass and heat balance equations of an individual snow grain, albeit after a transient regime. Next, we simulate snow saltation using high-resolution large-eddy simulations of the atmospheric surface layer with lagrangian snow particles, coupled with statistical models of aerodynamic, splash and rebound entrainment of particles from an underlying snow surface. It is found that the residence time of a typical saltating particle is shorter than the period of the transient regime, implying that using the TM solution might be erroneous.

In simulations with similar air and surface temperatures, these errors range between 25% for low-wind and low-saturation conditions and 40% for high-wind and high-saturation conditions. With a small temperature difference of 1 K between the air and the snow surface, the errors due to the TM model are already as high as 100% with errors rapidly increasing for larger temperature differences.
Ecosystem Monitoring for Conservation: When to Monitor and Use Biodindicators

Justine Shaw¹ (j.shaw6@uq.edu.au), Rachael Alderman², Melissa Houghton¹, Aleks Terauds³, Hugh Possingham⁴
¹The University of Queensland, Centre for Biodiversity Conservation Science, Brisbane, Australia, ²DPIPWE, Wildlife Management, Hobart, Australia, ³Australian Antarctic Division, Hobart, Australia, ⁴The Nature Conservancy, Washington, United States

Ecosystem monitoring is not high impact, novel research to undertake in Antarctica or the sub-Antarctic, as such it is often not supported. Yet in order to understand ecosystem change and detect climate change impacts or assess conservation targets, monitoring must occur. Due to economic and logistic constraints and a desire to minimise our footprint we have to rationalise when, where, what and how we monitor in the region.

On sub-Antarctic Macquarie Island we are developing an optimal monitoring strategy to determine the current ecosystem state and track change into the future following invasive species eradication and under climatic change. We will quantify if conservation targets are being achieved. In order to do this we must identify when, what and how we monitor the terrestrial ecosystem. Firstly, management objectives for the region were clearly define. Secondly, temporally and spatially explicit historic data were located and compiled from various sources. This provided us with a suite of taxa and ecosystem variables that could be monitored into the future. We then had to consider which were suitable as bio-indicators, with which to detect change. A gap analysis was undertaken to determine if management objectives could be determined with this suite of bio-indicators or if new monitoring had to be initiated to ensure greater coverage of taxa and features. Finally, we are determining how monitoring can be in repeatable, low impact and cost effective into the future.

Species on the Move in East Antarctic Terrestrial Communities

Sharon Robinson1 (sharonr@uow.edu.au), Melinda Waterman1,2, Diana King1, Johanna Turnbull1, Jessica Bramley-Alves1, Michael Ashcroft1, Ellen Ryan-Colton1, Jane Wasley1,3, Quan Hua2
1University of Wollongong, Centre for Sustainable Ecosystem Solutions, School of Biological Sciences, Wollongong, Australia, 2Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia, 3Australian Antarctic Division, Department of Environment, Kingston, Australia

Antarctica has experienced major changes in temperature, wind speed and stratospheric ozone levels over the last 50 years. Whilst West Antarctica and the peninsula showed rapid warming and associated ecosystem change, East Antarctica appeared to be little impacted by climate warming, thus biological changes were predicted to be relatively slow. Detecting the biological effects of Antarctic climate change has also been hindered by the paucity of long-term data sets, particularly for organisms that have been exposed to these changes throughout their lives. We monitored vegetation communities in the Windmill Islands, East Antarctica from 2000 to 2014 and found significant changes in species composition. In addition, we have shown that radiocarbon signals preserved along shoots of the dominant Antarctic moss flora can be used to determine accurate growth rates over a period of several decades, allowing us to explore the influence of environmental variables on growth. Stable isotopic measurements suggest that the observed effects of climate variation on growth are mediated through changes in water availability and most likely linked to the more positive phase of the Southern Annular Mode and changing westerly wind patterns. For cold remote locations like Antarctica, where climate records are limited and of relatively short duration, this illustrates that mosses can act as microclimate proxies and have the potential to increase our knowledge of coastal Antarctic climate change.
1985
Vascular Plants and Moss Responses to Passive Warming in Antarctica

Angelica Casanova-Katny1 (angecasanova@gmail.com)
1Universidad Catolica de Temuco, Escuela de Veterinaria Facultad de Recursos Naturales, Concepcion, Chile

In contrast to vascular plants, bryophytes are major components of green landscapes of Antarctica’s small ice-free areas. Mosses, with more than 100 species, extend from maritime Antarctica well into the continent. However, only two vascular plants colonized Antarctica, the native Deschampsia antarctica and Colobanthus quitensis. After long term passive warming, we found that vascular plants grew faster producing more seeds. In mosses, an increase of sporophyte production after passive warming both in monoecious (Bartramia patens) and dioecious (Polytrichastrum alpinum) was found. Sanionia uncinata is a dominant and pioneer moss on glacier moraine and covers most part of the ice-free areas on the South Shetland Archipelago. We found that S. uncinata facilitates the growth of the vascular plant D. antarctica in the field and we observed that experimental warming did not change this positive interaction. We study heat resistance, antioxidant capacity. We observed no change in photochemical efficiency between passive warming and control after seven years of treatments, however lipid peroxidation rises in warmed mosses during the experiment, indicating that S. uncinata has been affected by the long term treatment. We suggest that S. uncinata will be able to support the future scenario of warming, but desiccation will be important for the success of this moss and this will affect the interaction with other component of the tundra ecosystem.
There are several ecological traits that could explain the capabilities of invasive species for the colonization of new areas. Traits that promote invasiveness may largely vary due to the prevailing ecological limiting factors across climatic regions. Temperate and Tropical areas are subjected to a stronger biotic competition than in Polar Regions, while in contrast abiotic conditions of polar areas may result particularly stressful for plant invaders. The present study compiles and analyzes climatic, mechanistic and physiological traits from 70 reported non-native plants of 4 different plant families historically found at nine biogeographic areas within Arctic and Antarctic/Sub-Antarctic high latitudes. General invasiveness was related to wide macroclimatic tolerances observed from temperature and precipitation ranges. Furthermore, the number of sites colonized per species was related to other factors such as plant height, seed production and/or human facilitation. The observed patterns are discussed in light of global change scenarios, taxonomic relationships and cold areas regionalization.
Predicting Plant Invasion Risks to the Subantarctic Islands

Michelle Greve¹ (michelle.greve@up.ac.za), Rabia Mathakutha¹, Christien Steyn¹, Izak Blom¹, Steven L. Chown², Barnabas H. Daru³, Brad S. Ripley⁴, Wayne Dawson⁵, Franz Essl⁶, Holger Kreft⁷, Anche Louw⁸, Jan Pergl⁹, Petr Pyšek⁹, Patrick Weigelt⁷, Marten Winter¹⁰, Mark van Kleunen¹¹, Peter C. le Roux¹

¹University of Pretoria, Department of Plant and Soil Sciences, Pretoria, South Africa, ²Monash University, Monash, Australia, ³Harvard University, Cambridge, United States, ⁴Rhodes University, Grahamstown, South Africa, ⁵Durham University, Durham, United Kingdom, ⁶University of Vienna, Vienna, Austria, ⁷University of Göttingen, Göttingen, Germany, ⁸Stellenbosch University, Stellenbosch, South Africa, ⁹Academy of Sciences of the Czech Republic, Průhonice, Czech Republic, ¹⁰German Centre for Integrative Biodiversity Research, Leipzig, Germany, ¹¹University of Konstanz, Konstanz, Germany

Worldwide, alien invasive species constitute one of the greatest threats to biodiversity. Therefore, to prevent and manage invasions, it is of utmost importance to understand invasion risks. The remote Sub-Antarctic Islands harbour a unique flora and fauna. Although they are mostly considered to be fairly pristine and little impacted by humans, a number of alien species have established and spread on the islands. Indeed, along with climate change, invaders are considered the greatest threat to the native biodiversity of the islands. In this study, we first assess the risk of invasion for all Sub-Antarctic Islands. We use a global pool of invasive plant species to assess which global invaders have a high probability of establishing on the islands. Second, using a trait-based approach, we assess what characteristics of plants make them successful invaders once they arrive in the Sub-Antarctic. Our assessment indicates which species pose the greatest invasion risk and which islands are most at risk to invasion. Furthermore, we find that weedy, generalist species with few specialised defences against extreme weather are particularly effective invaders. Worryingly, these species are predicted to become significantly more successful with climate change, at the expense of the native species. Our results allow us to make recommendations on which species pose the greatest risk to the islands and to prioritise the eradication of alien plant species on Sub-Antarctic Islands.
Mechanistic Models to Improve Antarctic Biosecurity

Greta C. Vega, Grant Duffy, Rachel Leihy, Miguel Ángel Olalla Tárraga, Steven L. Chown

1King Juan Carlos University, Department of Biology and Geology, Physics and Inorganic Chemistry, Madrid, Spain, 2Monash University, School of Biological Sciences, Melbourne, Australia

Invasive species are one of the most important threats to Antarctic terrestrial biodiversity. While Species Distribution Models (SDMs) are a useful tool to assess the suitability of non-occupied areas for invasive species, the uniqueness of the Antarctic environment has proven a challenge. We apply a new mechanistic modelling approach that allows the inclusion of prior physiological data to predict the distribution of species, providing strong predictive power. Six non-native Collembola species have been recorded from the Antarctic Peninsula and many more from the Southern Ocean Islands, some identified as invasive. We therefore use this group as an exemplar for the model. In particular, Ceratophysella denticulata is an invasive species on several Southern Ocean Islands, and a high risk to others and to the continent. Therefore, we apply our approach to C. denticulata SDM using its native range and physiological characteristics, and validate our results with high resolution sample data from Marion Island (South Africa). The projection of our model shows a strong congruence with field-collected sample data. The projection of the model to seven other Southern Ocean Islands shows that C. denticulata would find suitable environments on four of them, resulting in a potential threat to the native soil fauna. Our results support the rigorous implementation of biosecurity protocols to prevent the arrival and establishment of alien species on the Southern Ocean Islands and Antarctica.
Geochemical Constraints on Particle Flux Processes in the Western Arctic Ocean

Melissa Sophia Schwab1 (melissa.schwab@erdw.ethz.ch), Joerg Dominik Rickli2, Jurek Blusztajn3, Steven Manganini3, H. Rodger Harvey3, Robie W. Macdonald5, Derek Vance2, Cameron McIntyre6, Timothy Ian Eglinton1

1ETH Zürich / Geological Institut, Zürich, Switzerland, 2ETH Zürich / Geochemistry & Petrology Institute, Zürich, Switzerland, 3Woods Hole Oceanographic Institute, Falmouth, United States, 4Old Dominion University / Ocean, Earth & Atmospheric Sciences, Norfolk, United States, 5Department of Fisheries & Oceans / Institute of Ocean Sciences, Sidney, Canada, 6Scottish Universities Environmental Research Centre, Glasgow, United Kingdom

A growing body of evidence suggests that delivery of particulate matter, including associated biogeochemically-relevant materials to the interior Canada Basin in the central Arctic Ocean is dominated by lateral inputs. The magnitude and origin of lateral inputs has substantial implications for central Arctic Ocean biogeochemical processes and the ecosystem they support, as well as on records preserved in underlying sediments. Coupled measurement of organic and inorganic tracers provides a promising approach to unravel the sources and cycling of particulate matter in the western Arctic Ocean. In this study we used carbon (13C, 14C) isotopes, as well as strontium and neodymium isotopes to constrain terrestrial and marine organic carbon sources and detrital sediment provenance, respectively. Potential implications of future changes in the flux and provenance of materials supplied laterally to the central Arctic Ocean in relation to ongoing ocean and climate change are assessed.

Our data show a predominance of marine organic carbon in the Bering and Chukchi Sea whereas the Beaufort Sea and the Canada Basin is more strongly influenced by terrestrial inputs, with Beaufort Sea Nd and Sr isotopic signatures suggesting the Mackenzie River as major contributor of detrital particles whereas the Chukchi Sea receives a mixture of Aleutian Arc and Mackenzie derived material.
Increase in Acidifying Water in the Western Arctic Ocean

Di Qi (qidi@tio.org.cn)
Third Institute of Oceanography, SOA, Xiamen, China

The uptake of anthropogenic CO2 from the atmosphere by the ocean has decreased seawater pH and carbonate mineral saturation state, a process known as Ocean Acidification (OA). It has been reported that the Arctic Ocean is particularly sensitive to climate change and that the aragonite mineral saturation state ($\Omega_{\text{arag}}$) will become undersaturated sooner than in other oceans. The extent and expansion rate of OA, however, are still unknown. Here we show that low $\Omega_{\text{arag}}$ waters were largely confined to 50-150 m depth and south of 80ºN in the 1990’s, but data from multiple trans-western Arctic Ocean cruises show that the extent of low $\Omega_{\text{arag}}$ waters has since expanded to 50-250 m and to 85ºN. The vertical distribution of the $\Omega_{\text{arag}} < 1$ water has increased by about six-fold between the 1990’s and 2010. Tracer data and model simulations suggest that the recent increase in Pacific Winter Water (PWW) transport, driven by anomalous circulation pattern and sea-ice retreat, is primarily responsible for the rapid expansion of the low $\Omega_{\text{arag}}$ water. Local carbon recycling and anthropogenic CO2 uptake have also played roles in increasing the extent of the affected area. Our new results indicate that rapid acidification has happened in the Arctic Ocean and is far more serious than that in the Pacific and Atlantic Oceans where decadal OA trends have recently been reported.
Glaciers, Icebergs and Silicon: Preliminary Findings from the ICY-LAB Expedition (Invited Speaker)

Katharine Hendry1 (k.hendry@bristol.ac.uk), Hong Chin Ng1, Rebecca Pickering2, Malcolm Woodward3, Melanie Leng4,5, Jacob Opher6, Alexander Brearley6

1University of Bristol, School of Earth Sciences, Bristol, United Kingdom, 2University of South Alabama, Dauphin Island Sea Lab, Dauphin Island, United States, 3Plymouth Marine Laboratory, Plymouth, United Kingdom, 4University of Nottingham, School of Biosciences, Nottingham, United Kingdom, 5NERC Isotope Geosciences Laboratory, Keyworth, United Kingdom, 6British Antarctic Survey, Cambridge, United Kingdom

The supply and distribution of dissolved silicon (Si) in the oceans is a key factor in the growth of marine diatoms, which precipitate biogenic silica (or opal). Rivers and groundwater have long been considered the major inputs of dissolved Si, which is released during the weathering of silicate rocks. Glaciers are known sources of both dissolved and particulate Si phases, but the impact on oceanic systems needs further quantification to produce a more robust global budget. The aim of the ICY-LAB project is to investigate the role of high-latitude processes on the Si marine cycle. Expedition DY081 (RRS Discovery, summer 2017) focused on characterising the physical and chemical properties of the shelf and slope waters off Southwest Greenland, and investigating the impact of meltwater dynamics and circulation on biological production and ecosystems. Here, we present some of the initial results from the project, including the distribution of dissolved nutrient phases and tracers of meltwater components in the water column. We use observational and experimental approaches to explore the role of both continental runoff and shelf sediments in glaciated regions in supplying dissolved nutrients into the offshore waters. Our findings improve the understanding of the Si cycling between terrestrial sediments, shelf processes and seawater in glaciated regions, which represents an important but understudied component of internal cycling as well as a key input into the oceanic Si budget.
Pulsed Iron input from Svalbard to the Arctic Ocean over the past 180 ka

Allyson Tessin1 (a.c.tessin@leeds.ac.uk), Christian Maerz1, Johan Faust1, Mattias Forwick2, Jens Matthiessen3, Matt O'Regan4, Bernhard Schnetger5
1University of Leeds, School of Earth and Environment, Leeds, United Kingdom, 2UiT The Arctic University of Norway in Tromsø, Tromsø, Norway, 3Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, 4Stockholm University, Department of Geological Sciences, Stockholm, Sweden, 5Institut für Chemie und Biologie des Meeres, Universität Oldenburg, Oldenburg, Germany

Climate warming in high latitude terrestrial regions has the potential to significantly influence ocean biogeochemical cycling through increased delivery of freshwater, nutrients, and organic material. Changes in iron (Fe) input from terrestrial regions is especially important because Fe is a bioessential micronutrient, can control the sedimentary cycling of macronutrients (phosphorus), and can increase sedimentary preservation of organic carbon. Sedimentary records of past biogeochemical cycling are, therefore, important to evaluate and predict the effects that changes in the input of Fe-rich terrigenous material to the Arctic Ocean will have on nutrient cycling and organic carbon burial.

During a 2015 Polarstern expedition, sediment cores were retrieved north of Svalbard, on the Yermak Plateau. Based on preliminary age constraints, the PS92/39-2 core includes sediments from the penultimate glaciation (MIS 6) to the Holocene. Here we present XRF analyses to quantify and evaluate changes in biogeochemical cycling in this region during the past two glacial cycles. Initial results indicate a series of high Fe delivery events during the record with Fe concentrations of up to 9.8 wt.%. Pulsed delivery of Fe is likely associated with increased delivery of material from northern Svalbard, which is dominated by Fe-rich Devonian red beds. Tight coupling between Fe and P concentrations throughout the record suggests dynamic nutrient delivery and burial in the region.
Constraining Silicate Weathering Fluxes in a High-arctic River using Li-isotopes

Melissa Murphy¹ (melissa.murphy@ucl.ac.uk), Emily Stevenson², Phillip Pogge von Strandmann¹
¹University College London, London Geochemistry and Isotope Centre (LOGIC), London, United Kingdom,
²University of Cambridge, Department of Earth Science, Cambridge, United Kingdom

Silicate weathering is an important driver in both the inorganic and organic C-cycles. CO₂ is removed from the atmosphere by the weathering of silicate rocks at the Earth’s surface, and is transported via rivers as bicarbonate (HCO₃⁻) to the oceans, and locked up as marine carbonates. Silicate weathering also delivers nutrients to the oceans, promoting organic carbon burial.

Understanding how cryospheric weathering processes and the presence of glaciers and permafrost may affect physical and chemical weathering fluxes in high-Arctic rivers, and thus CO₂ removal in such high-latitude regions, remains poorly understood. In order to investigate this, we sampled rivers draining into the glacially fed, permafrost-dominated Zackenberg River Basin, NE Greenland.

Based on dissolved major element chemistry, we can identify a silicate-rich end-member draining easily erodible Cretaceous sandstones and Tertiary basalts, and a carbonate-rich end-member draining from the Lindemanselven. Tributaries fed by the A.P. Olsen glaciers, and melt water streams that drain the Caledonian granitic gneissic basement are also geochemically distinct.

Riverine lithium isotopes are a unique tracer of silicate weathering processes that are unaffected by biology, carbonate weathering or primary lithology. Dissolved and suspended particulate Li isotopes will be presented for rivers draining into the Zackenberg River to assess the role of silicate weathering, and ultimately CO₂ drawdown, in this region.
Here we present evidence that zonal-mean climate and its changes can be understood in terms of a moist energy balance model (MEBM) that represents atmospheric heat transport as a simple diffusion of latent and sensible heat - as a down-gradient transport of moist static energy with constant diffusivity, as supported by comprehensive models and atmospheric reanalyses. Given patterns of local radiative feedbacks, radiative forcing and ocean heat uptake, the MEBM accurately predicts the evolution of zonal-mean temperature and atmospheric heat transport (moist and dry) as simulated by the ensemble of CMIP5 GCMs. These results suggest that, despite all of its dynamical complexity, the atmosphere essentially responds to energy imbalances by simply diffusing latent and sensible heat down-gradient. It further provides insights into
(i) the mechanisms of polar amplification and
(ii) how uncertainty in the spatial pattern of radiative feedbacks, forcing, and ocean heat uptake project onto uncertainty in polar warming.
In the absence of any spatial structure in feedbacks or forcing, polar amplification emerges due to enhanced poleward atmospheric heat transport associated with latent heat. When the full spatial structure of radiative feedbacks are accounted for, polar amplification emerges due to the feedbacks and is damped from a decrease in atmospheric heat transport into the Arctic. These results suggest that polar amplification is an inevitable feature of climate change.
The Two Major Sources of Uncertainty in Antarctic Climate Change Projections

David Schneider¹ (denschneid@ucar.edu)
¹NCAR, Boulder, United States

Some of the largest uncertainties in projected anthropogenic climate change impacts occur in or are tied to Antarctica and the Southern Ocean. Projected changes in Antarctic surface mass balance, sea ice extent, and surface temperature differ widely among current-generation climate models, and this uncertainty largely stems from two major sources, internal variability and structural uncertainty. In this presentation, I will highlight recent work with the Community Earth System Model that aims to characterize the range of structural (model physics) uncertainty in Antarctic climate change projections and to determine its importance relative to Antarctica’s large natural climate variability. In particular, I will present results from new experiments that address how the Southern Ocean sea ice and sea surface temperature responses to stronger westerly winds differ according to the model’s ocean temperature and salinity structure.
The Signature of Ozone Depletion in Recent Antarctic Precipitation Change

Jeremy Fyke¹, Jan T. M. Lenaerts² (jan.lenaerts@colorado.edu), Brooke Medley³
¹Los Alamos National Laboratory, Los Alamos, United States, ²University of Colorado, Boulder, United States,
³NASA Goddard Space Flight Center, Greenbelt, United States

Precipitation as snow is a primary control on Antarctic Ice Sheet (AIS) mass balance and its contribution to sea-level rise, with regional trends in snowfall at the interannual scale linked to patterns of broader atmospheric circulation variability. Long-term historical AIS precipitation trends and their underlying external climate drivers, however, remain inconclusive. Here, using a pair of climate model simulation ensembles, we uncover a strong spatial signature of ozone depletion-forced Antarctic precipitation change characterised by an overall increase in snowfall. Distinct areas of little change or precipitation decrease, arising from interaction between ozone depletion-forced atmospheric circulation changes and ice sheet topography, are outweighed by large-scale precipitation increases. This signature bears notable similarities to a new ice core-based reconstruction of Antarctic surface mass balance change and drives a significant increase in annual integrated precipitation (38 +/- 10 Gt over the 1986-2005 period or 51 +/- 11 Gt over the 1991-2005 period) that has the same magnitude as observed Antarctic mass loss and thus strongly dampens recent Antarctic sea-level rise contributions.
Dynamical Mechanisms of Anomalous Moisture Transport towards East Antarctica

Annick Terpstra1,2,3 (annick.terpstra@uib.no), Harald Sodemann2, Irina Gorodetskaya3
1University of East Anglia, Norwich, United Kingdom, 2University of Bergen, Geophysical Institute & Bjerknes Centre for Climate Research, Bergen, Norway, 3University of Aveiro, Centre for Environmental and Marine Studies, Aveiro, Portugal

During the last decade Antarctic ice sheet accumulation patterns exhibited large regional differences. While the total ice-sheet mass of Antarctica declined, East-Antarctica experienced increases in ice mass. During 2009 and 2011, this increase was caused by only a handful of intense precipitation events. In this study, we investigate such an episodic accumulation event, thereby exploring linkages between oceanic evaporation in subtropical regions and Antarctic ice-sheet accumulation.

We use both Eulerian and Lagrangian analysis to demonstrate that moisture transport towards East-Antarctica was facilitated by several cyclones of different scales. Moisture transport occurred in coherent air-streams, manifested initially as intense low-level jets embedded in the warm sector of the cyclone(s), followed by a transition to slantwise (isentropic) ascent before reaching the continent. Water vapor loading of this air-stream was driven by low-level convergence in the warm sector along the advancing cold-front, whereas the slantwise ascent phase of the moisture transport was characterized by moisture removal (precipitation). Oceanic evaporation along the filamentary structured, anomalous moisture transport area was virtually absent, indicative for long-range moisture transport during the event. In addition to the moisture transport mechanisms we identified moisture source regions associated with the event.
Impact of Sea Ice Anomaly on Antarctic Precipitation and its Source Attribution

Hailong Wang (hailong.wang@pnnl.gov), Jeremy Fyke, Jan Lenaerts, Jesse Nusbaumer, David Noone, Philip Rasch

1Pacific Northwest National Laboratory, Atmospheric Sciences and Global Change, Richland, United States, 2Los Alamos National Laboratory, Los Alamos, United States, 3University of A Colorado, Department of Atmospheric and Oceanic Sciences, Boulder, United States, 4NASA Goddard Institute for Space Studies, New York, United States, 5Oregon State University, Corvallis, United States

Modeling and experimental evidence suggests that Antarctic Ice Sheet (AIS) surface mass balance (SMB) increases in a warming climate due to increased precipitation. We use the Community Earth System Model (CESM) with an explicit water tagging capability to partition the causes of increased precipitation in high latitudes. Sensitivity experiments have been conducted to understand the impact of sea ice anomalies on regional evaporation, moisture transport, and source-receptor relationships for regional precipitation over the Antarctica. Three composites of sea ice concentrations (SIC), constructed from the 1800-year CESM Large Ensemble Project using mean, 10% lowest, and 10% highest southern hemispheric SIC years (and corresponding sea surface temperatures), respectively, have been employed to drive three atmosphere-only simulations. Moisture sources in twenty-five geographical regions are explicitly tracked using the water tagging capability to establish source-receptor relationships of vapor and regional precipitation over the Antarctica. Results show that vapor sources for Antarctic precipitation primarily originate from lower latitudes; however, the tagged vapor source regions in high latitudes have discernable changes in their contributions to regional precipitation over the Antarctic in response to the SIC changes. There is also a strong regional and seasonal variability in vapor source attributions.
The Arctic is home to a population of about four million and is experiencing significant economic and environmental transformations as a result of ongoing natural resource development and climate-change. Mitigation and/or adaption efforts will be necessary to maintain the proper functioning of infrastructure over intended lifespans. This study examines the spatial distribution of risks from projected climate-change to built infrastructure in the Arctic and examines the economic costs of climate-change impacts on human development.

Changes in environmental variables such as temperature, precipitation, permafrost, freeze-thawing cycles, and ground subsidence are estimated in order to evaluate the risks of various types of infrastructure including roads, railways, pipelines, and buildings. The areas of significant climate-change driven risks are determined across the circumpolar region. The costs of mitigation and adaption efforts are used to provide quantitative estimates of climate change impacts. The results of this assessment can be used as a tool for businesses, policymakers, and urban planners in order to guide sustainable development in the Arctic.
SmartICE: A Sea-ice Monitoring System for Arctic Communities and Industries

Trevor Bell¹,² (tbell@mun.ca)
¹Memorial University, Geography, St. John’s, Canada, ²SmartICE, Inuit Nunangat, Canada

SmartICE (smartice.org) is a northern social enterprise that puts into the hands of communities the technology that helps them adapt to unpredictable sea-ice changes, resulting from climate change. Inuit knowledge of sea ice has been acquired from millennia of observation and use. But in the last decades this traditional knowledge has become less effective in the face of unprecedented environmental changes. SmartICE is an award-winning (Arctic Inspiration Prize 2016, UN Momentum for Change 2017) climate change adaptation tool that integrates on-ice technology, remote sensing and Inuit knowledge to generate near real-time information on sea-ice conditions. It maintains a network of in situ and mobile sensors that measures and transmits sea-ice thickness data from community trails. It also maps sea-ice surface conditions from satellite imagery to inform safe travel choices. It uses information technology to generate accessible products that match the needs of community users. The SmartICE information system directly benefits public safety, food security, health and wellbeing, while supporting economic activities for communities (e.g., ice-based fisheries and tourism), especially during highly dynamic freeze-up and break-up periods. Through technological innovation and science, SmartICE strives to integrate and augment Inuit knowledge about local sea-ice conditions, not replace it, through involvement of Inuit in all aspects of its operation and decision-making.
In the face of an expected increase in Arctic ship operations, driven by climate change, improvements in ship technology, and a high demand for Arctic natural resources, the understanding and management of related risks is paramount. Our vision for safe and sustainable Arctic maritime transport is based on a holistic design approach incorporating the goal-based regulations (GBRs) of the recently enforced Polar Code. In contrary to traditional design rules, GBRs do not determine the required solution, but determine instead the required function(s) to meet the goal(s). This gives designers more freedom to apply new and innovative solutions, where a high (and known) level of safety and sustainability is achieved without compromising cost efficiency. However, to ensure that the goals of the Polar Code are met, it is first necessary to determine appropriate performance measures and acceptance criteria for all critical safety and sustainability functions of a ship, and to develop and validate related performance assessment methods. This requires comprehensive understanding of Arctic ship operations, the applied technologies, and their interactions. Thus, we are working towards our vision both by increasing the knowledge about specific technologies (e.g. cold-resistant steel), and by developing a holistic design framework for Arctic ships, considering both operational and regulatory demands. The overall aim is to enable better-informed design decisions, reducing the level of risk.
Various stages of deep-hole drilling in ice require local enlargement of boreholes in order to perform different technological operations, e.g. installation of a casing string or sidetracking. Such tasks are accomplished using dedicated mechanical and thermal borehole reamers.

The paper provides a brief analysis of existing designs of mechanical and thermal reamers, which was used as the basis to specify requirements for new reamer designs. Based on these requirements, innovative designs of mechanical and thermal reamers have been developed. The paper presents schematic diagrams of these reamers and describes their design features, principles of action and operation practice in details.
The United States Coast Guard is designing and building new heavy polar icebreakers to replace aging and increasingly obsolescent ships. We have developed and evaluated icebreaker operational requirements, seeking the greatest capability within the bounds of affordability. These ships must conduct the missions of U.S. Coast Guard (which include safety, security, and stewardship of U.S. waters) while serving the survey and science needs of our partner agencies across the federal government. In this presentation, I will outline the icebreaker acquisitions process, highlighting our outreach with the U.S. Navy, industry and international partners. I will discuss the concept of icebreaker operations in both the Arctic and Antarctic. I will present the key performance capabilities required of the vessel in terms of icebreaking, endurance, and interoperability, and the resulting design implications. I will discuss the capabilities that support U.S. Coast Guard maritime missions such as boat and aviation operations. Finally, I will detail the survey and science capabilities required of these icebreakers to increase our knowledge of the remote Polar Regions.
ANTOS (Antarctic Near-shore and Terrestrial Observation System), a SCAR Expert Group, is a biology-focused initiative to coordinate and harmonize efforts to assess environmental variability and change across the Antarctic continent and National Antarctic Programs. The primary aim for ANTOS is to foster and facilitate autonomous collection and sharing of long-term climate and associated environmental observations using standardized protocols and instrumentation in terrestrial and coastal habitats. The ANTOS draft technical guidelines include specifications for three tiers of ANTOS stations with increasing complexity and cost. The three-tiered approach aims to enable the widest possible deployment of ANTOS-compliant automatic weather stations across Antarctica and the broadest participation by National Antarctic Programs and Antarctic researchers.

Leveraging decades of development and experience from polar engineers and scientists, ANTOS platforms will be integrations of off-the-shelf products to maximize reliability and the ease of procurement and replacement. By presenting a technology overview of ANTOS to an audience of polar engineers and field scientists, we seek feedback on the current draft technical guidelines and wish to explore possible inclusion of emerging technologies. We particularly hope to collect information on the performance of various new battery and power technologies (e.g., LiFePO4 and methanol fuel cells) in polar settings.
The Laurentia-East Antarctica Connection Revisited

Ian Dalziel\textsuperscript{1} (ian@ig.utexas.edu)
\textsuperscript{1}The University of Texas at Austin, Institute for Geophysics, Jackson School of Geosciences, Austin, United States

Following the suggestion of Canadian geologists Bell and Jefferson, who compared the Proterozoic stratigraphy of southeastern Australia and western Canada, Moores and Dalziel published separate papers in 1991 proposing that the Pacific margins of East Antarctica-Australia and Laurentia had been juxtaposed prior to the opening of the Pacific Ocean basin in the Neoproterozoic. Following Moores, this became known as the Southwest United States-East Antarctica, ‘SWEAT’, hypothesis. Over the past quarter century several variations of the proposed juxtaposition have been suggested, and some authors have put forward reconstructions with Asian crustal blocks interposed between East Antarctica-Australia and Laurentia.

In a series of publications between 2004 and 2017, Goodge, Fanning and colleagues have demonstrated that morainal material originating under the East Antarctic ice sheet bears compelling similarity to the Laurentian craton. Detrital zircons in the Beacon Supergroup also have a distinctly Laurentian signature. There is, however, a significant difference between the reconstructions stemming from these studies and one taking into account the apparently Laurentian nature of the Mesoproterozoic volcanic rocks in Coats Land reported by Loewy and colleagues. The latter indicates that the ca. 1.0 Ga type- Grenvillian orogeny of Laurentia continues into the Maud orogen along the eastern margin of the Weddell Sea. The purpose of the presentation is to explore this discrepancy.
We present a new 3-dimensional model of the Antarctic lithosphere, integrating seismological and gravity gradient data in a self-consistent manner. Current studies on the lithospheric structure, in particular the Moho depth, of the Antarctic continent contradict each other in many cases, depending on the applied geophysical method. This has huge implications for considerations regarding the isostatic state of the continent despite ongoing glacial isostatic adjustment (GIA). We attempt to reduce inconsistencies and ambiguities from separate geophysical methods by combining multiple observational data in a thermodynamically self-consistent 3D model, considering temperature and petrology of the lithosphere, seismic body wave velocities, and isostasy. Gravity gradient data from ESA’s GOCE satellite mission are used to constrain the density distribution within the lithosphere. Our results indicate that Antarctica is largely in isostatic equilibrium, however, the topography of some regions seem to have components which cannot be explained by pure isostasy. The subsurface thermal field of our model can be used to derive the mantle’s viscosity for the purpose of GIA modelling. Our forward-calculated surface heat flow estimations may serve as background values for modelling basal melt rates of Antarctica’s ice sheets.
India-Antarctic Breakup: Constraints from New Geophysical Data

Wilfried Jokat1 (wilfried.jokat@awi.de), Tabea Altenbernd1, Wolfram Geissler1, Masakazu Fujii2, Graeme Eagles1, German Leitchenkov3, Karsten Gohl1
1Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Geophysics, Bremerhaven, Germany, 2National Institute for Polar Research, Tokyo, Japan, 3VNII Okeangeologia, St. Petersburg, Russian Federation

The India-Antarctica separation is still an open problem due to the absence of critical geophysical data. So far no wide-angle data existed along the conjugate margins of East India and the Enderby Land off East Antarctica to define the position and composition of the continent-ocean boundary - a pre-requisite for any sound reconstruction. Furthermore, along both margins only old marine magnetic random track data are available for identifying seafloor spreading anomalies to describe the drift of both continents in the Cretaceous. The Kerguelen Plateau, located just north of the East Antarctica coast, however, has been drilled several times providing the only reliable age constraint on the formation of this huge magmatic plateau. In general, the poor information resulted a wide variety of kinematic models for the drift of the India.

In the last years several newly acquired geophysical data provide new constraints on its drift. Two deep seismic sounding lines off Prydz Bay and across the Princess Elisabeth Trough show that oceanic crust is already present much closer to the present-day shelf break than previously known. Magnetic data acquired parallel to these lines provide excellent timing constraints for the initial breakup of India. Finally, marine magnetic data gathered in 2017 south of Sri Lanka indicate that here the oceanic crust is definitely younger than magnetic chron M0, questioning several kinematic models for the Indian Ocean.

The latest results will be presented.

Defining Blocks and Boundaries within the Gondwanan Kuunga Orogen

Jacqueline Halpin¹ (jahalpin@utas.edu.au), Nathan Daczko²,³, Ian Fitzsimons⁴, Joanne Whittaker¹, Jacob Mulder¹, Tobias Staal¹,⁵

¹University of Tasmania, Institute for Marine and Antarctic Studies, Hobart, Australia, ²Macquarie University, Department of Earth and Planetary Sciences, Sydney, Australia, ³Macquarie University, ARC Centre of Excellence for Core to Crust Fluid Systems and GEMOC, Sydney, Australia, ⁴Curtin University, Department of Applied Geology, Perth, Australia, ⁵University of Tasmania, School of Physical Sciences (Earth Sciences), Hobart, Australia

The East Antarctic region between Princess Elizabeth and Wilkes lands occupies a critical position in tectonic reconstructions, encapsulating part of the enigmatic Kuunga Orogen. Here, crust of broadly Indian affinity and Australian affinity is generally thought to have been juxtaposed during Ediacaran-Cambrian (~550-530 Ma) Gondwana amalgamation. However, a lack of identified ophiolite or consensus on the location and geometry of any sutures makes it difficult to incorporate the Kuunga Orogen into models of Gondwana evolution. If Indo-Antarctica and Australo-Antarctica had distinct geological histories, then a suture zone should juxtapose crust of different protolith age. This approach can constrain suture location from geochronology of available outcrop even when the suture itself is not exposed. Although this boundary might not be the only suture or the final suture, it is a fundamental paleo-plate margin and an important first step in determining the overall orogenic architecture.

Here we explore the implications of approaching this problem via integration of geological and geophysical data in a plate reconstruction framework. We present new zircon and monazite U-Pb geochronology, together with zircon Hf-isotope data, to examine the crustal evolution and affinity of rare coastal exposures of the Kuunga Orogen. Based on these integrated datasets, we suggest a fundamental terrane boundary intersects the Queen Mary Land coast, east of Mirny and west of Alligator Island.
Crustal Structure off Enderby-Wilhelm II Lands: Implication for Gondwana Breakup

German Leitchenkov\textsuperscript{1,2} (german\_l@mai.ru), Yulia Guseva\textsuperscript{3}, Viktor Gandyukhin\textsuperscript{3}, Alexander Golynsky\textsuperscript{1}, Andrey Kazankov\textsuperscript{3}

\textsuperscript{1}VNII Okeangeologia, St. Petersburg, Russian Federation, \textsuperscript{2}St. Petersburg State University, Institute of Erth Sciences, St. Petersburg, Russian Federation, \textsuperscript{3}Polar Marine Geosurvey Expedition, St. Petersburg, Russian Federation

The history of rifting and sea-floor spreading between India and Antarctica remained vague long time mainly because of data scarcity and insufficient depth resolution of seismic data off both continents. Revision of all available geophysical data (including recently derived) in the region off Enderby-Wilhelm II Lands (Antarctic sector between 35E and 100E) and published information on crustal structure of the eastern India margin based on commercial seismic data give much better understanding of break-up history of East Gondwana. The rifted continental margin off Enderby-Wilhelm II Lands shows variable crustal characteristics. Off eastern Enderby Land, it is 300-400 km wide and includes a 100-km-wide continent-ocean transition zone consisting mostly of exhumed mantle. The western Enderby Land, Princess Elizabeth Land and Wilhelm II Land margins are narrower and range in width from 50 to 200 km. The sea-floor spreading started in the eastern part of studied region (76E-100E) at about 130 Ma. Off western Enderby Land (55E-76E), early oceanic opening was compensated by mantle exhumation. The pole of rotation was located close to Gunnerus Ridge. The southern Kerguelen Plateau was the part of the India margin and was attached to the Antarctic plate due to a ridge jump at about 124 Ma. The sea-floor spreading between 36E and 66E occurred during CNS. It started at about 120 Ma off eastern Enderby Land and later off western Enderby Land.
A new tectonic boundary has been discovered beneath the Ross Ice Shelf (RIS), a 476,000 km² floating icesheet that obscures the seafloor topography and crustal structure of the West Antarctic rift system. Mapping of magnetic and gravity anomalies by the ROSETTA-Ice airborne survey (2015-2017) reveals a major break between cratonic East Antarctica and accreted crust of West Antarctica, midway across the Shelf ~300 km east of the Transantarctic Mountains. The Central High, a fault-riven block formerly identified and drilled in the Ross Sea, is found to span the tectonic boundary and continue south as a basement high separating two distinct crustal regions beneath the Ice Shelf. The modeled bathymetry shows a deep, smooth Ross-EAIS sector of dense crust that displays subdued, long wavelength magnetic anomalies. This contrasts with the shallow, more complex seabed in the ROSS-WAIS sector, comprising less dense crust with high amplitude, short wavelength magnetic anomalies. Modeling of geophysical data allows the identification of glacially-carved and sediment-filled troughs, faults, and tectonic transfer zones, together with magma conduits and centers. A revision of the existing tectonic framework for the Ross Embayment is needed to accommodate these new findings from the fuller characterization of sub-RIS extended crust. The presence of shallow and deep sectors have consequences for ocean circulation beneath Ross Ice Shelf and modes of past and future ice sheet retreat.

On behalf of the Rosetta-Ice Team, Columbia University, Lamont -Doherty Earth Observatory
The Greenland Ice Sheet is melting at an unprecedented rate, and as a result, fjords and continental shelves around Greenland are exposed to an increasing freshwater runoff. Yet the impact of high meltwater input on the biogeochemistry and productivity remains largely unquantified. To resolve the effect on Greenland's fjord, sampling was conducted in several fjords impacted by melting glaciers in Greenland and physical, chemical and biological gradients were studied from close to the glaciers towards the open sea. Hydrographic and biogeochemical data from several fjord systems adjacent to the Greenland ice sheet, suggest that ecosystem productivity is very differently regulated in fjords influenced by either land-terminating or marine-terminating glaciers. Our data shows that rising subsurface meltwater plumes originating from marine-terminating glaciers entrain large volumes of ambient deep water to the surface and consequently supply upwelling of nutrient-rich deep water. This sustains high phytoplankton productivity throughout summer in the fjord with marine-terminating glaciers. In contrast, fjords with only land-terminating glaciers lack this upwelling mechanism, and are characterized by lower productivity. These results suggest that a switch from marine-terminating to land-terminating glaciers can substantially alter the productivity in the coastal zone around Greenland with potentially large ecological and socio-economic implications.
Fjord Marine Ecosystem Response to Ice Shrinking in KGI: A Case of Marian Cove

In-Young Ahn¹ (iahn@kopri.re.kr)
²Korea Polar Research Institute (KOPRI), Division of Polar Ocean Sciences, Incheon, Korea, Republic of

King George Island (KGI) is located at the northern tip of the Antarctic Peninsula, one of the most rapidly warming regions on earth. About 90% of the island is covered by glaciers, and significant glacier retreat has been observed in many coastal areas including a small embayment, Marian Cove (~4.5 km long and ~1.5 km wide). Fast and consistent glacier retreat (ca. 1.9km during 1956-2017) has been reported in MC. Recent studies revealed a suite of environmental parameters with distinct gradients which were apparently developed by glacier retreat and consequent processes. These studies also demonstrated that spatial pattern of benthic communities was significantly associated with these environmental suites, suggesting MC as a model ecosystem for assessing and predicting climate impacts. As a follow-up, this year we started a new integrative and interdisciplinary project, CHAMP2050 (CHAnges in Coastal Marine Systems of the Antarctic Peninsula: A 2050 Outlook). In this presentation, we introduce latest findings from a long-term dataset on hydrology and phytoplankton communities, which also revealed strong influence of glacier retreat and melt-water processes. We also present further findings on the benthic communities, and suggest that current distribution of megabenthos reflect somehow successional processes in the past, which in turn may provide insight into future scenario in the Antarctic fjords.
Impacts of Greenland Ice Sheet Melt on Marine Carbon Cycling in Adjacent Fjords

Johnna Holding¹ (johnna@bios.au.dk), Mikael Sejr²
¹Aarhus University, Arctic Research Centre, Aarhus C, Denmark

The Greenland Ice Sheet (GIS) is melting at unprecedented rates increasing the freshwater content of the Arctic Ocean. Freshwater run-off influences circulation patterns and stratification in Greenland fjords and also introduces inorganic particles, which can limit light availability to photosynthetic organisms. Furthermore, recent glaciological studies have documented that GIS melt water contains significant amounts of bioavailable organic carbon, which are likely to impact microbial carbon cycling and thus potentially transform the coastal ecosystem around Greenland. In this presentation we will show the results of recent studies in a Greenland fjord influenced by land-terminating glaciers as a model for future glacier retreat, where primary production is limited by both light and vertical flux of nutrients due to strong stratification of the water column by freshwater run-off. Additionally, we will present the results of an experimental study, which follows the incorporation of allochthonous carbon from freshwater run-off into the microbial loop. As glaciers retreat, Greenland fjord ecosystems are likely to become less productive and dominated by heterotrophic processes. This may have consequences for the metabolic balance of the ecosystem that has a major role in contributing to the uptake of CO2 in the Arctic Ocean as well as affect the commercial and subsistence fisheries that take place in Greenland fjords.
The Glacial Influence on Fjord Ecosystems of the Western Antarctic Peninsula

Martin Truffer¹, Forrest McCarthy¹ (forrestmccarthy@hotmail.com), Peter Winsor¹, Douglas Brinkerhoff²
¹University of Alaska - Fairbanks, Fairbanks, United States, ²University of Montana, Missoula, United States

Glacially influenced fjord ecosystems on the Western Antarctic Peninsula are unusually productive, compared to their counterparts in the northern hemisphere. We hypothesize that this is due to low levels of glacial freshwater runoff, which leads to reduced burial of benthic organisms from turbid glacial waters. The mass loss of most of these glaciers occurs as a flux of solid ice into the ocean. A two-year study of Andvord Bay used timelapse cameras and remote sensing to derive a time series of ice flux, calving and sea ice cover. The biggest ice flux contributor to the bay, Bagshawe Glacier, is characterized by maximum flow velocities of 7 m/d and an ice flux of ~1.5 km³/yr. Calving events are episodic: in 2015/16, the majority of summer calving occurred in three big calving events that released large tabular ice bergs. These calving events were separated by a few much smaller events. Submarine melting has not been quantified, but is expected to be low due to cold water and little subglacial freshwater discharge to drive ocean circulation. This is also corroborated by the absence of a plume near the glacier front. The northern location of this glacier makes it subject to fundamental changes, should regional warming continue. At present, these glaciers do not have ablation areas. Future warming could lead to significant amounts of glacial runoff, with invigorated water circulation in the fjord and more subglacial sediment, with profound consequences for the fjord ecosystem.
In the coastal fjords of the West Antarctic Peninsula (WAP), especially in the northernmost area of Bransfield Strait, fast ice conditions have shown high variability within the past 25 years, resulting in year-to-year changes of coastal ecosystem productivity. In some recent years, late fast ice break-up resulted in exuberant blooms, potentially related to the variability of fast ice timing and duration. To resolve ice dynamics, we generated a model that uses local and regional sea ice cover, air temperature, wind direction and intensity as predictors for Potter Cove, King George Island (WAP). Daily sea ice cover data were obtained from digital photographs taken with a still camera at Carlini Station from 2009 to 2015. In-situ meteorological data were obtained from NCDC Surface Data Hourly Global dataset, and daily regional sea ice data from NSIDC Sea Ice Concentration dataset. An information-theoretic model selection scheme showed coastal ice duration was best predicted by models including all predictors, and that start and finish of the longest fast ice period responded differently to these variables. The fit of the models was consistently good, suggesting that coastal sea ice timing can be predicted using a combination of regional and local data. Since all analyses are automated and input data are freely available, this modeling tool can be used to analyze how coastal sea ice is linked to inshore bloom dynamics and coastal productivity in WAP fjordic systems.
Ecosystem Physics of a WAP Fjord: A Modeling Study of Key Controlling Factors

Lisa Hahn-Woernle\(^1\) (lisahw@hawaii.edu), Brian Powell\(^1\), Oyvind Lundesgaard\(^1\), Craig Smith\(^1\), Mark Merrifield\(^{1,2}\)

\(^1\)University of Hawaii at Manoa, SOEST, Honolulu, United States, \(^2\)Scripps Institution of Oceanography, UC San Diego, San Diego, United States

The FjordEco Project is evaluating the role of physical oceanographic processes and glacial input in fjord ecosystems along the Western Antarctic Peninsula (WAP). Between Dec 2015 and Mar 2017, three research cruises to Andvord Bay, a WAP fjord, were conducted to measure physical properties as well as the structure and function of pelagic and benthic biological communities. The sparse in situ oceanographic measurements allow estimates of processes such as nutrient upwelling and seasonal temperature variability. However, a lack of long-term measurements limits the identification of key controlling factors from observations alone. Therefore, we built a high-resolution numerical model (350 m) of Andvord Bay using the Regional Ocean Model System (ROMS) to explore physical processes influencing fjord ecosystem dynamics. The model includes tidal forcing as well as atmospheric forcing from the Regional Atmospheric Climate Model. Initial conditions and oceanic boundary conditions are based on observations. Key controlling factors of fjord dynamics and climatology were determined using adjoint sensitivity analysis. Results provide insights into the influence of sea ice and icebergs on the heat budget and light availability below the sea surface. Our sensitivity studies have improved understanding of the key controlling factors in the fjord and indicate potential ecosystem consequences of climate warming along the WAP.
Mean Global Ocean Temperatures during the Last Glacial Transition

Bernhard Bereiter1,2,3 (bereiter@climate.unibe.ch), Sarah Shackleton1, Daniel Baggenstos1,2, Kenji Kawamura4, Jeff Severinghaus1
1Scripps Institution of Oceanography, University of California, San Diego, GRD, La Jolla, United States, 2University of Bern, Physics Institute & Oeschger Centre for Climate Change Research, Bern, Switzerland, 3Swiss Federal Laboratories for Materials Science and Technology Empa, Dübendorf, Switzerland, 4National Institute of Polar Research, 10-3, Tokyo, Japan

Due to a lack of robust reconstructions and limited observations, little is known about the ocean temperature’s response to climate perturbations. While it is observed that the ocean takes up most of the ‘excess’ heat from the current global warming, its changes before the first observations (ca. 1865 CE) and in the future are uncertain. Considering the slow overturning time of the global ocean (centuries to millennia) which determines the responsiveness of global ocean temperatures to changing climate, much interest exists in reconstructing ocean temperatures for pre-industrial periods. Here, using a novel ocean temperature proxy based on atmospheric noble gases derived from trapped air in ice cores, we show that mean ocean temperature increased by 2.57 +/- 0.24°C over the last glacial transition (20,000 to 10,000 years ago) - a period of major global climate change. Our noble gas based reconstruction provides unprecedented precision and temporal resolution for the integrated global ocean and is not suffering any depth-, region-, organism- and/or season-specific effects intrinsic to such proxies/estimates available thus far. We find that mean ocean temperature is closely correlated with Antarctic temperature and has no lead or lag with atmospheric CO2, thereby confirming the important role of southern hemisphere climate for global climate trends. We also reveal an enigmatic 700-year warming during the early Younger Dryas that surpasses estimates of modern ocean heat uptake.
An Attempt to Reconstruct Planetary Radiative Imbalance over the Last 40,000 Yrs

Daniel Baggenstos\textsuperscript{1} (baggenstos@climate.unibe.ch), Marcel Häberli\textsuperscript{1}, Jochen Schmitt\textsuperscript{1}, Hubertus Fischer\textsuperscript{1}
\textsuperscript{1}Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern, Switzerland, Bern, Switzerland

Global climate change arises from an energy imbalance at the top of the atmosphere (TOA). The direct measurement of TOA radiative fluxes is difficult even today, such that most assessments of it are based on changes in the total energy content of the Earth system. We apply the same approach to estimate the long term evolution of the planetary radiative imbalance in the past.

The energy budget of the climate system is dominated by the ocean’s heat capacity. On Pleistocene timescales the latent heat changes associated with the waxing and waning of the large ice sheets are of similar magnitude as the ocean heat uptake. Ice core noble gas thermometry allows us to estimate changes in ocean heat content, while sea level reconstructions provide a measure for the contribution of the ice sheets from their latent heat release or consumption. The temporal derivation of the sum of these two dominant components should yield the planetary radiative imbalance.

We present measurements of noble gas derived mean ocean temperature from the EDC ice core covering the past 40,000 years. We infer TOA radiative imbalance as described above. As expected from the relatively stationary climates of the last glacial maximum and the Holocene, the radiative imbalance is close to 0.0 W/m\textsuperscript{2} in those periods. During the deglaciation a positive imbalance is maintained for \textasciitilde10,000 years, with two distinct peaks that reach up to 0.4 W/m\textsuperscript{2}, highlighting the importance of internal variability in the climate system.
Oceanic heat uptake carries the lion’s share of glacial/interglacial changes in the planetary heat content, and is thus the most integrative and representative parameter for quantifying long-term changes in the Earth’s energy budget. Here, we are focusing on peak glacial and interglacial conditions over the last 800,000 years, i.e. covering the last eight glacial and interglacial intervals. The only proxies for ocean temperatures during this time period so far were marine sediment cores which show strong variability of ocean temperatures both between and even within individual ocean basins as well as with depth.

The novel method of ice core noble gas thermometry allows us to reconstruct a global mean ocean temperature (GMOT) on the basis of physical principles. The xenon/krypton ratio in the atmosphere is a direct proxy for GMOT because of the temperature dependence of their solubility coefficients. The GMOT in past times can therefore be estimated using high-precision measurements of noble gas elemental ratios from gases trapped in glacial ice after appropriate correction for archive-specific effects.

We performed Xe/Kr analyses on around 100 ice core samples from the EPICA EDC and EDML ice cores from East Antarctica over up to the last 800,000 years. The measurements imply warmer ocean temperature during interglacials and significantly colder temperatures during glacial times quantitatively in line with deep ocean temperature reconstructions from sediment cores.
Sea ice is an important amplifier in the climate system, affecting the surface energy budget by reflecting incoming solar radiation and regulating the atmosphere-ocean exchange of heat and CO2. Our understanding of the long term (i.e. beyond the satellite era) interplay between sea ice and the climate system can be improved by examining how sea ice responded during a range of past climates. In particular, the last interglacial (LIG; 130,000 to 115,000 years ago) allows investigation of the sea ice response to warmer than present conditions. We compare multi-ice core data with δ18O model output for the early last interglacial Antarctic sea-ice minimum. The spatial pattern of δ18O across Antarctica is sensitive to the spatial pattern of sea-ice retreat. Local sea ice retreat increases the proportion of winter precipitation, depleting δ18O at ice core sites. However, retreat also enriches δ18O because of the reduced source-to-site distance for atmospheric vapour. The joint overall effect is for δ18O to increase as sea ice is reduced. Our data-model comparison indicates a winter sea-ice retreat of 67, 59 and 43 % relative to pre-industrial in the Atlantic, Indian and Pacific sectors of the Southern Ocean. A compilation of Southern Ocean sea-ice proxy data provides weak support for this reconstruction. However, most published marine core sites are located too far north of the 128,000 years BP sea ice edge, preventing independent corroboration for this sea ice reconstruction.
Using Ice Cores and Emulation to Reconstruct Last Interglacial Ice Sheets

Louise Sime¹ (lsim@bas.ac.uk)
¹British Antarctic Survey, Cambridge, United Kingdom

Far-field sea level records have provided evidence that parts of the Antarctic Ice Sheet and Greenland ice sheet were likely lost during the Last Interglacial (LIG) period, 116-129 thousand years ago. Reconstructing ice sheet changes within the LIG however remains a difficult problem. Sediment cores from beneath the West Antarctic Ice Sheet (WAIS) support the view that parts were lost within the last 1.3 million years but the timing of the loss is unknown. This lack of knowledge about the ice sheet changes during the LIG hampers our ability to calibrate models of potential ice sheet loss in the future.

Ice cores provide amongst the best dated proximal evidence of LIG change across the Antarctica and Greenland, it is therefore very helpful to use ice core measurements to provide constraints on the rate and timing of ice sheet changes. Holloway et al. (2016) explored the ice core signal of WAIS change; we found that ice sheet meltwater and/or ice sheet morphology changes would be recorded in the polar ice cores. Here we present our recent progress on reconstructing ice sheet changes. We simulate how LIG ice sheet and sea ice changes would be imprinted on Antarctic and Greenland ice cores using isotopically enabled climate model simulations of the LIG, and present initial results from applying an emulator (statistical) based approach to this problem, exploring the impact of ice sheet, meltwater, and sea ice changes on the ice core record.
The Effect of Northern Hemisphere Ice Sheet Topography on West Antarctic Climate

Tyler Jones¹ (tyler.jones@colorado.edu), William Roberts², Eric Steig³, Kurt Cuffey⁴, Bradley Markle⁵, James White⁵
¹University of Colorado, Institute of Arctic and Alpine Research, Boulder, United States, ²University of Bristol, BRIDGE, School of Geographical Sciences, Bristol, United Kingdom, ³University of Washington, Quaternary Research Center and Department of Earth and Space Sciences, Seattle, United States, ⁴University of California, Department of Geography, Berkeley, United States, ⁵University of Colorado, Institute of Arctic and Alpine Research and Department of Geological Sciences, Boulder, United States

The behavior of the Pacific climate system across the last deglaciation is widely debated. Resolving these debates requires long-term and continuous climate proxy records. Here, we investigate multi-year climate variability for the last ~31 ka using an ultra-high resolution and continuous water isotope record (dD, d¹⁸O, dxs) from the WAIS Divide ice core (WDC) in the Pacific sector of West Antarctica. We document an abrupt decline in the amplitude of dD and d¹⁸O multi-year climate variability at ~16 ka. Using the HadCM3, we demonstrate that the climates of both West Antarctica and the Indo-Pacific were substantially altered at ~16 ka by the same forcing mechanism: the lowering topography of the Laurentide and Cordilleran Ice Sheets (LCIS). In the tropics, the LCIS topography affects the rainfall patterns, which explains the Indonesian deglacial shift from expanded-grasslands to rainforest-dominated ecosystems. Similarly, the LCIS affects the tropical Pacific-to-West Antarctic teleconnection strength, which changes WDC multi-year climate variability. The dxs shows a different amplitude pattern than dD and d¹⁸O, for example, 3-7 yr dxs variability declines slowly from ~16 to 6 ka, whereas 3-7 yr dD and d¹⁸O variability declines abruptly at ~16 ka and reaches a minimum at ~10 ka. Initial results suggest that dxs could provide information about pan-Pacific changes in rainfall location, as well as the extent and movement of sea ice during deglaciation in West Antarctica.
Regional Cooperation in Antarctica: the Cases of Asia, Europe and South America

Andrea Colombo¹ (andrea.colombo@pg.canterbury.ac.nz)
¹University of Canterbury, Gateway Antarctica, Christchurch, New Zealand

International cooperation, with the aim to facilitate research in the Antarctic harsh and extreme environment, plays a pivotal role for the logistic support and for the deployment of scientific projects run by multiple nations. These cooperation can either be intra-continental or external; while inter-Antarctic cooperation are based on Antarctic regional area, external ones find their fundamentals in the geographical and political boundaries of every country.

This paper analyses the current situation of three different regional groups that find their roots, in an oversimplified way, in Asia, Europe and South America.

The Asian Forum for Polar Sciences (AFoPS), the European Polar Board (EPB) and the Reunión de Administradores de Programas Antárticos Latinoamericanos (RAPAL) are operating in Antarctica, and with the exclusion of the latter in both Poles, are an excellent example of logistic and scientific cooperation in Antarctica based on a regional scale.

My presentation attempts to further analyse the concept of regional cooperation in Antarctica and underline the importance of joint projects to fulfil scientific research that a single country might not be able to achieve on its own.
Accelerating changes and enhanced accessibility of the Arctic call for policymaking based on more and better science. Many of the observer states to the Arctic Council focus on science as the most significant element in their plans. We have mapped scientific capacities of national research programs over the Arctic spatial domain and examined the movement and usage of mobile and fixed research platforms. The scientific endeavors of observer states already form a critical link in the overall observation network and represent significant sources of the data required for sustainable development of the Arctic. There are mounting challenges in need of sound Arctic science, such as the Northern Sea Route, fisheries, or ocean acidification among many others. It is a legitimate question to ask how the Arctic as a whole is institutionally prepared to incorporate all available science, particularly that from observers. There are notable cases of scientific findings turned into policy in the Antarctic, for example the ozone-hole depletion, alien species, and others. In the Antarctic, institutional tools are present and in operation that allow for deliberations and decision-making processes engaging a whole range of stakeholders. Existing and even new arrangements in the Arctic may be inviting but are not inclusive enough, as we will illustrate in the presentation. More solid and embracive mechanisms are warranted to make the most use of observer contributions for the benefit of all.

The Impact of Arctic Scientific Cooperation Agreement on Non-Arctic States

Han Liu¹ (liuhan@pric.org.cn)
²Polar Research Institute of China, Shanghai, China

At the 10th Arctic Council Ministerial Meeting in May 2017, the third binding agreement Agreement on Enhancing International Arctic Scientific Cooperation was adopted, which would lower the barriers in international Arctic scientific cooperation, such as the difficulties in accessing research facilities and data. However, it seems that only the eight Arctic States benefit from such improved environment while non-Arctic States may be relegated to an inferior category in Arctic science. With the ratification of the Agreement in Oct. 2017 and the upcoming 2nd Arctic Science Ministeral Meeting in Oct. 2018, the degree of benefits to non-Arctic States under the Agreement needs to be carefully considered. Therefore, the main goal of this report is to discuss the influence of the Agreement on non-Arctic states’ approaches to Arctic scientific cooperation. In the first place, this report tries to critically analyze the main articles of the Agreement according to the international law as well as provides a description of its purposes and rule-making process. It then seeks to the influence of the Agreement on non-Arctic states’ participation in international Arctic scientific cooperation. The Sino-Russian Arctic scientific cooperation will be evaluated as a case study to explore the possibility of scientific cooperation between Arctic and non-Arctic states. In concluding, this report looks into the future and discusses challenges and opportunities for non-Arctic states.
The need to better connect Arctic science with decision-making is well recognized. Initiatives like ICARP-III and the Arctic Science Ministerial stress that Arctic science must be communicated beyond Arctic research community and underline the utmost importance of scientific information to advance constructive decision-making. To respond to those calls, in 2017 the International Arctic Science Committee (IASC) established Action Group on Communicating Arctic Science to Policy-Makers (CASP) - to enhance IASC capacity to provide advice on issues of science in the Arctic and the communication of scientific knowledge to policymakers. Arguably, IASC is very well positioned to serve as the primary source of information about Arctic science. It is the leading international Arctic scientific organization, which brings together all countries active in Arctic research and representatives of disciplines across humanities, social and natural sciences spectrum. The challenge to communicate Arctic science is, yet, paramount. Not only because of the unprecedented scale and pace of changes in the region, but also because of extremely dispersed nature of Arctic research. What is the role IASC can and should play in communicating Arctic science to decision-makers? What are its assets and limitations? CASP Action Group will deliver results of its work to IASC Council at the meeting in Davos. This paper builds upon its efforts, reflects on the CASP process and considers the next steps to take.
How Does Science Get into Policy in the Antarctic Treaty System?

David Walton¹ (dwhw@bas.ac.uk)
²British Antarctic Survey, Cambridge, United Kingdom

Governments declare that they want evidence based policy and scientists are asked to show how their science can be used for policy. Whilst there is now an apparently well defined route through SCAR Working and Information papers for the community into the CEP, ATCM and CCAMLR and another through national delegations it was not always so. What then are the key drivers that make some science more effective in Antarctic policymaking and how should you define outcomes when describing the effectiveness of the transfer? Using examples I will describe how topicality, risk, political expediency, practicability and affordability will always interact to determine if your efforts will result in a recognisable policy outcome and how and why this process can take some time.
Canada’s Diplomatic and Juridical Foreign Policy: Continental Shelf in the Arctic

Julia Schmied1 (j.schmied@utoronto.ca)
1University of Toronto, Munk School of Global Affairs, Toronto, Canada

Canada submitted in 2013 a complete process for the expansion of its continental shelf in the Atlantic Ocean, and a partial process to expand its continental shelf in the Arctic. Canada now has an extension to further their research and present a complete process to Commission on limits of the Continental Shelf (CLCS). In this sense Canada will present the United Nations Convention on the Law of the Sea with a focus as the most relevant issues to the expansion of the Canadian continental shelf in the Arctic.

Around the world, Governments have taken steps to include the most extensive adjacent sea areas in their jurisdictions, acting to exercise their rights onto overseas neighbours, assess the capabilities of its waters and the floor of the continental shelf. The praxis of States, in almost every aspect, has been implemented in line with the Convention, especially after entry into force and rapid acceptance by the international community as a parameter to all actions dealing with oceans and the Law of the Sea. The definition of the territorial sea contributed to the slowing of conflicting requirements. Navigation by the territorial sea and maritime Straits now is backed by legal principles. Coastal States already benefit from provisions that give them extensive economic rights over an area of 200 miles wide along their shoreline.
Since at least 34 million years ago, polar ice sheets have served as an important component of the Cenozoic climate system, yet many details of that history remain enigmatic, and a coherent model for cryosphere evolution remains elusive. Here, we establish a novel measure of Earth system sensitivity to obliquity forcing, quantified through the analysis of $\delta^{18}O$ data, which highlights distinct intervals in Earth system evolution and ice sheet history. We integrate this measure with direct records of Antarctic ice sheet (AIS) variability including sediment cores and seismic data. The results identify an increase in obliquity sensitivity associated with favourable astronomical configurations and key planetary thresholds in CO$_2$ concentrations and tectonics. The emergence of marine-based ice around Antarctica is coeval with enhanced obliquity sensitivity, and based on this, we establish a three phase AIS model (terrestrial-based ice sheet, marine-based ice sheet, and marine-based ice sheet with extensive sea ice). Long-term climate variability, and continental scale AIS expansion and retreat, is broadly commensurate with the 2.4-My-long eccentricity cycle. Maximum ice extent typically occurs during episodes of low obliquity variance and medium-to-high eccentricity. This integration of ice proximal and distal records provides a new coherent model for AIS evolution, with implications for future behaviour.
Given the position of the Ross Ice Shelf, which buttresses both the West and East Antarctic ice sheets, the potential future sea level contribution of its grounded ice drainage basins could be substantial. Here, we perform regional ice sheet model simulations to investigate past grounding line migration of the Ross Ice Shelf using the Parallel Ice Sheet Model (PISM) to better understand how the ice shelf system responds to environmental drivers. The regional simulations, performed at 10 km resolution, include both the Ross Ice Shelf and its grounded ice drainage basins, allowing for the grounding line to evolve through time. Climate forcing experiments are performed using different combinations of the temperature and accumulation reconstructions of the West Antarctic Ice Sheet (WAIS) Divide and EPICA Dome C ice cores, the output of two transient climate model simulations, and multiple SST and sea level proxy reconstructions. Differences in the pattern and timing of retreat between the model experiments highlight the relative impacts of atmospheric and oceanic changes and bathymetry on Ross Ice Shelf grounding line retreat. Our simulations are analysed in the context of the Roosevelt Island Climate Evolution (RICE) ice core and sediment cores from the Ross Sea and wider region. Together, these results provide insight into the environmental conditions that most strongly control grounding line changes, allowing inferences to be made for future controls on sea level rise.
Numerical models used to project future ice-sheet contributions to sea-level rise exploit reconstructions of post-LGM ice loss to tune model parameterizations. In the Weddell and Ross Sea sectors, reconstructions of West Antarctic Ice Sheet (WAIS) grounding line (GL) retreat history have been limited by lack of data south of the ice shelf calving fronts. We present new evidence from
(1) ice-penetrating radar showing Holocene ice rise evolution,
(2) the prevalence of subglacial radiocarbon and
(3) glacio-isostatic adjustment (GIA) modeling that collectively challenge prevailing views of Holocene WAIS behavior.

We show that the GL retreated more than 200 kilometers inland of its present position in these sectors, driven by climatic warming and sea-level rise, followed by GL re-advance to its current position, driven by GIA and ice rise formation. We explain these observations using an ensemble of ice-sheet simulations, using the PISM model suite. These simulations reproduce widespread post-LGM GL retreat well inland of its current location and later re-advance. These findings overturn the assumption of progressive Holocene GL retreat in the Weddell and Ross Seas and suggest that climate-initiated ice loss was reversed by GIA-driven stabilizing processes. Whether these processes could reverse present-day loss elsewhere in Antarctica on millennial timescales depends on poorly-known bedrock topography, mantle viscosity, climatic forcing and future ice-shelf stability.
Till from the margin of the major ice streams of the Weddell Sea Embayment contains detrital minerals with distinct age populations. These differences mean that they can be used as provenance tools to reconstruct past ice stream dynamics and determine the origin of iceberg-rafted debris (IRD) in the marine sediment record. Distinctive zircon age populations for each ice stream include - Institute Ice Stream: 560 Ma and 1070 Ma (dominant), Foundation/Academy Ice Streams: 505 Ma (dominant) and 1030 Ma, Recovery Glacier: 530 Ma (southern margin) and 1610 Ma (northern margin), and Slessor Glacier: 2260 Ma, 2345 Ma, and 2415 Ma. Many, but not all of these peaks are consistent with local bedrock sources suggesting measurable input from unexposed subglacial sources. Ar-Ar ages from detrital hornblende and biotite from the Foundation/Academy Ice Stream are typically younger than zircons, whereas till from the northern margin of Recovery Glacier has similar Ar-Ar age peaks as the zircon data. Comparison of these data with offshore U-Pb zircon and Ar-Ar signatures in tills from the Ronne (west), Hughes (central), and Filchner (east) sectors allow us to constrain LGM ice flow paths. The data suggest the Foundation Ice Stream flowed east of Berkner Island at some time during the LGM and that input from the Slessor/Bailey Glaciers was very limited in extent. If the Recovery Glacier bed is underlain by rocks of the Beacon Supergroup, the Recovery extended into the eastern Filchner trough.
Diverse Landscapes Beneath Pine Island Glacier Influence Ice Flow

Robert G. Bingham¹ (r.bingham@ed.ac.uk), David G. Vaughan², Edward C. King², Damon Davies¹, Stephen L. Cornford³, Andrew M. Smith², Robert J. Arthern², Alex M. Brisbourne², Jan De Rydt², Alastair G.C. Graham⁴, Matteo Spagnolo⁵, Oliver J. Marsh⁶, David E. Shean⁷

¹University of Edinburgh, Edinburgh, United Kingdom, ²British Antarctic Survey, Cambridge, United Kingdom, ³Swansea University, Swansea, United Kingdom, ⁴University of Exeter, Exeter, United Kingdom, ⁵University of Aberdeen, Aberdeen, United Kingdom, ⁶oliver.marsh@canterbury.ac.nz, Christchurch, New Zealand, ⁷University of Washington, Seattle, United States

The retreating Pine Island Glacier (PIG), West Antarctica, presently contributes ~5-10% of global sea-level rise. PIG’s retreat rate has increased in recent decades with associated thinning migrating upstream into tributaries feeding the main glacier trunk. To project future change requires modelling that includes robust parameterisation of basal traction, the resistance to ice flow at the bed. However, most ice-sheet models estimate basal traction from satellite-derived surface velocity, without a priori knowledge of the key processes from which it is derived, namely friction at the ice-bed interface and form drag, the resistance to ice flow that arises as ice deforms to negotiate bed topography. Here, we present high-resolution maps, acquired using ice-penetrating radar, of the bed topography across parts of PIG. Contrary to lower-resolution data currently used for ice-sheet models, these data show contrasting topography across the ice-bed interface. We show that these diverse subglacial landscapes impact on ice flow, and present a challenge for modelling ice-sheet evolution and projecting global sea-level rise from ice-sheet loss.
A Varied Subglacial Landscape under Thwaites Glacier, West Antarctica

Knut Christianson1 (knut@uw.edu), Nicholas Holschuh1, John Paden2, Sridhar Anandakrishnan3
1University of Washington, Seattle, United States, 2University of Kansas, Lawrence, United States, 3Pennsylvania State University, University Park, United States

Deglaciated landscapes, whether subaerial or submarine, are often host to a rich panoply of subglacial landforms. These landforms are formed and shaped by interactions between the ice and underlying substrate, and thus have implications for the flow of the overlying ice. Robust interpretations of the relationship between the ice and its substrate based on subglacial landforms that remain after deglaciation have been inhibited by a dearth of high-resolution observations of currently glaciated subglacial landscapes. Here we present two detailed gridded subglacial topographies, obtained using 3-dimensional radar tomography, from Thwaites Glacier, West Antarctica, where ice flows over a highly variable bed. One grid is located ~170 km downstream from the ice divide where ice is moving ~100 m/yr. Here the ice advects over a broad basin and then flows into a subglacial ridge. A deep canyon (~400 m) cuts through this ridge. Relatively soft sediments on the downstream side of the basin suggest that a large subglacial lake may have formed in this location. Multiscale glacial lineations are also observed in the subglacial basin. The second grid is located ~300 km downstream of the ice divide where the ice is moving ~350 m/yr. A large crag and even more extensive multiscale subglacial lineations are observed here. Our results suggest that multiple subglacial landforms form in close geographic proximity due to heterogeneous basal conditions.
Quantifying Drivers of Internal Variability of Sea Ice

Dirk Olonscheck¹ (dirk.olonscheck@mpimet.mpg.de), Thorsten Mauritsen², Dirk Notz¹
¹Max Planck Institute for Meteorology, Ocean in the Earth System, Hamburg, Germany, ²Max Planck Institute for Meteorology, Atmosphere in the Earth System, Hamburg, Germany

The rapid decline of Arctic sea ice in the last decades is superimposed by strong interannual variability. The mechanisms that cause internal variability of sea ice are debated. Many studies suggest that sea-ice variability is driven considerably by radiative feedbacks (e.g. Hall 2004, Letterly et al 2016, Kashiwase et al, 2017), ocean or wind forcing (e.g. Arthun and Eldevik 2012, Ogi et al 2010, Park et al 2015), while others suggest atmospheric temperature variability as the key driver (e.g. Deser et al 2000, Ding et al 2017).

To resolve this contradiction, we here quantify how much the suggested drivers contribute to the total sea-ice variability in the fully coupled global climate model MPI-ESM-LR. We perform and analyse experiments in which the radiative effects of clouds, water vapour and surface albedo, and the forcing by surface winds and meridional oceanic heat transport are decoupled from the overall climate.

Our experiments show that radiative feedbacks, ocean and wind forcing are not the key drivers of Arctic sea-ice variability. In total, they cause about 1/4 of the total variability. We show that sea-ice variability instead is primarily driven by direct thermal coupling to tropospheric temperature, which is consistent with other global climate models, reanalysis and observations.
Production of Stable Land-fast Ice Bridges in the VP and MEB Models

Mathieu Plante1 (mathieu.plante@mail.mcgill.ca), Bruno Tremblay1, Martin Losch2
1McGill University, Atmospheric and Oceanic Sciences, Montreal, Canada, 2Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

Land-fast ice is an important component of the Arctic system, yet its representation in large-scale sea ice models remains a challenge, partly due to the difficult parameterization of ice fracture that governs the stability of ice bridges. This study aims at improving our understanding of how the ice bridges are maintained by the formation of ice arches at the land-fast ice edge. In particular, the process at which arching fractures are developed is investigated and their sensitivity to the yield curve parameters is discussed. We also stress that the model configuration and the coast morphology are also largely influential in determining the timing and shape of the arching fractures.

Using an ideal channel configuration, we perform a range of experiments in which the model material parameters are varied to determine their relation to the strength of the ice cover. These experiments are made using both the Maxwell Elasto-Brittle and the Viscous-Plastic rheology, which are implemented using the same numerical framework. This allows us to isolate the differences in the modelled ice bridges (and ice fractures) that are due to the different choice of rheology from those that are introduced by the different model parameters, such as the time resolution and discretization.

Interplay between Arctic Sea Ice Dynamics and State in HighResMIP

David Docquier¹ (david.docquier@uclouvain.be), François Massonnet¹,², Neil F. Tandon³, Jeremy P. Grist⁴, Thierry Fichefet¹

¹Université catholique de Louvain (UCL), Earth and Life Institute, Louvain-la-Neuve, Belgium, ²Barcelona Supercomputing Center, Earth Sciences Department, Barcelona, Belgium, ³Environment and Climate Change Canada, Climate Research Division, Toronto, Canada, ⁴National Oceanography Centre, University of Southampton Waterfront Campus, Southampton, United Kingdom

Sea ice area, thickness and volume have substantially decreased in the Arctic Ocean since the beginning of the satellite era. As a result, sea ice strength has been reduced, allowing more deformation and leading to increased sea ice drift speed. We investigate the links between sea ice dynamics and what we call ‘sea ice state’ (concentration and thickness) using a process-oriented approach. Our methodology is applied to various global climate models coupling the atmosphere, ocean and sea ice, and participating to the High Resolution Model Intercomparison Project (HighResMIP), within the framework of the EU Horizon 2020 PRIMAVERA project. Model results are compared to different observation datasets. We show that some models can capture the observed relationships between sea ice drift speed, concentration and thickness with more or less accuracy. The domain choice for computing diagnostics and metrics is crucial for our analysis. The impact of model resolution is also assessed and reveals lower Arctic sea ice area and volume with finer grid size, but the effect on the volume depends on the model used. This is correlated to higher northward ocean heat transport with finer grid size. In terms of sea ice dynamics, the impact of resolution on drift speed is less straightforward and really depends on the month of the year. Further analysis is needed to understand the root causes of the model differences.
Evaluating Sea Ice Processes in CMIP5 Models Using Concentration Budgets

Caroline Holmes¹ (calmes@bas.ac.uk), Thomas Bracegirdle¹, Paul Holland¹

¹British Antarctic Survey/NERC, Cambridge, United Kingdom

The ability of coupled climate models to recreate observed sea ice behaviour is a natural subject of scrutiny, given their use in projecting future sea ice change. The contrasting trends of Arctic and Antarctic sea ice during the satellite era, and difference in ability of CMIP5 climate models to represent them, means it is crucial to work towards a process-based understanding of sea ice biases.

We seek to understand the thermodynamic and dynamic origins of biases in the seasonal cycle of sea ice area, in both hemispheres, in the CMIP5 multi-model ensemble. This question will be addressed through the use of sea ice concentration budgets calculated from daily sea ice and drift diagnostics, evaluated against a recent eight-year budget derived from observations.

I will present a novel evaluation of the budget terms in the available ensemble. These will be discussed in the context of biases in the underlying drift fields, possible sources in oceanic or atmospheric processes, and the implications for seasonal biases in sea ice area. Previous work based on a single model family has suggested a compensating error whereby too-strong model ice dynamics may be balanced by excess melt. I will discuss the impact of sampling uncertainty- in time, physical space, and 'model space'- on the robustness of this conclusion.
Earth System Models do not reproduce the observed increase in Antarctic sea ice extent which may be due to the unrealistic representation of ice shelves. We investigated the response of sea ice to increasing freshwater input from ice shelves using the Community Earth System Model with the Community Atmosphere Model version 5 [CESM1(CAM5)]. We conducted model experiments adding fresh water as if from ice shelf melt with a linear increase in the rate of input over the period 1980-2013. We found that an increase in the rate of change of freshwater input of \( \sim 45 \text{ Gt yr}^{-2} \) was sufficient to offset the negative trend in sea ice area in CESM1(CAM5), although the freshwater input by the end of the experiment was larger than observed at that time.
Climate models struggle to capture observed Antarctic sea-ice extent trends, which has critical consequences for sea-ice projections. To tackle this, it is often suggested to develop models at high spatial resolution. In this study we focus on the September sea-ice extent in prototype simulations for the “High Resolution Model Intercomparison Project” (HighResMIP). Scenario simulations (RCP8.5) are performed with the AWI Climate Model (AWI-CM) at “high-resolution” in both ocean and atmosphere (HR) and “low-resolution” (LR) under the same protocol.

Compared to LR, HR predicts a much weaker warming signal around Antarctica in austral winter for the end of this century (2070-2099) relative to 1976-2005. This may partly be explained by the different sea-ice mean states in LR and HR. However, we also observe increased extent variability and strongly reduced rates of sea-ice decrease. Specifically, HR shows excessive polynya-like features in the Weddell Sea in the pre-satellite era, followed by a stable September sea-ice extent until ~2050. “Mixed-resolution” runs (HR ocean with LR atmosphere, and vice versa) attribute this difference in trends and variability to the HR ocean, independent of the atmospheric resolution.

In light of the observed stable Antarctic September sea-ice extent and the recent return of the Weddell polynya, we will discuss possible common mechanisms and implications for other modelling centres participating in HighResMIP.
Late Autumn Boundary Layer Observations in the Ross Sea from the PIPERS Project

John Cassano¹ (john.cassano@colorado.edu), Peter Guest², Kelly Schick³
¹University of Colorado, CIRES / ATOC, Boulder, United States, ²Naval Postgraduate School, Monterey, United States

The Polynyas, Ice Production and seasonal Evolution in the Ross Sea (PIPERS) project spent mid-April to mid-June 2017 in the western Ross Sea observing the atmosphere, ocean, and sea ice states to estimate sea ice production and water mass transformation in the Ross Sea. The meteorological observations during PIPERS included a ship-based weather station, radiometers, and ceilometer, a flux tower deployed during ice stations, and radiosonde and unmanned aerial system (UAS) measurements. Ship-based and radiosonde observations were made during transects through Terra Nova Bay during a strong katabatic wind event with winds in excess of 30 m s⁻¹. Bulk estimates of the turbulent fluxes during this event ranged from several hundred to over 1000 W m⁻². A sequence of radiosonde measurements during the transects provide detailed observations of the downstream evolution of the katabatic air mass as it passed over the Terra Nova Bay polynya, documenting a downstream decrease in wind speed and an increase in boundary layer temperature and depth. UAS profiles through the lowest 1000 m of the atmosphere, repeated at hourly to several hour frequencies, documented the temporal evolution of the boundary layer during multiple ice stations. Both well mixed and inversion conditions were observed and the time evolution from these UAS profiles will be used in conjunction with the flux tower measurements to describe boundary layer processes occurring over the sea ice covered Ross Sea.
Low-level Sublimation of Antarctic Snowfall Due to Katabatic Winds

Alexis Berne1 (alexis.berne@epfl.ch), Jacopo Grazioli2, Jean-Baptiste Madeleine3, Christophe Genthon4, Richard Forbes5, Hubert Gallée4, Gerhard Krinner4

1EPFL, LTE, Lausanne, Switzerland, 2MeteoSwiss, MDR, Locarno-Monti, Switzerland, 3UPMC/LMD, Paris, France, 4IGE, Grenoble, France, 5ECMWF, Reading, United Kingdom

Over the Antarctic continent, precipitation (snowfall) is the most important input of the ice sheet mass budget. The margins of Antarctica are characterized by persistent katabatic winds, supplying the low level of the atmosphere with air masses of low relative humidity, originating from the elevated Antarctic plateau. Despite the importance of these winds for the climate of coastal regions, their interaction with snowfall has not been quantified so far. In this contribution, we show, using unprecedented remotely-sensed data (X-band and long series of K-band radar data) collected in Dumont d’Urville on the coast of Adélie Land, that katabatic winds lead to a significant low-level sublimation of snowfall. At the scale of individual precipitation events, sublimation is inversely proportional to the intensity of precipitation, because more developed systems can extend further into the continent and eventually saturate the low levels of the atmosphere. This phenomenon is reproduced as well with the simulations of three different atmospheric models, that are used to extend our findings to the entire continent. In quantitative terms, sublimation in the lowest kilometer of the atmosphere, before deposition, accounts for about 17% of total snowfall over the entire continent and up to 35% on the margins of East Antarctica.
Precipitation over Antarctica is poorly known but was recently re-examined thanks to new radar instruments deployed by the APRES3 team (Antarctic Precipitation, Remote Sensing from Surface and Space), which gave access to precipitation profiles over the French coastal station of Dumont d’Urville. These precipitation events are characterized by sublimation of snow in lower atmospheric layers [Grazioli et al., Cryosphere 2016, PNAS 2017]. The understanding of these events is essential to improve our knowledge of the Antarctic climate and to obtain reliable estimates of snowfall over coastal areas. We modelled these events using the IPSL climate model and nudged simulations zoomed over the Dumont d’Urville area reaching a 25 km resolution. We observed in our simulations that the altitude where sublimation starts to dominate is too high compared to the field observations. Furthermore, the modeled snowfall sublimation process is not as strong as observed. Concerning our analysis over the whole Antarctic continent, we find that the IPSL climate model tends to underestimate the snowfall rates but to overestimate the occurrence of precipitation events. The model thus predicts a realistic annual accumulation rate by a compensation of the two biases. In this study, we will explore the sensitivity of the model to new parametrizations of cloud to snow conversion, sublimation, sedimentation and riming of snowflakes.
High Precipitation Events across the Antarctic Continent

John Turner\(^1\) (jtu@bas.ac.uk)

\(^1\)British Antarctic Survey, Cambridge, United Kingdom

A knowledge of the processes responsible for precipitation over the Antarctic is essential for the correct interpretation of the signals in ice core. While the many depressions that ring the Antarctic are responsible for most of the precipitation in the coastal region, in the interior of the continent there is an almost daily fallout of clear-sky precipitation or diamond dust. It has been known for some time that there can be significant falls of precipitation on the Antarctic plateau from short-lived intrusions of maritime air, however, the broadscale distribution and frequency of such events has not been documented. I will present fields of occurrence of high precipitation events based on high resolution model output and show that they can make a significant contribution to the annual total precipitation even on the high interior plateau and that their variability dictates the inter-annual variability of total precipitation.
Precipitation is the dominant source term in the surface mass balance of the Antarctic Ice Sheet (AIS). However, direct observations of this quantity are scarce and often limited to proxies. In 2006, the Cloudsat satellite was launched carrying a 94-GHz nadir-looking radar on board, able to detect precipitation profiles. This instrument allowed to get a first coherent observational dataset of radar reflectivity, snowfall rates and ice water content for the whole AIS. However, these data products have not yet been evaluated over the AIS and only a very coarse-resolution snowfall map for the AIS is currently available (Palerme et al., 2014).

In this study, the individual tracks for the whole Cloudsat record are geostatistically interpolated (kriging). Microwave scattering information obtained from satellites in the A-train is used as an external parameter in the interpolation, in order to capture the spatial structure of the precipitation systems. As such, a high-resolution (0.1° x 0.2°) climatological snowfall map for the whole AIS is obtained. The product is evaluated against three ground-based vertically pointing 24 GHz Micro Rain Radars and shows adequate matches for both individual event evaluation as for long-term records including significant improvements compared to previous studies. It therefore has the potential to be used by the modeling community for the evaluation of their climate models and small-scale process evaluation as e.g. snowfall shadow zone detection.
Spectral Measurements of Radiation on King George Island (Antarctic Peninsula)

Raul Cordero¹ (raul.cordero@usach.cl), Alessandro Damiani¹, Sarah Feron¹
¹Universidad de Santiago de Chile, Santiago, Chile

Double monochromator-based instruments developed according to the specifications defined by the World Meteorological Organization (WMO) and the Network for the Detection of Atmospheric Composition Change (NDACC), can produce high quality spectral measurements with relatively low uncertainties. These instruments are able carry out absolute measurements of the solar spectrum, and therefore they are useful as a reference for calibration or validation of other instruments, satellite products, and radiative transfer models.

Since the solar spectrum is modulated by the ozone, clouds, albedo and aerosols, our measurements can be exploited in order to track the temporal evolution of these parameters. We present a summary of spectral measurements carried out since 2011 at our station on King George Island (62oS; Antarctic Peninsula/Southern Ocean) by using a Double monochromator-based instrument that complies with specifications of NDACC.

The measurements have been exploited in order to retrieve the ozone Column, the aerosol column, and the cloud modification factor. The latter is particularly important since this area is known to have one of the high cloud fraction in the planet. Spectral measurements carried out at the Izaña Observatory (Tenerife, Spain), in Hannover (Germany) and in Chajnantor (Atacama Desert), were used for further comparisons.
A Physical Wave Mixing Parameterisation for the Polar Regions

Stefanie Rynders\textsuperscript{1} (s.rynders@noc.ac.uk), Yevgeny Aksenov\textsuperscript{2}, Gurvan Madec\textsuperscript{2}, George Nurser\textsuperscript{1}, Daniel Feltham\textsuperscript{3}

\textsuperscript{1}National Oceanography Centre, Southampton, United Kingdom, \textsuperscript{2}L’OCEAN Sorbonne Universités, Paris, France, \textsuperscript{3}University of Reading, Reading, United Kingdom

Breaking waves cause mixing of the upper water column and present mixing schemes in ocean models take this into account through surface roughness. Sea surface roughness in the polar regions depends on significant wave height and sea ice bottom roughness. Surface roughness is commonly parameterised using significant wave height from local wind speed, ignoring the effect of sea ice. We present results from simulations using modelled surface roughness instead, which accounts for the presence of sea ice and the effect of swell. The simulations use the NEMO ocean model coupled to the CICE sea ice model in a one-degree configuration, with wave information from the ECWAM model of the European Centre for Medium-Range Weather Forecasts (ECMWF). The new mixing formulation affects vertical heat fluxes to and from the sea ice, which in turn affects sea ice concentration and ice thickness. The mixed layer depth under sea ice is improved, without affecting mixed layer depth in ice-free regions.

Wave heights in a large part of the Arctic are increasing and expected to increase further due to sea ice retreat and a larger wave fetch. Therefore wave mixing and other aspects of wave and sea ice coupling will become more important in the future.
Signatures of mesoscale and submesoscale ocean eddies, fronts and filaments are ubiquitously manifested in sea ice patterns, particularly in marginal ice zones. However, localized and intermittent sea ice heating and advection by ocean eddies are currently not accounted for in climate models and may contribute to their biases and errors in sea ice forecasts. Here we use a submesoscale-resolving global ocean-sea ice model to demonstrate that a substantial sea ice area in both Arctic and Southern Oceans is strongly affected by ocean eddies that induce large sea ice vorticity, redistribute its mass via Ekman dynamics, and impact its melt rates via lateral and vertical advection of warm waters. When the sea ice weakens as its concentration falls below about 60%, the sea ice vorticity starts to correlate with the underlying ocean vorticity at spatial scales of about 5-50 km. The increasing similarity between the sea ice and the ocean currents dramatically diminishes the ice-ocean drag. This implies that the sea ice can no longer dissipate ocean eddies, and the combined sea ice–eddy system nearly conserves its energy and angular momentum. Our results suggest that a continuing sea ice melt should lead to an intensification of the upper ocean turbulence, which could affect the underlying large-scale circulations as well as vertical heat and tracer fluxes.
The Marginal Ice Zone in Antarctica can have an area of up to $18 \times 10^6$ km$^2$ in winter, influencing the upper layers through brine rejection and increased drag from sea ice movement. The freshwater flux associated with sea ice processes is a strong buoyancy forcing on upper ocean mixing, and can cause submesoscale instabilities. However, despite its large extent, this region remains poorly undersampled, and is the biggest missing link in climate models. Here, we present tagged elephant seal data from the Bouvet Island - Dronning Maud land region, over the austral winter of 2008. We show tagged seal data is an underused, and viable, dataset to estimate wintertime submesoscale fluxes in the Marginal Ice Zone. We assess the resolution of the seal data, and find that the peak sampling rates are 10 m vertical, 8 km horizontal and 6 hours spacing. Using this data, we estimate submesoscale fluxes between March and September, revealing four distinct regimes: summer stratification, sea ice formation/brine rejection, open lead events and wintertime stable mixed layer. Short time-scaled events, such as the opening of leads, are compared to regional wind forcing and local sea ice concentrations to identify air-sea ice-ocean momentum fluxes. This improved understanding of upper ocean processes under sea ice will help to identify the drivers of sea ice variability in the region.
Upper Ocean Evolution Across the Beaufort Sea Marginal Ice Zone

Craig M. Lee¹ (craig@apl.washington.edu), Luc Rainville¹, Jason Gobat¹, Lee Freitag², Sarah Webster¹
¹University of Washington, Applied Physics Laboratory, Seattle, United States, ²Woods Hole Oceanographic Institute, Applied Ocean Physics and Engineering, Woods Hole, United States

The observed reduction of Arctic summertime sea ice extent and expansion of the marginal ice zone (MIZ) have profound impacts on the balance of processes controlling sea ice evolution. Four long-endurance autonomous Seagliders followed the retreating Beaufort Sea ice edge to repeatedly occupy sections that extended from open water, through the marginal ice zone, deep into the pack during summer 2014. Gliders penetrated up to 200 km into the ice pack, under complete ice cover for up to 10 consecutive days. Sections reveal strong fronts where cold, ice-covered waters meet waters that have been exposed to solar warming, and O(10 km) scale eddies near the ice edge. In the pack, Pacific Summer Water and a deep chlorophyll maximum form distinct layers at roughly 60 m and 80 m, respectively, which become increasingly diffuse as they progress through the MIZ and into open water. The isopynal layer between 1023 and 1024 kg m⁻³, just above the Pacific Summer Water, consistently thickens near the ice edge, likely due to mixing or energetic vertical exchange associated with strong lateral gradients in this region. This presentation will discuss the upper ocean variability, its relationship to sea ice extent, and evolution over the summer to the start of freeze up.

Linking Ocean Convection to the Recent ice Edge Retreat along East Greenland

Kjetil Våge1 (kjetil.vage@uib.no), Lukas Papritz1, Lisbeth Håvik1, Mike Spall2, GWK Moore3
1University of Bergen, Geophysical Institute, Bergen, Norway, 2Woods Hole Oceanographic Institution, Woods Hole, United States, 3University of Toronto, Toronto, Canada

Warm subtropical-origin Atlantic water flows, as an extension of the Gulf Stream, northward across the Greenland-Scotland Ridge into the Nordic Seas where it relinquishes heat to the atmosphere and gradually transforms into dense Atlantic-origin water while circulating around the basin. Before returning southward as part of the East Greenland Current, a major contributor of dense water to the Denmark Strait overflow, the Atlantic-origin water subducts beneath a layer of cold, fresh surface water and sea ice. Here we show, using measurements from autonomous ocean gliders deployed from fall 2015 to spring 2016, that the Atlantic-origin water was re-ventilated while transiting the western Iceland Sea in winter. This re-ventilation is a recent phenomenon made possible by the retreat of the ice edge toward Greenland, which had previously insulated the waters of the East Greenland Current from the atmosphere. The fresh surface layer that characterizes this region in summer is diverted toward the Greenland shelf by enhanced onshore Ekman transport induced by stronger northerly winds in fall and winter. Severe heat loss from the ocean to the atmosphere offshore of the ice edge subsequently triggers convection which further transforms the Atlantic-origin water. This re-ventilation is a counterintuitive occurrence in a warming climate, and highlights the difficulties inherent in predicting the behaviour of the complex coupled climate system.
The Iceland Greenland Seas Project: Oceanographic Highlights

Robert Pickart\textsuperscript{1} (rpickart@whoi.edu), Kjetil Våge\textsuperscript{2}, Leah McRaven\textsuperscript{1}, Frank Bahr\textsuperscript{1}, Ian Renfrew\textsuperscript{3}, Kent Moore\textsuperscript{4}

\textsuperscript{1}Woods Hole Oceanographic Institution (WHOI), Physical Oceanography, Woods Hole, United States, \textsuperscript{2}University of Bergen, Bergen, Norway, \textsuperscript{3}University of East Anglia, Norwich, United Kingdom, \textsuperscript{4}University of Toronto, Toronto, Canada

A coordinated meteorological and oceanographic field campaign over the Iceland and southern Greenland Seas is scheduled for February and March 2018. The main goal is to document the ventilation of the densest water feeding the lower limb of the Atlantic meridional overturning circulation (AMOC) and to quantify the associated atmospheric forcing. Particular focus will be on cold-air outbreaks and their forcing of oceanic convective overturning in the vicinity of the marginal ice zone. We will characterize the spatial variation and temporal evolution of the oceanic mixed layer in relation to the hydrography and the circulation of the region, including the presence of boundary currents and interior gyres. We will also investigate the exchange of water between the Greenland and Iceland Seas across the West Jan Mayen Ridge. Finally, the connection between the newly ventilated water and the pathways providing dense water to Denmark Strait will be addressed.
Chemical weathering is an important process for regulating biogeochemistry of Antarctic lakes and coastal oceans surrounding the Antarctica and atmospheric CO2 consumption. There are about ten thousand surface and subglacial lakes where these processes could play an important role in supplying nutrients to the organism and CO2 consumption in silicate weathering reactions. However, this process in extreme environments, particularly in the Antarctic lakes, is less studied compared to tropical river basins. Sr isotopes are generally less affected by physical and biological processes, hence, used as a robust proxy for chemical weathering. To study chemical weathering processes and assess its role, water samples were collected from 10 lakes in the Larsemann Hill oasis, East Antarctica. These samples were analyzed for major ions, dissolved Sr and its isotopes ($^{87}\text{Sr}/^{86}\text{Sr}$). Dissolved [Sr] and $^{87}\text{Sr}/^{86}\text{Sr}$ ranges from 0.09 to 0.69 µM and 0.71104 to 0.7121 respectively. All the data in the mixing plot between $^{87}\text{Sr}/^{86}\text{Sr}$ and 1/Sr shows three clusters which indicate three possible sources such as weathering of silicate, sea spray, and atmospheric dust. We have made an attempt to fingerprint the sources and their apportionments using dissolved Sr, $^{87}\text{Sr}/^{86}\text{Sr}$ together with the inverse model. This study would improve our understanding of chemical weathering processes in extreme environments and its role in CO2 sequestration and regulating biogeochemistry in Antarctic lakes.
Weathering in Siberia and Li Isotopes in the Lena and Yenisey Rivers

Don Porcelli\textsuperscript{1} (donald.porcelli@earth.ox.ac.uk), Per Andersson\textsuperscript{2}, Mel Murphy\textsuperscript{1,3}, Oleg Pokrovsky\textsuperscript{4}, Philip Pogge von Strandmann\textsuperscript{3}, Joachim Katchinoff\textsuperscript{1,3}, Liselott Kutschner\textsuperscript{2,6}, Catherine Hirst\textsuperscript{2,6}, Trofim Maximov\textsuperscript{7}, Anatoly Prokushkin\textsuperscript{8}

\textsuperscript{1}Oxford University, Earth Sciences, Oxford, United Kingdom, \textsuperscript{2}Swedish Museum of Natural History, Geosciences, Stockholm, Sweden, \textsuperscript{3}University College London, Earth Sciences, London, United Kingdom, \textsuperscript{4}CNRS, Toulouse, France, \textsuperscript{5}Yale University, Geology and Geophysics, New Haven, United States, \textsuperscript{6}Stockholm University, Geological Sciences, Stockholm, Sweden, \textsuperscript{7}North-Eastern Federal University, 74International Center for BioGeoScience Education and Scientific Training, Yakutsk, Russian Federation, \textsuperscript{8}Russian Academy of Sciences, Sukachev Institute of Forest, Krasnoyarsk, Russian Federation

The Lena River drains a vast area (2.5Mkm\textsuperscript{2}) in eastern Siberia that is largely underlain by permafrost, and is a major contributor of nutrients, trace elements, and water to the Arctic Ocean basin. The Yenisey River drains a similar area in western Siberia, though the extent of permafrost coverage varies widely and includes permafrost-free areas. These watersheds have been sampled as part of programmes to understand weathering and the hydrological transport of nutrients and trace elements to the Arctic Ocean.

Lithium isotopes are widely used as a measure of the extent of clay formation and so incongruent weathering processes of silicate weathering in a watershed, and so provide valuable information on how weathering in cold regions occurs. Data has been collected for waters from tributaries across both the Lena and Yenisey basins and draining smaller watersheds representing a range of different conditions, including underlying lithology, topography, extent of permafrost, and mean annual temperature. A wide range of Li concentrations and isotope compositions were found, which likely reflect a range of weathering and lithological controls and variations in water-rock interaction time, parameter that are likely to be sensitive to active layer processes. However, the overall range of values was similar to that found in other major global rivers, so that the effects of climate on Li isotope compositions and concentrations are complex.
Seasonal Change of Geochemical Sources and Processes in the Yenisei River

Ruth Hindshaw¹, Théo Le Dantec², Nikita Tananaev³, Roman Teisserenc²
¹University of Cambridge, Cambridge, United Kingdom, ²Université de Toulouse, ECOLAB, Toulouse, France, ³Melnikov Permafrost Institute, Yakutsk, Russian Federation

The Yenisei River has the highest annual discharge of all the rivers draining into the Arctic Ocean and therefore changes in the chemical flux composition would have a profound effect on the nutrient input to the ocean. The hydrological cycle of this region is predicted to change due to changing precipitation patterns and thawing permafrost. By studying the seasonal changes in the geochemistry of the river, information on which end-member sources are important under different hydrological conditions can be gained and therefore provide a basis to model future change.

In this study 50 water samples were collected throughout 2012 from Igarka, 670 km from the river mouth, and analysed for their major ion composition. To further investigate the sources and processes affecting the geochemical composition of the stream water, a subset of 10 samples, covering the full range in discharge, were analysed for Sr, Mg and Li isotopes. The radiogenic Sr isotopic composition is higher in summer compared to winter, indicating a change in the relative contribution of sources. There is negligible seasonal variation in Mg isotopes and a 4 permil variation in Li isotopes with lower values at high discharge. In this contribution we will discuss the potential sources and processes contributing to the observed variation (or lack of) in the three isotope systems and how this knowledge can be used to inform models of future changes in the major element fluxes from the Yenisei to the Arctic Ocean.
Estimates from field studies, remote sensing and modelling all suggest around 5% of global dust emissions originate in the high latitudes (≥50°N and ≥40°S), a similar proportion to that from the USA (excluding Alaska) or Australia. This paper identifies contemporary sources of dust within the high latitudes and their role within local, regional and hemispherical environmental systems. Field data and remote sensing analyses are used to identify the environmental and climatic conditions that characterize high latitude dust sources in both hemispheres. Examples from the Arctic and Southern Ocean-Antarctica regions are used to demonstrate and explain the different regional relationships among dust emissions, glacio-fluvial dynamics, sea-ice and snow cover. The relative timing of dust input to high latitude terrestrial, cryospheric and marine systems determines its short to medium term environmental impact. This is highlighted through quantifying the importance of locally-redistributed dust as a nutrient and sediment input to high latitude soils in the Arctic and marine systems around Antarctica.
Methane is as a strong greenhouse gas and its emission from thawing permafrost could cause an accelerating effect on global warming and acidification in the ocean. To better understand the consequences for Arctic marine environments, we used a complex biogeochemical model to explore the local effects of methane seeps caused by permafrost thawing. Permafrost found in the outer part of Eastern Siberian Arctic Shelf (ESAS) has mostly degraded, and represents an area where methane fluxes are very high. For that reason, we focused on simulating the biogeochemical changes in the water column resulting from methane seeps for the ESAS region. Bubbles from a single seep area tend to dissolve at about the same depth above the seafloor, resulting in the formation of methane-rich layers within the water column. At the same time, parts of ESAS are seasonally covered by ice, serving as an almost impermeable lid for methane fluxes and promoting the formation of methane-rich layers in the surface waters. To explore the state of the water column we used a 1D Ice-Pelagic-Benthic transport model coupled to the biogeochemical models Bottom RedOx Model and the European Regional Seas Ecosystem Model.

The results show significant local impacts of the subsea methane source on marine biogeochemistry on seasonal timescales. As subsea permafrost thawing is expected to continue, our modelling approach may also be useful for parameterizing long-term impacts on Arctic marine biogeochemistry.
Controls on Fluxes of Labile DOC from the Kuparuk River to the Arctic Ocean

Rose Cory1 (rmcory@umich.edu), Tyler King2, George Kling3, Beth Neilson4
1University of Michigan, Earth and Environmental Sciences, Ann Arbor, United States, 2Utah State University, Logan, United States, 3University of Michigan, Ecology and Evolutionary Biology, Ann Arbor, United States, 4Utah State University, Civil and Environmental Engineering, Logan, United States

Thawing permafrost soils may increase export of dissolved organic carbon (DOC) to rivers, where this DOC may be converted to CO2 or partially degraded by sunlight as it is transported to the Arctic Ocean. The concentration, composition, and lability of DOC to complete and partial photo-degradation were quantified in the Kuparuk River (arctic Alaska) during ice-free summer seasons of 2011-2017. DOC characterization, supporting water chemistry and hydrological measurements were conducted along a 350 km transect from the Kuparuk River headwaters in the Brooks Range to its mouth at the Arctic Ocean, and from major tributaries entering the river. River surveys were done each year during the freshet, the height of summer, and later in summer when thaw depth was maximum. Seasonal variability in downstream trends in DOC composition and lability indicated influences of water residence time, prior light exposure, and different sources of DOC. DOC composition suggested a greater proportion of DOC in the Kuparuk River from deeper mineral soils towards the end of the summer coincident with maximum thaw depth. Overall, there was little change in DOC lability to complete and partial degradation from the headwaters to the Arctic Ocean. This finding suggests that in-stream degradation of DOC to CO2 may be offset by inputs of fresh, labile DOC with distance downstream, indicating that coastal waters of the Arctic Ocean may receive DOC labile to conversion to CO2.
East Antarctic shield preserves a history of ~ 4 billion years that includes remnants of every major orogenic event. One way of characterizing these events is by studying the metamorphic evolution of the limited coastal outcrops and nunataks. Larsemann Hills and Brattstand bluff are present along the coast of Princess Elizabeth Land (PEL) and form a fragment of the extensive granulitic East Antarctic shield. It was considered to be a Grenvillian tectonic belt until recent geochronological data which proves it to be a significant Pan African belt. The time frame between 1000 and 500 Ma is obscure and possesses no firm age data except for few published detrital zircon ages of 750-900Ma.

Our investigations of metapelites from Larsemann hills indicate metamorphic assemblage developed at ~500 Ma as estimated from chemical geochronology of texturally constrained monazite. No Grenvillian age has been recorded, which supports the idea of Pan African dominance in the area. Monazite ages obtained from the pelitic granulites of Brattstrand bluff and adjacent Svenner Island are 820±56 Ma and 734±31 Ma; partially reset at 486±21 Ma and 494±56 Ma respectively. The 700-800 Ma orogeny represents a hitherto less recognized mountain building event in this sector. The resetting can be ascribed to the Pan-African event which formed the Larsemann hills. This work substantiates evidence of ~800 Ma event in Brattstrand bluff and adjacent islands.
Integrating geophysics with geology, and specifically geochronology, reveals the complex tectonic history of Dronning Maud Land, East Antarctica, which is a crucial element for Rodinia and Gondwana reconstructions. We recognise three major tectonic provinces: a westernmost part with Kalahari, Africa, affinities and an easternmost part from about 35°E with Indo-Antarctic affinities; sandwiched in between these two blocks, is an extensive region with juvenile Neoproterozoic crust (ca. 990-900 Ma), the Tonian Oceanic Arc Super Terrane (TOAST) that shows very limited signs of a pre-Neoproterozoic history. We have tested the spatial extent of the TOAST by a regional moraine study that confirm the lack of older material inland, though latest Mesoproterozoic juvenile rocks frequently do occur in the glacial drift and probably record a slightly earlier precursor of the TOAST inland. The TOAST records 150 Ma of almost continuous tectono-metamorphic reworking at medium- to high-grade metamorphic conditions between ca. 650 to 500 Ma. This long-lasting overprinting history is thought to record protracted accretion of ocean island arc terranes and the final amalgamation of East Antarctica along the major East African-Antarctic Orogen. There is no sign of significant metamorphic overprint immediately after the formation of TOAST. Therefore, these island arcs may have formed independent of or peripheral to Rodinia and may reveal major accretionary tectonics outboard of Rodinia.
Plate Tectonics and Basin Formation at South Pole

Fausto Ferraccioli1 (ffe@bas.ac.uk), Tom Jordan2, Rene Forsberg3, Arne Olesen3, Graeme Eagles4, Kenichi Matsuoka5, Tania Casal6

1British Antarctic Survey/NERC, Geology and Geophysics, Cambridge, United Kingdom, 2British Antarctic Survey/NERC, Cambridge, United Kingdom, 3DTU Space - National Space Institute, Lyngby, Denmark, 4Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, 5Norwegian Polar Institute, Tromsø, Norway, 6European Space Agency/ESTEC, Noordwijk, Netherlands

The tectonic boundary between East and West Antarctica is one of the most fundamental features of the continent but is particularly poorly understood between the Weddell Sea Rift and South Pole. During the 2015-2016 Antarctic campaign we flew an extensive aerogeophysical survey, collecting 30,000 line km of radio echo sounding, airborne gravity and aeromagnetic data over the region. Linear gravity lows within the Pensacola-Pole Basin reveal a system of interconnected and glacially overdeepened grabens flanked by horst blocks. The grabens likely originated within the Jurassic Transantarctic rift system, and may have been reactivated in response to Cretaceous-Cenozoic far-field stresses, which also affected the East and West Antarctic rift systems respectively.

The magnetic data reveal a composite Precambrian crustal block northeast of the Pensacola Pole Basin. We call it the Recovery Block, and suggest that it may form the “missing link” between the subduction-related Ross Orogen and a Pan-African age collisional and transpressional suture zone identified in the Shackleton Range. Overall, we interpret our new gravity and magnetic data compilations to reveal a wider and more distributed Mesozoic plate boundary zone between East and West Antarctica, which included several smaller microplates. We propose that this was a strike-slip dominated distributed plate boundary, which kinematically linked the eastern margin of the Weddell Sea Rift System with the Pensacola-Pole Basin.
Crustal Terranes in the Gondawanan Lützow-Holm Complex of East Antarctica

Daniel J. Dunkley1,2,3 (kwaidanother@gmail.com), Kazuyuki Shiraishi2, Yoichi Motoyoshi2, Yoshikuni Hiroi2,4, Tomoharu Miyamoto5, Tomokazu Hokada2, Monika A. Kuisak3

The Lützow-Holm Complex (LHC) of east Antarctica was assembled during and metamorphosed at high-T during the formation of Gondwana. The intense nature of orogenesis obscures geological relationships, especially in Lützow-Holm Bay, where recumbent folding was extensively reworked by ductile shearing. Ion microprobe dating and Hf isotopic analysis of zircon in gneisses across the LHC provides a window into pre-orogenic geological history, revealing a juvenile late Archean igneous basement in the south of the bay that was marginally affected by ca. 2.1-1.8Ga magmatism. The remainder of the LHC is composed of juvenile late-Mesoproterozoic igneous crust with minor volcanism at ca. 630Ma. The boundary between these domains is completely transposed by Gondawanan orogensis; however, geological independence is suggested from detrital zircon in metasediments deposited on either domain, which have no common provenance. We suggest that these domains represent different geological terranes, herein named the Skallen and Ongul Terranes for the older and younger basements, respectively. A high-T metamorphic history is shared by the terranes, from ca. 610Ma to ca. 510Ma, an extended period of orogenesis typical of long-lived high-T orogens that assemble large continental blocks. Evidence of earlier orogenesis is lacking except in a couple of localities on the Prince Olav Coast, where ca. 1020Ma arc magmatic rocks and metasediments were metamorphosed at high T around 960Ma.
A New Thermochronometric Evaluation of Central Transantarctic Mountain Formation

Stuart N. Thomson¹ (thomson@email.arizona.edu), Peter W. Reiners¹, Kathy J. Licht², Sidney R. Hemming³, Christine M. Kassab²
¹University of Arizona, Department of Geosciences, Tucson, United States, ²Indiana University Purdue University Indianapolis, Department of Earth Sciences, Indianapolis, United States, ³Lamont-Doherty Earth Observatory Columbia University, Earth and Environmental Sciences, Palisades, United States

The Transantarctic Mountains (TAM) form one the longest mountain belts on Earth, but are unusual as they have been dominated by extension tectonics related to development of the West Antarctic Rift System since ~100 Ma. A lack of a post-Jurassic onshore stratigraphic record means that TAM uplift and erosion history has been informed largely indirectly by thermal histories recorded by apatite fission track (AFT) thermochronometry. Traditionally these results are interpreted as recording erosion related to episodic rift flank faulting and uplift in the Early and Late Cretaceous, and Paleogene. However, more recent studies have proposed alternative explanations for TAM formation, including a vast Mesozoic sedimentary basin that buried the TAM until Paleogene rift-related inversion; Cretaceous extensional collapse of a high elevation “Altiplano-like” plateau; and that central TAM peak elevations increased by ~50% owing to isostatic rebound in response to post-Eocene glacial incision. To help resolve this debate, we present new results from multiple thermochronometers (apatite and zircon FT and (U-Th)/He dating) in the central TAM. Thermal histories that best predict our initial results favor slow cooling through the Mesozoic, a period of elevated heat flow coeval with onset of rifting at ~100 Ma, and onset of glacial incision-related accelerated cooling at ~34 Ma. Our initial data also rule out episodic cooling episodes, and long-term burial beneath a Mesozoic sedimentary basin.

Zircons from the Granite Harbour Intrusives, Northern Victoria Land, Antarctica

Martina Menneken¹ (martina.menneken@fu-berlin.de), Timm John¹, Andreas Läufer², Jörg Giese¹
¹Freie Universität Berlin, Earth Sciences, Berlin, Germany, ²Bundesanstalt für Geowissenschaften und Rohstoffe (BGR), Hannover, Germany

The Wilson Terrane in northern Victoria Land appears to be the leading edge of the East Antarctic craton and was intruded by the calcalkaline magmatic arc of the Early Paleozoic Ross Orogen, i.e. the Cambro-Ordovician Granite Harbour Intrusives (GHI). Previous data suggested that subduction processes started at least at ca. 550-530 Ma, but may have started much earlier at 580-560 Ma based on arc-derived detrital zircon ages (1). In this study, zircons and their host rocks from the GHI have been investigated with respect to regional evolution of continental crust as well as the reliability of zircon as a recorder of crustal formation.

We present a combination of U-Pb, $\delta^{18}$O, trace element and inclusion data of zircons from these granitoids, as well as geochemical analyses of accessory apatite. With careful evaluation of zircon-U-Pb-age data and related isotopic, chemical, and mineralogical features, our study shows that even I-type granitoids do not have a simple formation history. Instead our results present a history of early (from about 580 Ma onwards) magmatic- and fluid alteration events, in contrast to simple inheritance. Our data thus supports that magmatic arc evolution in the Wilson Terrane was related to Andean-style, long-lived, migrating accretionary processes at the East Gondwana active continental margin.

Kongsfjorden on the west coast of Spitsbergen has undergone significant changes over the last decades. Warmer Atlantic advection has decreased wintertime sea ice formation and increased melting of marine terminating glaciers. This raises the question how this affects phytoplankton productivity and composition. Drivers of phytoplankton productivity and composition in central and inner Kongsfjorden were assessed using four years of pigment monitoring (2014-2017) and detailed observations during spring (2014) and summer (2015). Increasing irradiance correlated to chl-a of all taxonomic groups from February to mid-April that increased from the low values observed during the polar night. Stratification was initiated during April and May, coinciding with a diatom dominated surface bloom in inner Kongsfjorden. This suggested that spring blooms are initiated further into the fjord due to reduced sea ice cover. Surface depletion of winter nutrients characterized the post bloom period from June to October, where flagellates of diverse taxonomic groups dominated. Nutrient addition experiments showed that nitrate rapidly simulated biomass growth, but did not change phytoplankton composition. Furthermore, variability in biomass correlated to episodic wind mediated nutrient upwelling near the glaciers. Overall, our research suggest that the recent changes in Kongsfjorden cause spatial changes in phytoplankton biomass and composition, whereas temporal changes are less clear.
Arctic marine ecosystems are commonly assumed to be highly sensitive, and their structure and function are predicted to suffer significantly from ongoing climate change. Community shifts are likely to result from changes in key physico-chemical drivers, such as increased temperature and CO₂, but there is little autecological data on most Arctic species to support any specific predictions as to how sensitive they are, or how future communities may be structured. Lacking such empirical data, we extracted collection records for 90 Arctic and boreal taxa from the Barents Sea region from the OBIS database. A coupled climate-ocean model (SINMOD) was used to both hindcast and project temperature and carbonate saturation states (omega) for sample locations. These data provided ‘realized niche’ distributions in three dimensions (depth, temperature, omega) for each benthic taxon, and this niche space was compared with projected values for these variables in the region for 2090-2099. Preliminary results indicate that, contrary to many predictions, calcifying taxa are no more sensitive to changing environmental conditions than non-calcifiers. In addition, Arctic taxa were similarly no more susceptible to predicted changes than boreal taxa. These results highlight the weakness of general statements regarding sensitivity of taxa on biogeographic or physiological grounds, and suggest that more basic biological data on Arctic taxa are needed for improved projections of climate impacts.
Zooplankton in Changing Arctic Seas: Examples from West Greenland Ecosystems

Eva Friis Møller¹ (efm@bios.au.dk), Mikael Sejr², Anders Mosbech¹, Torkel Gissel Nielsen³
¹Aarhus University, Roskilde, Denmark, ²Aarhus University, Aarhus, Denmark, ³Technical University of Denmark, Lyngby, Denmark

With reduced sea ice cover, increased melt water discharge and pelagic primary production the transfer to higher trophic levels through zooplankton will change; e.g. species composition, phenology and productivity of the zooplankton community may be altered. In this presentation, we use dataset from coastal waters of west Greenland to discuss the impact of melting ice (glacial and sea ice) and primary productivity on the zooplankton community. Data from Disko Bay (69.23°N, 52.52°W) sampled with high temporal resolution during spring blooms in the period 1996 to 2012 are used to evaluate phenology and species changes within the dominant zooplankton genus *Calanus* on a decadal scale. Further north along the Greenland west coast the arctic species *Calanus hyperboreus* dominate, and we use distribution data (from 71- 76°N) to discuss how difference in ice cover/glacial impact influence their productivity and phenology, and how this may impact higher trophic levels exemplified by the dominant avian predator Little Auk (*Alle alle*).
Zooplankton Productivity in Arctic Estuarine Habitats under a Changing Climate

Alexei Pinchuk1 (aipinchuk@alaska.edu), Leandra Sousa2, Johanna Vollenweider3
1University of Alaska - Fairbanks, College of Fisheries and Ocean Sciences, Juneau, United States, 2North Slope Borough, Wildlife Management, Barrow, United States, 3NOAA, Fisheries, Juneau, United States

The low-lying North American Arctic coast is characterized by numerous lagoons that are utilized by marine mammals, waterfowl, and seabirds, and many of which have been providing important subsistence resources for local peoples for centuries. Arctic lagoons are poorly described because of their remoteness and difficulty to access by survey vessels. Food webs in the Arctic lagoons are thought to be dominated by benthic detritivores dependent on microbial processing of terrestrial carbon. Recent findings of dense aggregations of lipid-rich, fast-growing omnivory copepods in the brackish water estuarine habitats suggest high levels of pelagic primary and secondary production in summer and, therefore, an efficient pelagic food web. We synthesized data on composition and distribution of zooplankton, fish diets and physical processes that may influence estuarine communities in the coastal Chukchi and Beaufort seas to address the following fundamental question: how may changing climate conditions structure and influence trophic diversity in Arctic lagoons during ice-free summer time.
Is the Shallow Kitikmeot a Marine Zoogeographic Barrier in the Canadian Arctic?

Gérald Darnis¹ (gerald.darnis@qo.ulaval.ca), Caroline Bouchard², Maxime Geoffroy³, Catherine Lalande¹, Cindy Grant¹, Philippe Archambault¹, Mathieu Leblanc¹, Louis Fortier¹

¹Université Laval, Quebec City, Canada, ²Greenland Climate Research Center, Greenland Institute of Natural Resources, Nuuk, Greenland, ³Fisheries and Marine Institute of Memorial University of Newfoundland, St. John’s, Canada

Lack of information on large-scale spatial patterns of zooplankton, fish and benthos distribution limits our knowledge of ecological connectivity within the Canadian Arctic marine ecosystem and, thus, the ability to develop predictions about the ecosystem response to the multiple effects of Arctic warming and increased human activity. We used data collected from 2005-2017 as part of the ArcticNet annual expeditions across the Canadian Arctic Archipelago and the Kitikmeot Marine Ecosystems Study to map the distribution of Arctic cod (*Boreogadus saida*), zooplankton and benthos from the Beaufort Sea in the west to the mouth of Lancaster Sound in the east. Arctic cod larvae and adults were rare, and the large copepods *Calanus hyperboreus*, *C. glacialis* and *Metridia longa* much less abundant in all years in the shallow (< 100 m) south Kitikmeot, compared to deeper areas to the west and east where these organisms usually dominate in terms of biomass. By contrast, benthos biomass and diversity were relatively high compared with surrounding areas. Low biomass of *Calanus* species can partly explain the limited populations of vertebrate predators such as the Arctic cod, seabirds and the bowhead whale in the south Kitikmeot. The combination of shallow depths, slow water circulation and late sea-ice breakup suggests that this region acts as a significant barrier reducing West-East exchange among populations of pelagic fish like the Arctic cod and of key oceanic zooplankton.

Phytoplankton Production in Arctic and Sub-Arctic Oceans: The Role of Diatoms

Diana E. Varela1 (dvarela@uvic.ca), David W. Crawford2, Karina E. Giesbrecht3, Jennifer E. Long2, Ian A. Wrohan3, Adrian O. Cefarelli4, Shea N. Wyatt2, Lucianne M. Marshall2

1University of Victoria, Department of Biology, and School of Earth and Ocean Sciences, Victoria, Canada, 2University of Victoria, Department of Biology, Victoria, Canada, 3University of Victoria, School of Earth and Ocean Sciences, Victoria, Canada, 4Universidad Nacional de La Plata, División Ficología, Facultad de Ciencias Naturales y Museo, La Plata, Argentina

This presentation will address spatial and temporal patterns in phytoplankton production and nutrient concentrations in the Arctic and sub-Arctic marine waters surrounding North America. Results from the International Polar Year Canada-3-Oceans project and other programs (e.g. GEOTRACES, Distributed Biological Observatory) conducted during the last decade show that phytoplankton production in marine Arctic and sub-Arctic waters is highly variable from region to region, with hotspots of activity in the Chukchi Sea, the Canadian Arctic Archipelago and Baffin Bay. These high production sectors markedly contrast with the oligotrophic waters of the Canada Basin. We will zoom into those Arctic hotspots and describe the role of diatoms in total phytoplankton production, nutrient cycling and particle dynamics in the pan-Canadian Arctic from the NE Pacific to the NW Atlantic Oceans. We will present results from experimental manipulations in the eastern and western Arctic using the radioisotope 32Si and a novel fluorescent probe (PDMPO) as tracers of whole-assemblage and genus-specific diatom production. Despite the dominance of diatoms in several Arctic regions, the rates of silicon, nitrogen and carbon production were several times higher in the western Arctic (Chukchi Sea) than in the eastern production hotspots. These studies provided benchmark data against which future estimates can be compared to better predict the effects of climate change on high-latitude marine ecosystems.
Deformation tests on ice from the Greenland ice cores GRIP, GISP, NGRIP and NEEM reveal that ice from the glacial and interglacial have very different flow properties. By combining with repeated measurements of the deformation of the deep boreholes in Greenland the different flow properties of ice is discussed. The discussion is broadened out to discuss the basal processes of the deep ice and conditions for oldest ice in Greenland and Antarctica to be stratigraphic and not folded and disturbed.
An Andean Ice-core Based Holocene Biomass Burning Record of the Amazon Basin

Dimitri Osmont1,2,3 (dimitri.osmont@psi.ch), Michael Sigl1,3, Margit Schwikowski1,2,3
1Paul Scherrer Institute, Laboratory of Environmental Chemistry, Villigen PSI, Switzerland, 2University of Bern, Department of Chemistry and Biochemistry, Bern, Switzerland, 3Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland

The Amazon Basin is known to be one of the most important worldwide contributors to biomass burning emissions. However, past fire activity is still poorly known due to the complex linkages between fires, climate and humans. Biomass burning proxies such as black carbon (BC) measured in ice cores can improve our understanding and bring new constraints on models. BC consists of aggregates of carbonaceous spherules produced by the incomplete combustion of fossil fuels and biomass from both anthropogenic and natural origin. Here, we present the first Andean BC ice-core record, derived from Illimani glacier, Bolivia, which spans the entire Holocene back to the last deglaciation 13 000 years ago. A strong seasonality, with BC peaking in the dry season, can be observed due to the combined effects of biomass burning emissions from the Amazon Basin, transport and deposition. Slightly increasing BC concentrations are visible in the 20th century, potentially reflecting an anthropogenic contribution. Long-term BC variations follow regional climatic trends along the Holocene, with higher concentrations during dry/warm periods such as the mid-Holocene (8500-5500 BP) or the Medieval Warm Period and lower values during cold/wet periods like the last deglaciation or the Little Ice Age. Except for the 20th century, a similar temporal variability was observed in a BC record from two Antarctic ice cores, for which South America is assumed to be the dominant source area.
Ice-core Evidence of Earliest Copper Metallurgy in the Andes 2700 Years Ago

Anja Eichler1,2 (anja.eichler@psi.ch), Gabriela Gramlich1,2,3, Thomas Kellerhals1,2, Leonhard Tobler1,2, Thilo Rehren4,5, Margit Schwikowski1,2,3
1Paul Scherrer Institute, Laboratory of Environmental Chemistry, Villigen, Switzerland, 2Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland, 3University of Bern, Department for Chemistry and Biochemistry, Bern, Switzerland, 4University College London, Institute of Archaeology, London, United Kingdom, 5HBKU Doha, College for Humanities and Social Sciences, Doha, Qatar

The importance of metallurgy for social and economic development is indisputable. Advances in agriculture, warfare, transport, cookery, and the entire Industrial Revolution are impossible without metal. Historically, Andean copper (Cu) in particular was an essential resource of wealth for pre- and post-colonial societies and still plays a central economic role in many South American countries today. Despite of this importance the onset of extensive Cu metallurgy in South America is still debated. Here we present a 6500-years Cu emission history for the Andean Altiplano, based on ice-core records from Illimani glacier in Bolivia, providing the first complete history of large-scale Cu smelting activities in South America. We find earliest anthropogenic Cu pollution exceeding the natural background range during the Early Horizon period ~700-50 BC. This work highlights the importance of considering changes in the natural background of heavy metal deposition to deduce earliest stages of prehistoric extractive metallurgy from natural archives. Our results imply that the onset of intensified Cu smelting in South America occurred during the central Andean Chiripa and Chavin cultures ~2700 years ago. This study provides for the first time substantial evidence for extensive Cu metallurgy already during these early cultures. In our work we further provide archeological artefacts to document changing Cu metallurgy in South America during the past 2700 years.
Heterogeneous Reduction of Glaciers in the High Mountains of Asia during HCO

Shugui Hou1 (shugui@nju.edu.cn), Chaomin Wang1, Wangbin Zhang1, Margit Schwikowski2, Yetang Wang3, Shuangye Wu4, Chiara Uglietti2, Theo Manuel Jenk2, Koji Fujita5, Hongxi Pang1, Hao Xu1
1Nanjing University, School of Geographic & Oceanographic Sciences, Nanjing, China, 2Paul Scherrer Institute, Laboratory of Environmental Chemistry, Villigen PSI, Switzerland, 3Shandong Normal University, College of Geography and Environment, Jinan, China, 4University of Dayton, Department of Geology, Dayton, United States, 5Nagoya University, Graduate School of Environmental Studies, Nagoya, Japan

Glaciers in the high mountains of Asia (HMA)—encompassing the Himalayas, Karakoram, Kunlun Shan, Tian Shan and Qilian Shan mountains — form the headwaters of major river systems that provide fresh water for over 1.4 billion people in Asia. Their future changes and consequent impact on water resources are hindered mainly due to a paucity of past glacier variation data. Here we provide 14C age of bottom ice of eight glaciers in the HMA, and estimate that, during the Holocene climate optimum (HCO), glaciers in the Qilian Shan Mountains almost disappeared completely, while lost over 80% of its present glacier area in the Himalayas, and over 40% in the central Tibetan Plateau and in the Tian Shan Mountains. Remarkably, glaciers in the west Kunlun Mountains showed a negligible reduction during the HCO, implying that the recent “Karakoram anomaly” identified by remote sensing data may persist on millennial time scale. Thus we suggest that most part of the present glaciers in the HMA excluding the west Kunlun and Karakoram regions might develop since the Neoglacial. Our results suggest that the modern spatial variations of glacier in the HMA are an enduring feature on millennial time scale, thus providing a wide application for the water resource management and adaption in the HMA.
Investigating the Microscopic Location of Trace Elements in Glacier Ice

Sven Erik Avak1,2,3 (sven.avak@psi.ch), Marcel Guillong4, Oscar Laurent4, Thorsten Bartels-Rausch1, Margit Schwikowski1,2,3, Anja Eichler1,3
1Paul Scherrer Institute, Laboratory of Environmental Chemistry, Villigen PSI, Switzerland, 2University of Bern, Department of Chemistry and Biochemistry, Bern, Switzerland, 3University of Bern, Oeschger Centre for Climate Change Research, Bern, Switzerland, 4ETH Zurich, Institute of Geochemistry and Petrology, Zurich, Switzerland

Past atmospheric pollution can be reconstructed from high-alpine ice core trace element records. Due to the current global temperature increase glaciers at high altitudes are in danger to melt, strongly altering the information originally stored in these archives. The preservation of impurities with respect to meltwater percolation depends on their microscopic location in firn and ice, i.e. segregation to grain surfaces versus incorporation into the lattice. Here, we present for the first time a comprehensive study on the microscopic location of trace elements in glacier ice using two different approaches.

Firstly, we indirectly assessed the location of trace elements by analyzing their concentration records in an ice core from the Swiss Alps affected by an inflow of meltwater using ICP-MS. Our results suggest that atmospheric concentration levels of the investigated trace elements are a major driving force explaining their microscopic location in ice. Abundant pollutants such as Ca, Mg, Mn, Na and Zn are mostly segregated to grain boundaries, prone to meltwater relocation. Rare elements including Ag, Bi, Cs, Sb and W are rather incorporated into the ice lattice, indicated by a strong preservation of these species. Secondly, we directly analyzed the microscopic location of trace elements in ice using cryocell laser ablation ICP-MS. This study aims to evaluate the potential of trace elements as environmental proxies in glaciers partially affected by melting.
Accurate ice core chronology is essential to examine the sequences, durations and phasing of climatic records. A chronology for the Dome Fuji (DF) ice core (DFO-2006, for 340 kyr BP) was constructed by synchronizing variations in O2/N2 of occluded air with local summer insolation, with stated 2σ error of about 2 kyr (Kawamura et al., 2007). However, it was found that DFO-2006 at ~100 kyr BP and ~129 kyr BP (end of Termination II) are older by ~3 kyr and ~2 kyr, respectively, than U-Th radiometric dating of Chinese speleothems with stated 2σ error of < 1 kyr (Cheng et al., 2009; Fujita et al., 2015). Poor quality of the O2/N2 data due to diffusive gas loss during core storage in “warm” freezer (-25 °C) may be responsible for the discrepancies. Here, we re-analyzed O2/N2 to improve the DF chronology for 80 - 165 kyr BP, using the samples stored at -50 °C. After careful tests, we found that ~1-cm-thick surface layer must be removed to eliminate the effect of gas loss for ~20 years. With our new O2/N2 data, the DF chronology was revised with the matching technique of Kawamura et al. (2007). The new DF chronology agrees with the speleothem chronology within 1.2 kyr. In particular, the DF age at the end of Termination II agrees with the speleothem chronology and the AICC2012 ice core chronology within ~1 kyr. The results suggest that O2/N2 in the DF core faithfully records local summer insolation, and that the revised chronology greatly improved from DFO-2006.

700 Predictions: Update on the SEARCH Sea Ice Outlook from 2008 to 2017

Lawrence Hamilton¹ (lawrence.hamilton@unh.edu), Julienne Stroeve²
¹University of New Hampshire, Sociology Department, Durham, United States, ²National Snow and Ice Data Center, Boulder, United States

Each Arctic summer since 2008, the Sea Ice Outlook (SIO) has invited researchers and the engaged public to contribute predictions regarding the September extent of Arctic sea ice. The public character of SIO, focused on a number whose true value soon becomes known, brings elements of constructive gamification and transparency to the science process. Updating earlier analyses, we look back on the performance of almost 700 predictions made over a full decade of SIO activity. In 2017, statistically-based methods outperformed coupled ice-ocean-atmosphere modeling, but in past years that was not always the case. Past retrospectives noted a pattern of easy and difficult years, corresponding roughly to dominance by climate or weather. Difficult years, in which most predictions are far from the observed extent, tend to be those exhibiting large positive or negative excursions from the overall downward trends. 2017 was a difficult year, with September ice extent more than half a million square kilometers above its quadratic trend. The observed extent fell outside the interquartile range of SIO predictions as a whole, although well within the IQR of statistical predictions made in July and August. Close prediction remains elusive, but the median of SIO predictions demonstrably outperforms naïve methods including linear and quadratic trends, or persistence. Prediction has been difficult because summer weather strongly affects September ice extent, in this transitional Arctic era.
Regional Arctic Sea-ice Prediction: Potential versus Operational Forecast Skill

Mitch Bushuk¹ (mitchell.bushuk@noaa.gov), Rym Msadek², Michael Winton¹, Gabriel Vecchi³, Tony Rosati¹, Xiaosong Yang¹, Rich Gudgel¹
¹Geophysical Fluid Dynamics Laboratory, Princeton, United States, ²CNRS / Cerfacs, Toulouse, France, ³Princeton University, Princeton, United States

Seasonal predictions of Arctic sea ice on regional spatial scales are a pressing need for a broad group of stakeholders, however, most forecast skill assessments to date have focused on pan-Arctic sea-ice extent (SIE). In this work, we present a direct comparison of potential and operational seasonal prediction skill for regional Arctic SIE. This assessment is based on two complementary suites of seasonal prediction ensemble experiments performed with a global coupled climate model. First, we assess the operational prediction skill for detrended regional SIE using a suite of retrospective initialized seasonal forecasts spanning 1981-2017. These retrospective forecasts are found to skillfully predict regional winter SIE at lead times of 3-11 months and regional summer SIE at lead times of 1-4 months, owing partially to subsurface ocean temperature and sea-ice thickness initial conditions, respectively. Second, we present a suite of perfect model predictability experiments with start dates spanning the calendar year, which are used to quantify the potential regional prediction skill of this system. These perfect model experiments reveal that regional Arctic SIE is potentially predictable at lead times beyond 12 months in many regions, substantially longer than the current operational skill of this system. The skill gap identified in this work indicates a promising potential for future improvements in regional SIE predictions.
Subseasonal Forecast of Arctic Sea Ice Concentration via Statistical Approaches

Lei Wang¹, Xiaojun Yuan¹ (xyuan@ldeo.columbia.edu), Cuihua Li²
¹Columbia University, Lamont-Doherty Earth Observatory, Palisades, United States

Subseasonal forecast of Arctic sea ice has received less attention than the seasonal counterpart, as prediction skill of dynamical models generally exhibits a significant drop in the extended range (>two weeks). The predictability of pan-Arctic sea ice concentration is evaluated by statistical models using weekly time series for the first time. Two statistical models, the Vector Autoregressive model and Linear Markov model, are evaluated for predicting the 1979-2014 weekly Arctic sea ice concentration (SIC) anomalies at the subseasonal time scale, using combined information from the sea ice, atmosphere and ocean. The Vector Autoregressive model is slightly inferior to the Markov model for the subseasonal forecast of Arctic SIC. The cross-validated forecast skill of the Markov model is found to be superior to both the anomaly persistence and damped anomaly persistence at the lead time > 3 weeks. Surface air and ocean temperatures can be included to further improve the forecast skill for lead time > 4 weeks. The long-term trends in SIC due to global warming and its polar amplification contribute significantly to the subseasonal sea ice predictability in summer and fall. Both statistical models also exhibit much better skill than the NOAA operational dynamical model in most cases except for the 1-week lead in summer.
Predictive Skills Evaluation of Subseasonal to Seasonal Arctic Sea Ice Forecasts

Lorenzo Zampieri1 (lorenzo.zampieri@awi.de), Helge Goessling1, Thomas Jung1,2
1Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Climate Dynamics Section, Bremerhaven, Germany, 2University of Bremen, Institute of Environmental Physics, Bremen, Germany

Seasonal sea ice forecasts are becoming a demanding need since human activities in the Arctic are increasing. This study evaluates the predictive skills of the forecast systems contributing to the Subseasonal to Seasonal Prediction Project, focusing on the sea ice edge position. As verification metric, we employ the Spatial Probability Score and its decompositions. This is designed to quantify the correctness of the forecasted sea ice spatial distribution when compared to the observations. Moreover, the SPS allows a probabilistic description of both forecasted and observed sea ice.

Our findings reveal that some of the forecast systems are promising, exhibiting better predictive skills than the observation-based climatology and persistence of the initial condition. The results also point to critical biases concerning the data assimilation procedure and the tuning for some of the models. Comparing different versions of the ECMWF forecast system, we show the improvements brought by the employment of a fully coupled sea ice model instead of an approach based on the sea ice prescription. Given the increasing availability of new and better sea ice observations and the potential future development of the forecast systems, the formulation of reliable Arctic sea ice predictions at the considered time scales appears to be a realistic target for the scientific community.
Evaluating Roughness as a New Source of Arctic Summer Sea Ice Predictability

Jack Landy1 (jack.landy@bristol.ac.uk), Michel Tsamados2,3, Julienne Stroeve2,3, Jens Ehn4, David Barber4, Randy Scharien5
1University of Bristol, School of Geographical Sciences, Bristol, United Kingdom, 2Centre for Polar Observation and Modelling, London, United Kingdom, 3University College London, Earth Sciences, London, United Kingdom, 4University of Manitoba, Centre for Earth Observation Science, Winnipeg, Canada, 5University of Victoria, Department of Geography, Victoria, Canada

Although melt ponds on Arctic sea ice evolve in stages, ice with smoother surface topography typically allows the pond water to spread over a wider area, reducing the ice-albedo and accelerating further melt. We have quantified this relationship between premelt surface roughness and summer sea ice albedo using simulations of meltwater distributed on statistical topographies. Our method, applied to ICESat observations of the winter sea ice roughness, could account for 85% of the variance in summer ice albedo observed by AVHRR during the 2000s [Landy et al., Albedo feedback enhanced by smoother Arctic sea ice, GRL 2015]. Thus, winter sea ice roughness offers an exciting route for potentially bridging the reported May-June barrier in summer sea ice predictability.

Here we present ongoing efforts through the ScIMiTaR project (forecasting summer Sea Ice MelT from winter ice Roughness) to develop a new multi-decade sea ice surface roughness product from various data sources, including ICESat, Cryosat-2 and MISR. To improve the resolution of roughness measurements to ~1 km, we are developing a facet-based radar scattering model to simulate Cryosat-2 return echoes from LiDAR scans of sea ice topography. Finally, we will discuss plans to initialise the Los Alamos sea ice model: CICE with winter surface roughness data, benefiting from the added predictability offered to forecast summer sea ice conditions (ice melt rate, breakup timing) from the roughness data at a lead time >6 months.
Since 2001, we have been forecasting the climatic fields of the Antarctic sea ice (SI) at the Argentine Naval Hydrographic Service with different techniques that have evolved with the years. Forecast is based on the results of Principal Components Analysis applied to SI series (S-Mode) that gives patterns of temporal series with validity areas and, to SI fields (T-Mode) that give us the form of the SI fields anomalies based on a classification of 16 patterns. Each T-Mode pattern has unique atmospheric fields associated to it. Therefore, it is possible to forecast whichever atmosphere variable we decide for the Southern Hemisphere. The forecast gives the probability of occurrence of the different patterns. Only those with higher value are used to compose the fields to obtain the final result. S-Mode and T-Mode are monthly updated with new data. We used Monthly Polar Gridded Sea Ice Concentrations database derived from satellite information generated by NASA Team algorithm provided monthly by the National Snow and Ice Data Center. Data begins in November 1978. During 2016 we introduced multilayer Perceptron (neuronal network) with supervised learning and a back-propagation algorithm to improve the forecast. It was implemented through the use of surface air temperature and pressure anomalies fields that were associated with the different sea ice anomaly patterns to simplify the density of input data and avoid a non-converging solution.
Signy Island (60.7S, 45.6W) is one of the smaller islands in the South Orkney Islands group. The island is low-lying, but is situated just a few km south of the much larger Coronation Island, which rises to over 1200 m elevation. A UK research station was established on Signy Island in 1947 and operated a basic climatological observing programme from 1947 to 1996. On 30 January 1982, a daily maximum temperature of +19.8°C, recently recognised by the World Meteorological Organisation as a record for the Antarctic region, was reported by the station.

Examination of global atmospheric reanalysis fields shows that the record temperature was associated with southward advection of an exceptionally warm air mass from the subtropical South Atlantic. However, during the southward passage of this air mass over the cold Southern Ocean, there was rapid cooling of the lowest kilometre of the atmosphere, leading to near-surface temperatures that were not exceptional for this region. At the time of the observed record temperature, the wind at 1 km had a strong northerly component and was thus blowing across the high topography of Coronation Island towards Signy Island. Using a high-resolution (1 km horizontal grid spacing) simulation made with the WRF model, we demonstrate that the flow across Coronation Island generated a föhn wind that brought relatively unmodified warm air down towards the surface over Signy Island, giving rise to the observed record high temperature.
Ross Sea Climate Variability from MODIS Air Temperature and Climate Simulations

Marwan Katurji1 (marwan.katurji@canterbury.ac.nz), Hanna Meyer2, Pierre Roudier3, Thomas Nauss3, Peyman Zawar-Reza1
1University of Canterbury, Geography, Christchurch, New Zealand, 2Philipps-Universität Marburg, Geography, Marburg, Germany, 3Landcare Research, Palmerston North, New Zealand

Regional and local atmospheric circulation patterns influence the near-surface air temperature variability of the Ross Sea Region (RSR). Providing meteorological context to spatio-temporal patterns of air temperature allows for a better interpretation of climate variability that impact biodiversity, ecology and hydrology. We utilize multi-scale datasets, which are capable of resolving synoptic and mesoscale meteorological processes controlling the near-surface air temperature variability of the RSR. This work uses a MODIS and machine learning based daily air temperature dataset (1 and 10km resolution from 2002 to 2016) and mean sea level pressure data from regional climate simulations. Self-organizing maps are used to reveal intra-annual patterns of the synthesized datasets that are supported by atmospheric circulation forcing. This includes cases from the localized McMurdo Dry Valley warming episodes caused by foehn winds, and regional scale West Antarctic and Transantarctic Mountain coastline warming episodes resulting from cyclonic-induced northerly air streams. This research presents a unique approach of synthesizing satellite, ground based, and numerical climate datasets to study surface climate variability at a high spatial resolution across the entire Ross Sea region. This work is the basis to investigate inter-annual variability and sensitivity of near-surface air temperature associated with changes of circulation patterns.
Evaluation of Models using Radio Sounding Observations on the Antarctic Plateau

Gerit Birnbaum¹ (gerit.birnbaum@awi.de), Konstantin Krueger¹, Christof Luepkes¹, Michael Schaefer², Jan Melchior van Wessem³, Gert Koenig-Langlo¹, Bernd Loose¹
¹Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, ²University of Leipzig, Leipzig, Germany, ³University of Utrecht, Utrecht, Netherlands

Three global reanalysis products, the regional climate model RACMO and the weather forecast system AMPS were evaluated against profiles obtained from radio soundings on the Antarctic plateau. Measurements at Kohnen Station, which represent independent in situ data, were performed in Jan 2006, Dec 2013 and Jan 2014 four times a day. JRA-55 had the most accurate temperature profiles, MERRA-2 the best relative humidity profiles and ERA-interim the smallest errors in wind speed profiles. Biases and root mean-square errors vary considerably with altitude in the troposphere and in the tropopause region. Surface or elevated inversions in the lowermost 1000 m are captured quite differently. ERA-interim always shows a surface inversion with thickness and temperature increase that hardly vary in the course of a day. The frequency of surface and elevated inversions is better captured at 00 and 06 UTC compared to 12 and 18 UTC in JRA-55 and MERRA-2 as well as in the two regional models, which indicates that processes in the boundary layer, which lead to an erosion of a surface inversion are still poorly represented in the models. All reanalyses and regional models are able to simulate a low-level jet. However, ERA-interim, RACMO and AMPS underestimate the frequency at all four times. Similar evaluations were performed using routine radio soundings at South Pole and Dome C in 2016. Results indicate that processes in the boundary layer are also not captured well during Austral winter.
Impact of Anthropogenic Forcing on High Latitude Southern Hemisphere Circulation

James Pope¹ (japope@bas.ac.uk), Andrew Orr², Gareth Marshall², Luke Abraham²

¹British Antarctic Survey, Cambridge, United Kingdom, ²NCAS Chemistry, Cambridge, United Kingdom

We examine the impact of the individual and combined effects of three anthropogenic forcings on high-latitude Southern Hemisphere circulation through a novel suite of climate model simulations. Using the UK Met Office Unified Model (UM) coupled to the UK Chemistry and Aerosols (UKCA) interactive climate-chemistry model, we investigate the climatic response due to ozone depletion, and increases in both greenhouse gases and anthropogenically-produced aerosols. A suite of experiments, comprising a ‘control’ and seven further ‘perturbed’ runs, covering all possible individual and combinations of the three different forcings. The control-run is forced by pre-industrial concentrations of greenhouse gases, ozone depleting substances, and aerosols, while the perturbed experiments comprise the control simulation plus fixed present-day values of one or more of the forcings. We focus our results on the effect of the forcing(s) on the Southern Hemisphere Annular Mode (SAM), which is the principal mode of atmospheric variability at southern high latitudes, although we also look at changes in meridional circulation around Antarctica, which play a major role in climate variability across the continent. Individual forcing responses in our model are consistent with previous studies. However, in contrast to some other studies, we find that the effect of the individual forcings are not linear when compared to the simulation combining all three forcings.
Atmospheric rivers (AR) transport large amounts of moisture from subtropics to mid- and polar latitudes. Their important role in intense precipitation and anomalous snow accumulation has been already demonstrated for East Antarctica (Gorodetskaya et al, 2014). Such extreme events are particularly challenging for both weather prediction and climate models, especially in the Polar regions where measurements are very sparse. The Antarctic Circumnavigation Expedition (ACE) provided a unique opportunity to perform continuous radio soundings of the atmosphere onboard a ship as it circumnavigated Antarctica during December 2016 - March 2017. In this study we target several AR events observed during ACE that brought intense precipitation over the Southern Ocean and the ice sheet coastal areas. Using vertical profiles of temperature, humidity and wind from radiosondes we calculate moisture fluxes and locate levels of warm and moist advection, study low level jets, identify cloud boundaries, and follow the profiles evolution along with cyclone development. The data allow the first-ever direct observation of the vertically integrated water vapor amount and transport in an AR over the Southern Ocean. These measurements give a unique opportunity to evaluate models, reanalysis and satellite products. Possible mechanisms that feed the ARs with moisture as well as the large-scale forcings favoring convergence and the strong coherent moisture advection are explored.
Upper Slope Processes and the Distribution of Life on the Antarctic Seafloor

Alix Post¹ (alix.post@ga.gov.au), Phil O’Brien², Leanne Armand²,³, Stuart Edwards⁴
¹Geoscience Australia, Canberra, Australia, ²Macquarie University, Sydney, Australia, ³Australian National University, Canberra, Australia, ⁴CSIRO Oceans & Atmosphere, Hobart, Australia

The seafloor of the Antarctic upper continental slope is a dynamic and varied environment. The upper slope is influenced by oceanographic processes, including export of dense shelf waters, upwelling of Circumpolar Deep Waters and strong along slope flow and mixing associated with the Antarctic Shelf Front. These features can enhance the productivity of the surface waters and influence the food supply to the seafloor. The interplay between oceanographic and glacial processes over long time periods has created a complex morphology of dense gully networks, rugged submarine canyons and broad sediment ridges.

The upper slope is of biological significance as an area often proposed as a refugia for shelf biota during glacial cycles and as the interface between shelf and deep sea species. This study draws on case studies from the East Antarctic margin to understand the processes that drive the modern distribution of benthic biota on the upper slope. These studies illustrate how the seafloor biota are shaped by oceanographic, glacial and sedimentary processes. Flow of dense shelf waters through shelf incising canyons off the George V margin influences the occurrence of Vulnerable Marine Ecosystems, while variations in gully types on the Sabrina upper slope creates heterogeneity in the occurrence and diversity of sessile suspension feeders and mobile fauna. The upper slope provides a unique setting for understanding how the benthic biota respond in a dynamic environment.
El Niño and La Niña Signals in the Reproduction of Antarctic Echinoderms

Laura Grange1 (l.j.grange@noc.soton.ac.uk), Lloyd Peck2, Amanda Bates1, Paul Tyler1
1University of Southampton, Ocean and Earth Science, Southampton, United Kingdom, 2British Antarctic Survey, Cambridge, United Kingdom

Ongoing impacts of climate change are well established and predicted to continue at an unprecedented rate. Superimposed on this backdrop of environmental change is an increase in the frequency and severity of extreme weather events. Fluctuations in extreme events have been implicated as major mechanistic drivers of ecological responses to climatic trends, often being more relevant than variances in mean climate. They are, however, infrequent and underestimated. In addition, ecologists have historically focused on quantifying the effects of locally measured components of weather as opposed to regional modes of climate variability that integrate over multiple local variables, and facilitate a more holistic approach when researching climate change effects. Here we investigate the impact of local and large-scale climate cycles on reproduction in two Antarctic echinoderms over 17 years of monthly samples. We report long-term trends in reproductive performance, measured as gonad index and egg size, and observe extreme El Niño and La Niña signals in the reproduction of both polar taxa. We identify the complex interplay between food supply, seawater temperature, and faunal energy allocation strategies as key drivers of reproductive responses, where climate extremes underpin long-term trends in biological flexibility. The infrequency of extreme weather events thus underscores the need for long-term biological time series to better predict faunal responses to future climate change.
More Losers than Winners in a Century of future Southern Ocean Seafloor Warming

Huw Griffiths¹ (hjg@bas.ac.uk), Andrew Meijers¹, Thomas Bracegirdle¹
¹British Antarctic Survey, Cambridge, United Kingdom

The waters of the Southern Ocean are projected to warm over the coming century, with potential adverse consequences for native cold-adapted organisms. Warming waters have caused temperate marine species to shift their ranges poleward. The seafloor animals of the Southern Ocean shelf have long been isolated by the deep ocean surrounding Antarctica and the Antarctic Circumpolar Current, with little scope for southward migration. How these largely endemic species will react to future projected warming is unknown. By considering 963 invertebrate species, we show that within the current century, warming temperatures alone are unlikely to result in wholesale extinction or invasion affecting Antarctic seafloor life. However, 79% of Antarctica’s endemic species do face a significant reduction in suitable temperature habitat (an average 12% reduction). Our findings highlight the species and regions most likely to respond significantly (negatively and positively) to warming and have important implications for future management of the region.
On 12 July 2017, the Larsen-C Ice Shelf calved one of the largest icebergs originating from the Antarctic Peninsula ever recorded, leaving an area of 5,800 km² of seabed newly exposed to open marine conditions. The calving of A68 offers a unique scientific opportunity for fundamental research to address questions focused on the mobility and colonisation capacity of benthic fauna. In early 2018 an international, multidisciplinary science group on-board the RRS James Clark Ross investigating the benthic biodiversity beneath the Larsen-C, will address the hypothesis that: “Prior to the calving of iceberg A68, the benthic fauna beneath the ice shelf probably comprised oligotrophic assemblages resembling deep-sea Weddell Sea systems. The calving of A68 will now lead to rapid colonisation by new species that will significantly transform the benthic ecosystem within 3 to 5 years.” Our survey, including stations both outside and inside the pre-calving ice front, coupled with stations in the region of Larsen-A&B will comprise trawls, corers, towed camera systems, CTD, and echo-sounders. We will sample from the surface to the seafloor. Our holistic approach will enable us to collect information on the assemblage structure, biodiversity and abundance of the in-, epi-, and supra-benthic meio-, macro- and mega-fauna, setting a baseline for future research. In this presentation we will report our preliminary results from the expedition.

High Beta Diversity of Microbes in Southern Ocean Abyssal Water Masses

Swan Li San Sow\textsuperscript{1,2} (swanlisan.sow@csiro.au), Levente Bodrossy\textsuperscript{1}, Thomas W. Trul\textsuperscript{1,3}, Phillip W. Boyd\textsuperscript{2,3}, Eric J. Raes\textsuperscript{4}, Jodie van de Kamp\textsuperscript{1}, Mark V. Brown\textsuperscript{5}, Andrew Bissett\textsuperscript{1}

\textsuperscript{1}Commonwealth Scientific and Industrial Research Organisation (CSIRO), Oceans and Atmosphere Flagship, Hobart, Australia, \textsuperscript{2}University of Tasmania / Institute for Marine and Antarctic Studies, Hobart, Australia, \textsuperscript{3}Antarctic Climate and Ecosystems Cooperative Research Centre, University of Tasmania, Hobart, Australia, \textsuperscript{4}Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, \textsuperscript{5}University of New South Wales, School of Biotechnology and Biomedical Sciences, Sydney, Australia

The Southern Ocean (SO) is known to be an important site for carbon dioxide sequestration and dominates many key biogeochemical nutrient cycles through microbially driven processes. The pelagic dark ocean hosts up to 60\% of heterotrophic activity, but knowledge on the community structure of these heterotrophic microbes and their interaction with the surface community is still scarce. This study greatly expands our understanding of SO microbes within the deeper water masses with interest on the roles of ocean circulation in structuring microbial biogeography. At two multi-latitudinal transects from the Indian (71-99\textdegree{}E) and Pacific sector (170\textdegree{}W) of the SO, we sampled seawater from the full water column at 8 depth points and examined bacterial, archaeal and eukaryotic community compositions through high resolution 16S and 18S rRNA tag sequencing. We found the biogeographical distribution of microbes were explained in part by distinct water masses hydrographies, but bacteria and archaea from deeper (Antarctic bottom-lower circumpolar) water masses, which spread across a wide range of latitudes, displayed niche communities with varying abundances of specific phylotypes that were not explained by hydrography or geographical distance. The abrupt changes in phylotype abundances corresponded with crossing frontal zones in surface waters, suggesting that the varying communities of surface water masses influences community compositions in deeper water masses.
Distributional Shifts of Two Antarctic Metazoans under Climate Change Scenarios

Evgeny Pakhomov1,2,3 (epakhomov@eos.ubc.ca), Gabriel Reygondeau2, Angus Atkinson4, Simeon Hill5, Volker Siegel6

1University of British Columbia, Earth, Ocean and Atmospheric Sciences Department, Vancouver, Canada, 2Institute for the Oceans and Fisheries, University of British Columbia, Vancouver, Canada, 3Hakai Institute, Heriot Bay, Canada, 4Plymouth Marine Laboratory, Plymouth, United Kingdom, 5British Antarctic Survey, Natural Environment Research Council, Cambridge, United Kingdom, 6Thuenen Institute of Sea Fisheries, Hamburg, Germany

Distributional range shift is a well-known species response to climate fluctuation and has been documented for various taxonomical groups in different parts of the global ocean. Circum-Antarctic habitats of the Antarctic krill, Euphausia superba, and pelagic tunicate, Salpa thompsoni, were modelled using presence only environmental niche models. KRILLBASE and the Southern Ocean CPR data were used. An ensemble suit of models, including species range envelope, non-parametric probabilistic ecological niche, boosted regression trees and maximum entropy models, were used to predict the past, present and future distributions of both species. Habitat shifts of both species and their potential contemporary and projected overlap were investigated under two IPCC: RCP2.6 and 8.5. The overlap in krill and salp niches/habitats appear to be significant in the Scotia Sea and Indian Sector of the Southern Ocean as well as in coastal regions, except perhaps the Ross Sea. Both species showed a southward shift in distribution under climate change scenarios, which was most profound under the RCP8.5 scenario. Predictions demonstrated that since 1950s the habitat overlap increased and stabilized. This suggested the persistence of the habitat overlap under climate change projections with a potential increase in inter-species interactions and in competition for limited space between both species. Potential “winners” and “losers” with implications for the high Antarctic ecosystem are discussed.
Microbial Loop and Organic Carbon Dynamics in Kongsfjorden during June 2011

Bhaskar Parli1 (bhaskar@ncaor.gov.in), Jane Theophile Paul-Bhaskar2, Nuncio Murukkesh1, K.P. Krishnan2, S Rajan3
1NCAOR, Ocean Science Group, Vasco da Gama, India, 2NCAOR, Vasco da Gama, India, 3INCOIS, Hyderabad, India

Depthwise vertical distribution of microbial components including samples of bacterioplankton, phytoplankton assemblages, heterotrophic nanoflagellates and picoplankton and water samples for chlorophyll a (chl a) and organic carbon were analysed at nine stations in Kongsfjorden during Arctic summer in 2011. Phytoplankton abundance (excluding picoplankton) decreased with depth and their surface abundance ranged from 2.56 x 10³ cells L⁻¹ at K1 (mouth) to a maximum of 16.76 x 10³ cells L⁻¹ at K7 (outside Ny-Ålesund). On the other hand, picoplankton abundance ranged from 0.3 x 10³ cells L⁻¹ (K4 & K7) to 8 x 10³ cells L⁻¹ (K7). Heterotrophic bacterial and nanoflagellate abundance ranged from 7.4 x 10⁶ (K1 and K2) to 665 x 10⁶ cells L⁻¹ (K4) and 2.6 x 10³ cells L⁻¹ (K7) to 21.6 x 10³ cells L⁻¹ (K3), respectively. Prymnesiophyceae (44.5%), Dinophyceae (30.4%) Chlorophyceae (10.9%) and Bacillariophyceae (9.1%) were the major phytoplankton groups. Dominance of dinoflagellates indicated post-spring bloom scenario. Column integrated biomass of picoplankton, nanoflagellate and heterotrophic bacteria ranged from 3.3 x 10⁻⁵ to 8.3 x 10⁻³ µM-C, 5 x 10⁻³ to 0.01 µM-C and 3.3 to 27 µM-C, respectively. Multivariate analyses of the data indicate that abiotic factors like light availability played important role in controlling the phytoplankton community distribution. The dynamics of carbon and its partitioning within microbial loop is also discussed.
Organic Carbon Sources in Arctic and Subarctic Atlantic Fjord Sediments

Johan Faust\textsuperscript{1} (j.faust@leeds.ac.uk), Jochen Knies\textsuperscript{2,3}
\textsuperscript{1}University of Leeds, Leeds, United Kingdom, \textsuperscript{2}Geological Survey of Norway, Trondheim, Norway, \textsuperscript{3}CAGE - Centre for Arctic Gas Hydrate, Environment and Climate, Department of Geology, UiT the Arctic University of Norway, Tromsø, Norway

During the past decade fjords attract notice as important shelf areas for carbon burial due to relatively high sedimentation rates as well as high organic matter (OM) input. As terrigenous derived OM is more resistant to remineralization than marine OM, a comprehensive knowledge of the carbon source is crucial to better constrain OM burial rates in fjord sediments. Recent findings indicate that the majority of the OM in fjord sediments globally to be terrigenous derived. However, these findings are based only on a very few studies from the North Atlantic region. To improve the understanding of the controlling factors on OM sedimentation in mid- and high-latitude fjord systems we investigate the OM sources of highly productive arctic fjords off the Lofoten Islands, northern Norway and compare our results with available and new C\textsubscript{org}/N\textsubscript{org} and $\delta^{13}$C\textsubscript{org} data from various arctic and subarctic fjord systems in Mid-Norway, western Svalbard and East Greenland. Our results show that in Northern Norwegian fjords the sedimentary OM is primarily controlled by marine productivity variations and marine C\textsubscript{org} values of up to 4.4 wt.% indicate that this region is a hotspot for marine C\textsubscript{org} burial. Moreover, the amount of terrigenous OM is generally higher in Arctic fjords compared to Norwegian (Boreal) fjords and marine water inflow versus freshwater runoff seems to be an important controlling factors of the OM composition in fjord sediments.
Errors in Marine vs. Terrestrial Carbon Sequestration Budget for Arctic Region

Manish Tiwari¹ (manish@ncaor.gov.in), Vikash Kumar²
¹National Centre for Antarctic & Ocean Research, Vasco-da-Gama, India, ²National Centre for Antarctic & Ocean Research, Headland Sada, India

The Arctic region holds a disproportionate importance in the global carbon cycle. The changing sea cover due to the global warming may likely change the relative marine vs. terrestrial organic carbon deposition in the region. It is therefore important to have an accurate estimate of relative carbon burial flux for which the carbon isotope ratio ($\delta^{13}C$) and carbon to nitrogen ratio (C/N) of the sedimentary organic matter (SOM) are the most widely used tracers. These proxies that are so reliable in other parts of the world have significant limitations in the Arctic region due to various proxy-specific uncertainties resulting in gross differences in relative burial flux calculations. This allowed us to better constrain the marine and terrestrial end-member carbon isotopic composition, which we found to be anomalously more depleted (marine $\delta^{13}C \sim -24\%$) and enriched (terrestrial $\delta^{13}C \sim -22.5\%$), respectively, than usually assumed. This particular result also provides the explanation for the high $\delta^{13}C$ of SOM from central Arctic despite a high terrestrial input that remained a puzzle since reported. We find that the bound inorganic nitrogen (ammonium attached to the clay minerals) forms a significant proportion of total nitrogen concentration and should be removed to avoid an underestimation of terrestrial contribution. Using these new values, we find that the terrestrial contribution to the organic carbon deposition in the Arctic has been severely underestimated.
One of the main features of Eurasian Arctic Seas is the huge amount of fresh water coming from great Siberian rivers: Ob, Yenisei, Lena whose input is about 2000 km³/year into the Arctic Ocean basin. Depending on annual discharge and wind stress riverine water can either accumulate on the shelf or according to Carmack et al (2015) transformed riverine water moves eastward along the Eurasian shore as a narrow and shallow flow. This flow contains huge amount of organic and inorganic matter coming to the Arctic Ocean with continental runoff (Gordeev et al, 1996). Thus, the existing mechanism moves the nutrient and carbon in the Arctic and our goal is to determine the volume of the transported substance and the possible degree of impact on the Eurasian coastal ecosystem.

In August-September 2017 Shirshov Institute of Oceanology (SIO) organized cruise of RV “Academician Mstyslav Keldysh” to East-Siberian Sea. Along the vessel course (through the Kara and Laptev Seas) direct measurements of temperature and salinity were conducted as well as sampling from the surface layer. Chemical analysis of the samples included nutrients (P, Si and N in dissolved forms) and carbonate system parameters (alkalinity and pH). We also calculated concentration of DIC, \( \Omega_{\text{ca}} \) and \( \Omega_{\text{ar}} \) and \( \text{pCO}_2 \) in surface water. The primary analysis of the data confirmed the existence of the eastern fresh water transfer and determined the possibility of estimating the content of nutrients and carbon in these waters.
Small Scale Distribution and Composition of Organic Carbon in Arctic Soils

Carsten W. Mueller1 (cmueller@wzw.tum.de), Sebastian Zubrzycki2, Isabel Prater1, Lena Zoor1, Janet Rethemeyer3, Jenny Kao-Kniffin4

1TU Munich, Chair of Soil Science, Freising, Germany, 2University Hamburg, Hamburg, Germany, 3University Cologne, Institute of Geology and Mineralogy, Cologne, Germany, 4Cornell University, Department of Horticulture, Ithaca, Germany

Tremendous amounts of organic carbon (OC) are stored in permafrost-affected soils in the Arctic. The ongoing warming will change the accessibility and bioavailability of the previously frozen soil organic matter (SOM). Although OC stocks and C fluxes in the Arctic are extensively studied, there is only scarce information on the small scale (pedon scale) distribution and composition of organic matter in differently stabilized fractions. However, this information is crucial to understand and model the fate of differently bioavailable SOC. By combining bulk analytical methods (e.g. C and N analyses, 14C, NMR spectroscopy) with state of the art spectromicroscopic techniques (e.g. NanoSIMS) it is possible to unravel processes stabilizing organic carbon reaching from the formation of organo-mineral associations to soil aggregation. We will present results from Alaska and Siberia demonstrating the distribution of distinct SOM fractions with soil depth. Using NMR spectroscopy, we were able to demonstrate that free SOM particles showed larger amounts of rather labile C (O/N alkyl-C) in comparison with SOM particles occluded in mineral soil structures. Soil OM directly associated with minerals showed rather similar chemical compositions due to comparable effects on SOM sorption by minerals. These results clearly indicate that mechanisms like soil aggregation and the formation of organo-mineral associations play also a role for SOM bioavailability in permafrost-affected soils.

Source and Age of Soil Carbon in the Sør Rondane Mountains of East Antarctica

Lori A. Ziolkowski¹ (loriz@sc.edu), Steffi Lutz², Liane G. Benning²,³,⁴, Jenine McCutcheon⁴
¹University of South Carolina, School of Earth, Ocean, and the Environment, Columbia, United States, ²GFZ German Research Centre for Geosciences, Section 4.4: Interface Geochemistry, Potsdam, Germany, ³Free University of Berlin, Department of Earth Science, Berlin, Germany, ⁴University of Leeds, School of Earth and Environment, Leeds, United Kingdom

On Antarctica, cold temperatures and months of darkness create a near inhospitable environment. Yet, microbial life has been shown to thrive in some regions of this polar desert leading to the production of organic carbon. The highest abundances of organic carbon are found in lakes and where microbes inhabit rocks (endoliths), with less known about the organic carbon within soil. Presently, it is not well constrained if soil organic carbon is produced locally within the soil or produced elsewhere and subsequently transported to the soils. In an effort to further our understanding of the processes contributing to Antarctic soil organic carbon, we studied the microbial community and organic carbon abundance and composition in soils collected in the Sør Rondane mountains, 200 km inland, in East Antarctica. Using a suite of samples that range from lake-side soils with deposits of macroalgae to dry high elevation soils devoid of visible life, we will report on the organic carbon abundance, isotopic (¹³C, ¹⁴C) composition, and microbial composition of soil organic carbon in order to determine variations in the carbon composition. Additionally, the microbial community composition of the soils will provide insight into the relative contribution of autotrophic and heterotrophic organisms. This work will provide the first estimates of carbon abundance and age as linked to the microbial community in soils from a previously understudied region of East Antarctica.
Antarctica was at a centre position within Gondwana and holds a key position for any plate tectonic reconstruction related to its break-up history. North Victoria Land (NVL) is located at the Pacific end of the Transantarctic Mountains (TAM), which represent the uplifted western shoulder of the West Antarctic Rift System. The basement of the TAM formed during subduction of the Palaeopacific Ocean under E Gondwana during the Ross Orogeny. Major uplift of the TAM commenced around the Eocene-Oligocene boundary following sediment accumulation within the wide “Mesozoic Victoria Basin”. This long-lasting geological history led to highly anisotropic crust that is susceptible to repeated reactivation. We present evidence for a polyphase structural evolution of NVL after initial break-up of Gondwana at ca. 180 Ma coeval with the Ferrar volcanic event. Mainly Neogene NW-SE striking dextral strike-slip tectonics with local transtension and transpression controls the present structural architecture of NVL. It may be interpreted as dynamic response to intra-oceanic fracture zones between Australia and Antarctica extending into NVL and the Ross Sea. Dextral strike-slip overprints two older increments:

(i) WNW-ESE striking sinistral tectonics of possibly late Mesozoic-early Paleogene age within a transform margin setting between Australia and Antarctica,
(ii) ENE-WSW directed extension of NVL continental crust possibly coeval to Adare Trough spreading in Eocene-Oligocene times.
West Antarctica hosts the large West Antarctic Rift System (WARS), a region of continental extension which has formed during several stages of rift reactivation from the Cretaceous through the Cenozoic. Anomalously high geothermal flux has been reported within WARS at the WAIS Divide ice core drilling site and Subglacial Lake Whillans, which is consistent with estimates in the Thwaites Glacier (THW) catchment from airborne radar based techniques. Together, these observations suggest that elevated geothermal flux characterizes large sectors of WARS. Moreover, subglacial volcanic activity has been recently documented along the ECR, where a swarm of deep long-period earthquakes was registered in 2010 and 2011 by the POLENET seismic network.

Here we analyze magnetic anomalies in the context of other aerogeophysical data in central WARS, along THW, Pine Island (PI), and eastern Marie Byrd Land (MBL), in order to evaluate the distribution of potential hotspots in the region. We identify three different regions with distinct magnetic character and correlate each one of them to specific stages of tectonic and magmatic activity in WARS. Our interpretation supports both the hypothesis that MBL was tectonically and magmatically reactivated multiple times during the Cretaceous and that a hotspot was emplaced there later in the Cenozoic, therefore pointing to a hotter MBL compared to THW and PI.
A Multi-domain Lithospheric Model of East Antarctica

Tobias Staal1,2 (tobias.staal@utas.edu.au), Anya M Reading1,3, Jacqueline Halpin1, Joanne Whittaker1
1University of Tasmania / Institute for Marine and Antarctic Studies, Hobart, Australia, 2University of Tasmania / Earth Sciences, Hobart, Australia, 3University of Tasmania / Mathematics and Physics, Hobart, Australia

The geology of East Antarctica is poorly constrained and covered by ice which can be several kilometers thick, however, these hidden and inaccessible rocks are of major interest in interdisciplinary studies linking the solid Earth and cryosphere. Subglacial geothermal heat flux is an important parameter for ice sheet models and depends on heat production within the crust, but also the deep geothermal gradient that is defined by the lithospheric structure. Seismic tomography studies derive lithosphere thickness and structure, but the resolution is relatively low, and the smoothed models don't reflect the amalgamation of lithospheric terranes that formed the continent. We combine geophysical constraints from seismic properties and potential field data, with geological knowledge from the sparse Antarctic outcrops and from Gondwanan neighbours in a plate reconstruction framework. We use Bayesian inference to suggest the most probable boundaries by using a multivariate prior. The boundaries form a segmentation of the Antarctic lithosphere and can be weighted with probabilistic significance and location. The result is presented as a first draft of a multi-domain tessellated terrane map of the East Antarctic lithosphere. We believe that this approach will be useful in estimating both basal lithosphere and crustal contributions to heat flux, and is a robust stepping stone towards more refined models.
Crustal and Lithospheric Structure Beneath the Antarctica Based on Gravity Data

Ravi Kumar Muppidi¹ (mravi@iigs.iigm.res.in), Bijendra Singh¹, D.S Ramesh¹, V.M Tiwari², C.D Reddy¹, Ajay Dhar¹

¹Indian Institute of Geomagnetism, Solid Earth Group, Navi Mumbai, India, ²National Geophysical Research Institute, Hyderabad, India

Investigation of deep crustal and lithospheric structures is essential to understand the nature of geodynamical processes beneath the Antarctica Plate. We present a hybrid approach comprising isostasy and spectral analysis to decompose the observed gravity field into its deep crustal and lithospheric components and derived density cross sections beneath the Antarctica plate using integrated 2D modelling of gravity, topography and geoid data incorporating constraints from seismic information. We also present new crustal and lithospheric thickness maps based on integrated modeling of elevation and geoid and thermal analysis. This approach assumes local isostasy, thermal study state, and linear density increase with depth in the crust and temperature-dependent density in the lithospheric mantle and our result compares well with the depth of Moho and LAB derived from seismic and tomographic models. It is observed that most of the east Antarctica high topographic region is isostatically compensated by thick crust based on Airy model. For example, depth of the Moho discontinuity beneath the Gamburtsev Sub glacial Mountain is inversely correlated with surface topography. Our new lithospheric thickness map derived from 3D inversion of lithospheric field component brings out distinct features like thin lithosphere in the west (100-150Km) and thickening of the lithosphere in the east Antarctica (160-220Km) and therefore east Antarctica appears to similar to other stable cratons.
We develop a new seismic structure model for Antarctica and surrounding oceans to depths of 700 km using more than 300 far-southern hemisphere seismic stations. We calculate full-waveform synthetics for 3D earth models using a spectral element method, and fit the entire 3-component waveforms. The new model overcomes the limitations of previous spatially- and depth-limited regional models and low-resolution global models. In East Antarctica, the results reveal fast seismic velocities extending to 250 km depth beneath Wilkes Land and the Gamburtsev Mtns. In contrast, fast velocities extend to only 100-150 km depth beneath the Lambert Graben, Enderby Land, and portions of Dronning Maud Land, consistent with younger or tectonically disrupted lithosphere. The West Antarctic coast from Marie Byrd Land to the Antarctic Peninsula is underlain by low velocity mantle. The slow anomalies along the Amundsen Sea coast connect to an offshore velocity anomaly beneath elevated bathymetry, suggesting a thermal anomaly that is associated with a larger geodynamic process. We estimate the mantle viscosity structure from the seismic structure assuming laboratory-derived relationships between seismic velocity, temperature, and rheology. The results indicate several orders of magnitude variation in viscosity, with extremely low viscosity ($< 10^{20}$ Pa s) beneath the Amundsen Sea coast, consistent with low viscosity inferred by glacial isostatic uplift models constrained by GPS data.
Deep Structure and Geodynamics of the Antarctic Plate with the Tomography Data

Rudolf Greku1 (r.greku@gmail.com), Alexander Litvinov1, Tatyana Greku1
1Institute of Geological Sciences / National Academy of Sciences of Ukraine, Geology and Geoecology of Antarctica, Kiev, Ukraine

This article contains the tomographic modeling results of the Antarctic Plate up to the depth of 5,300 km. Density anomalies were calculated relative to PREM with the EGM2008 geoid model using the gravity tomography method (www.uac.gov.ua/SitePages/Home/atlas.aspx). The hot and ascending Ross Plume, the cooled and subducted Kerguelen-Conrad Plate masses and the Antarctic Continent are the main structures of the Antarctic Plate bounded by the mid-ocean ridges. The Ross Plume extends from the depth of 2,800 km up to the surface within some sectors of the marginal ridges. Surface-continental density anomalies have a radial orientation from the South Pole. Distribution of density anomalies within the oceanic lithosphere is determined by the movement of divergent and transform spreading centers. The density anomalies of the Antarctic Peninsula and the Continental East Antarctic are shown up to the depths of 2,800 km.

The cross-section along the ridge of the Plate boundary for a distance of 40,000km is shown. Intraplate and interplate geodynamics is shown along cross-sections and lateral slices up to the depths of 2,800 km. Coupling of Arctic and Antarctic can be seen only at the layers of the mantle-core. The slice at the 5,300 km-deep consists of four symmetrically located density anomalies of different signs. They come together both in Arctic and Antarctic. That is shown on the global maps with the Lambert Projection.
Reductions in seasonal ice and changes in organic carbon fluxes are influencing benthic communities in Arctic shallow shelves, which can have critical consequences for ecosystem productivity. We describe multi-year changes of macrobenthic communities in the “hot-spot” areas of benthic biodiversity and biomass in the northern Bering and Chukchi Seas identified in the Distributed Biological Observatory. Our goal was to assess benthic vulnerability to increasing temperature and ice decline, and its effect on the food webs and ecosystem productivity. We examined potential implications of changes in ice cover for trophic positions of selected species and potential food sources along a latitudinal gradient and in relation to environmental data. Benthic organisms were collected from southwest of St. Lawrence Island, in the Chirikov Basin, the southeast Chukchi Sea, and Barrow Canyon, at the same stations from 2007 to 2015. Samples for compound-specific stable isotope analysis of amino acids were collected in each ‘hot-spot’ in 2015. Changes observed include a decline of biomass, a switch in some dominant species, and an increase in species diversity in recent years. Variation in $\delta^{13}C_A$ and $\delta^{15}N_A$ values reflect differences in food source and trophic level shifts. The compound specific isotope analysis is consistent with the capacity of some benthic species to shift from deposit to active suspension feeding as environmental conditions change.
High Export Flux and Benthic Biomass Indicate Warming Sensitivity in a WAP Fjord

Craig R. Smith1 (craigsmi@hawaii.edu), Andrew Sweetman2, McKenna Lewis1, Maria Vernet3, Lindsey Ekern3, Clifton Nunnally4, Amanda Ziegler1
1University of Hawaii at Manoa, Oceanography, Honolulu, United States, 2Heriot-Watt University, The Lyell Centre for Earth and Marine Science and Technology, Edinburgh, United Kingdom, 3University of California San Diego, SIO, San Diego, United States, 4Louisiana Universities Marine Consortium, Chauvin, United States

Rapidly-warming West Antarctic Peninsula (WAP) fjords are hotspots of pelagic and benthic biomass/biodiversity. The drivers of fjord productivity, and benthic sensitivity to climate warming, remain poorly known. Our FjordEco Project integrates field/modeling studies in Andvord Bay to explore how (1) glacial and oceanographic processes enhance fjord productivity and biodiversity, and (2) increased meltwater/sediment inputs from climate warming may alter these ecosystems. Field studies in Andvord Bay in Dec 2015 and Apr 2016 indicated intermittently high primary production throughout the fjord but did not resolve the location of highest seasonal export flux. We use benthic ecosystem parameters to integrate summer seafloor POC flux and identify fjord areas of high benthic food availability. Sediment Chl-a was low throughout the fjord in Dec, but 10-fold greater in Apr, with highest levels in the inner fjord 1-km from fast-flowing glaciers. Seafloor carbon respiration also was enhanced in Apr, with highest rates near glaciers. Megabenthic abundance matched the patterns of food availability with an inner fjord peak, while macrofaunal abundance/biomass peaked in mid fjord, 10 km from glaciers. We hypothesize that macrofauna are more sensitive than megafauna to the burial stress in the inner fjord due to lower mobility/body size. Our results suggest that warming enhanced meltwater/sediment input near tidewater glaciers will alter inner-fjord hotspots of productivity/biodiversity.
Seasonality and Spatial Variability of Epifaunal Recruitment in the Arctic

Marta Ronowicz¹ (martar@iopan.pl), Anna Sowa³, Katarzyna Walczyńska², Piotr Bałazy¹, Janne Søreide³, Piotr Kukliński¹,⁴, Agata Weydmann⁴

¹Institute of Oceanology, Polish Academy of Sciences, Sopot, Poland, ²University of Gdansk, Gdansk, Poland, ³University Centre in Svalbard, Longyearbyen, Poland, ⁴Natural History Museum London, London, United Kingdom

Recruitment process is one of the first steps of community development and has a substantial consequence for population dynamics and structure.

The main aim of the project was to investigate seasonal variability of larvae recruitment in the Arctic fjord - Isfjorden (West Spitsbergen) in relation to location (two sites under the influence of Atlantic versus transformed fjordic waters), depth and predation impact. Samples were collected every third month (July 2016, October 2017, January 2017, April 2017, July 2017), at two sites and two depths with the use of SCUBA. At each site two experimental constructions with panels were deployed: first one covered with a cage and second one - uncovered, to assess the predatory impact on recruiting epifauna. Meroplankton was collected with three different types of gear in order to examine the larvae occurrence in different layers of water column: on the bottom using vacuum pump manipulated around and under rocks, 2 m above the bottom - net towed horizontally by divers and WP2 net. In addition the influence of environmental factors (temperature, salinity, suspension concentration, sedimentation flux, light penetration) on colonization was studied. The study shows that larvae are present in the water column all year round with a peak of occurrence in summer season. The recruitment pattern follows the trend of meroplankton abundance and recruitment was the highest in summer months.
Fjords along the West Antarctic Peninsula (WAP) are productive ecosystems where seasonal phytodetritus pulses sustain rich benthic communities. However, the timing and intensity of phytodetritus pulses, and benthic community response, remain unevaluated. We used a calibrated seafloor camera to study the arrival and utilization of phytodetritus over a 9-month period (Dec 2015 - Sept 2016) in Andvord Bay, a typical northern WAP fjord. We developed automated color-recognition methods to quantify phytodetritus on the seafloor and measured fecal cast production by the dominant deposit feeder, an ampharetid polychaete. An intense phytodetritus pulse led to a rapid, 5-fold increase in deposit-feeding rate, indicating tight coupling between plankton blooms and benthic detritivores in the fjord. Nonetheless, ampharetids fed throughout the time-series, suggesting that phytodetritus can sustain fjord benthos into winter, consistent with the “foodbank” hypothesis (Mincks et al. 2005). Despite high ampharetid feeding rates, the bulk of phytodetritus was not consumed by deposit feeders but appeared to degrade by microbial processes or macrofaunal not visible in images. This contrasts with similar depths (~500 m) on the open shelf where phytodetritus was consumed rapidly by mobile megafauna (Sumida et al. 2014), highlighting substantial differences in pelagic-benthic coupling and carbon cycling in WAP fjords versus the less productive open shelf.
Exploring Life-cycle Adaptations in a Sympagic Amphipod: Is it Truly Sympagic?

Erin Kunisch¹ (erin.kunisch@uit.no), Magnus Drivdal², Jørgen Berge¹, Bodil Bluhm¹, Malin Daase¹, Rolf Gradinger¹, Haakon Hop¹,², Igor Melnikov⁴, Øystein Varpe³,⁵, Mikko Vihtakari³

¹UiT The Arctic University of Norway, Tromsø, Norway, ²Akvaplan-niva, Tromsø, Norway, ³Norwegian Polar Institute, Fram Centre, Tromsø, Norway, ⁴Shirshov Institute of Oceanology, Moscow, Russian Federation, ⁵University Center in Svalbard, Longyearbyen, Norway

Sea ice supports a diverse range of sympagic species found within brine channels and at the sea ice-water interface. *Apherusa glacialis* (an Arctic gammarid amphipod) is typically found under sea ice and considered an important trophic link between primary producers and upper trophic-level predators. While much is known about its distribution and behavior when associated with sea ice, its potential ability to occur away from sea ice is less clear, and adaptive roles of a pelagic stage have been hypothesized (Berge et al. 2012). Pan-Artic pelagic catch data was analyzed in order to determine the occurrence of *A. glacialis* away from sea ice to better understand how ocean currents can be used for transport to better ice conditions. We found *A. glacialis* present in depth-stratified net hauls (range: 13-3400 meters) throughout the Arctic Ocean, and at different times of year. In Svalbard waters during the polar night, a small number of deep-water net hauls (n=8, range: 200-2000 meters) found gravid females in good body condition. Assuming *A. glacialis* indeed conduct vertical migrations, particle trajectories from a coupled ocean-sea ice model were incorporated to evaluate the possible distribution and migration patterns of this species. We assess how *A. glacialis* might use the Arctic Ocean spatially (both in horizontal and vertical dimensions) and throughout the year, and discuss potential responses and consequences during a period of diminishing sea ice coverage.
Tracing Sources of Carbon: Trophic Web Overlap between Antarctic Seals

Luis Huckstadt¹ (lahuckst@gmail.com), Matt McCarthy², Birgitte McDonald³, Paul Koch⁴, Daniel Crocker⁵, Daniel Costa¹

¹University of California Santa Cruz, Ecology and Evolutionary Biology, Santa Cruz, United States, ²University of California Santa Cruz, Ocean Sciences, Santa Cruz, United States, ³Moss Landing Marine Labs, Moss Landing, United States, ⁴University of California Santa Cruz, Earth and Planetary Sciences, Santa Cruz, United States, ⁵Sonoma State University, Department of Biology, Rohnert Park, United States

We investigated the trophic ecology of two species of Antarctic phocids along the western Antarctica Peninsula: the southern elephant (Mirounga leonina) and crabeater seal (Lobodon carcinophaga) using stable isotope analyses (SIA). Our objectives were

(1) to evaluate what trophic webs of the western Antarctica Peninsula are impacted by these species, and

(2) to accurately define the trophic position (TP) of both species.

Crabeater seals consistently having significant lower values for both δ¹³C and δ¹⁵N than elephant seals. Despite their more restricted spatial ranges, crabeater seals showed larger variability in their isotopic values, likely a result of seasonal shifts in the composition of the coastal phytoplankton community. Using SIA of amino acids we were able to discriminate between three food webs that are impacted by crabeater and elephant seals: a coastal, intermediate and oceanic food web. As predicted, most crabeater seals occupy a coastal trophic web, whereas elephant seals are fueled by both oceanic and coastal trophic webs. Most individuals occupy similar TPs when comparing values within species (TP crabeater seal coastal = 2.12, TP elephant seal oceanic = 3.21), however, the TPs of both species of seals is similar for those individuals in the intermediate trophic web (TP crabeater seal intermediate = 2.96, TP elephant seal intermediate = 3.29), which could indicate krill consumption by elephant seals.
The IceCube Neutrino Observatory as an Instrument for Glaciology

Martin Rongen¹ (rongen@physik.rwth-aachen.de)
¹RWTH Aachen University, III. Physikalisches Institut, Aachen, Germany

The IceCube Neutrino Observatory instruments about 1 km³ of deep, glacial ice below the geographic South Pole with 5160 optical modules to register the Cherenkov light of passing relativistic, charged particles. After discovering a diffuse flux of high-energy cosmic neutrinos in 2013, there is now an on-going search to identify the astrophysical sources.

This effort relies heavily on an ever more precise understanding of the optical scattering and absorption properties of the instrumented ice. In turn IceCube can now provide a unique insight into the glacier which, due to the large distances observed, is in many ways complimentary to ice cores. Most notably we observe a dependence of the scattering length on the propagation direction of the photons, with the direction of least scattering being aligned with the local flow direction of the ice. In this talk a depth dependent measurement of the strength of this anisotropy will be presented and possible explanations of the effect in the context of the distribution of scattering impurities in the crystal fabric are going to be discussed. This contribution is presented on behalf of the IceCube collaboration.
Glacial Dust Sources: Constraints from Radiogenic Isotopes and Raman Mineralogy

Barbara Delmonte1 (barbara.delmonte@unimib.it), Chiara Ileana Paleari1, Sergio Andò1, Biancamaria Narcisi2, Giovanni Baccolo1, Mélanie Baroni3

1University Milano-Bicocca (UNIMIB), Milano, Italy, 2ENEA, Rome, Italy, 3CEREGE, Aix-en-Provence, France

We investigate dust provenance during the last glacial period in central East Antarctica (Dome B) by coupling the radiogenic isotope composition of dust (\(^{87}\text{Sr}/^{86}\text{Sr}, ^{143}\text{Nd}/^{144}\text{Nd}\)) with single-grain Raman mineralogical analyses of a statistically-significant number of dust particles. This latter technique allows identifying mineral species and polymorphs within the samples. Through these two powerful complementary approaches, complemented by microscopic observations, we confirm the southern South American provenance of glacial dust in Antarctica. In addition, for the first time we highlight the important role of the exposed Patagonian continental shelf and glacial outwash plains of southern Patagonia at the time when sea level reached its minimum, as evidenced by the presence of abundant aragonite particles in some samples along with diatom valves of marine benthic/epiphytic species as well as freshwater species living today in the northern Antarctic Peninsula and southern South America (Delmonte et al., 2017). Our study also demonstrates that the variable dust particle sorting recorded in central East Antarctic ice cores reflects transport variability from a unique source area. Thus, through this proxy the evolution of the past atmospheric circulation in central East Antarctica during Holocene is going to be investigated in tandem with local temperature, humidity sources, volcanic forcing and solar activity in the framework of the Franco-Italian SOLARICE ice core project.
Lead Isotopes from the Oldest Two Climate Cycles in the EPICA Dome C Ice Core

Changhee Han1,2 (hch@kopri.re.kr), Laurie J. Burn-Nunes3, Tseren-Ochir Soyol-Erdene4, Yeongcheol Han1, Soon Do Hur1, Paul T. Vallelonga5, Paolo Gabrielli6, Carlo Barbante7, Claude F. Boutron8, Sungmin Hong2

Pb isotopic compositions are recovered from the oldest two glacial-interglacial cycles recorded in the EPICA Dome C ice core on the East Antarctic plateau providing 800,000-year climatic records. This is to trace the origin of the dust that into the Antarctica during the period before the Mid-Brunhes Event (~43 kyr BP). All sample handling and analytical operations were performed inside a Class 10 clean room provided with High-Efficiency Particulate Air (HEPA) multi-staged filtration (Curtin University) and under class 10 laminar airflow bench or booth in class 1000 clean laboratories (KOPRI). Pb isotopic compositions have been determined using thermal ionization mass spectrometry (TRITON, Thermo Scientific). Pb isotopic compositions show variations in changing climate due to relative proportions of mineral dust and volcanic Pb. Similar to previous studies, it was confirmed that the main source of Antarctic dust was Patagonia during glacial period. The results also demonstrate that Pb in EDC ice was influenced by less radiogenic non-crustal Pb when the contribution from volcanic emissions appears to be important. This suggests that radiogenic volcanoes of the Antarctic interior were not active during the period before MBE. Our data also indicate that the source of less radiogenic non-crustal Pb is oceanic island including New Zealand.
Reconstructing atmospheric composition during distinct climate periods is a central focus of ice core research, and incorporation of fluorescent organic matter (OM) characterization is improving our understanding of Earth’s paleoecological history. Polar and alpine ice contain significant records of preserved carbon as OM, thus identifying OM origin and reactive nature become essential targets, not only for atmospheric reconstructions, but also to project potential impacts upon release in a warming climate. We present the OM fluorescent characterizations from Antarctic (West Antarctic Ice Sheet), Arctic (Greenland and Canada), and high alpine (Wyoming, USA) ice cores, encompassing OM fluctuations over long- and short-term time and spatial scales. Variability of ice core OM fluorescence signatures among datasets reflected ecosystem changes as a function of climate. Complex, terrestrially derived fluorescent OM was a signature of the youngest Antarctic and Greenland ice cores only. More-labile fluorescent OM was reported over spatial and temporal scales for all ice cores, indicating simple, low molecular weight, and less aromatic chemical species preserved ubiquitously. Outspreading ice core research to routinely incorporate fluorescent OM characterization in polar and alpine studies is still in its infancy, but has value to the cryosphere community and other aquatic and terrestrial fields as disintegrating icy reservoirs of OM release their contents in a warming climate.
High-resolution Analyses of Black Carbon and Dust in a Greenland Ice Core

Kumiko Goto-Azuma1,2 (kumiko@nipr.ac.jp), Yoshimi Ogawa-Tsukagawa1, Yutaka Kondo1, Remi Dallmayr1,3, Motohiro Hirabayashi1, Jun Ogata1, Kyotaro Kitamura1, Kenji Kawamura1,2, Hideaki Motoyama1,2, Sumito Matoba4, Moe Kadota4, Teruo Aoki5, Nobuhiro Moteki6, Sho Ohata6, Tatsuhiro Mori7, Makoto Koike8, Yuki Komuro8, Akane Tsushima8, Naoko Nagatsuka1

An ice core to the depth of 225 m was drilled at the SIGMA-D site, Northwest Greenland, in 2014 under the SIGMA (Snow Impurity and Glacial Microbe Effects on Abrupt Warming in the Arctic) project (Matoba et al., 2015). We analyzed the ice core to the depth of 113 m using a Continuous Flow Analysis (CFA) system, which was recently built at the National Institute of Polar Research (NIPR), Japan. The NIPR CFA system allows high resolution analyses of black carbon (BC), stable isotopes of water, microparticles, electric conductivity, and trace elements (Na, K, Mg, Ca, Fe, and Al). We used a recently developed Wide-range SP2 (Single Particle Soot Photometer, Droplet Measurement Technologies) for BC analysis. While a normal SP2 detects BC particles in the size range between 70 and 800 nm, the Wide Range SP2 enabled us to detect BC particles in the size range between 70 and 4000 nm (Mori et al., 2016).

Here we report the variability of BC and dust species over the past 350 years. BC concentrations started to increase in the 1890s, reached its maximum in the 1930’s - 1940’s, and decreased again since then. The increase is likely due to anthropogenic input. We also find anthropogenic changes in size distribution of BC as well as seasonality. Dust-originated species Ca, Fe and Al show higher concentrations during the first half of the 19th Century, which might be related to cooler climate during that period.
A Comprehensive Study of the Drivers of Surface Snow Isotopes in Greenland

Hans Christian Steen-Larsen1 (hanschr@gfy.ku.dk), Maria Hoerhold2, Martin Madsen3, Sepp Kipfstuhl2, Jason Box4, Anne-Katrine Faber5, Diana Vladimirova3, James White6, Emilie Capron3, Mari Jensen5, Iben Koldtoft3, Kerim Nisancioglu5, Helen Pilar3

1University of Bergen, Geophysical Institute & Bjerknes Centre for Climate Research, Bergen, Norway, 2Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, 3Center for Ice and Climate, Niels Bohr Institute, University of Copenhagen, Copenhagen, Denmark, 4Geological Survey of Denmark and Greenland, Copenhagen, Denmark, 5University of Bergen & Bjerknes Centre for Climate Research, Bergen, Norway, 6University of Colorado at Boulder, INSTAAR, Boulder, United States

Ice cores from polar ice sheets can be used to reconstruct past climate. However, an increasing number of studies highlight the influence of post-depositional processes altering the isotopic composition of surface snow on top of polar ice sheets. These processes are not accounted for by interstitial molecular diffusion and redistribution of snow and will influence the mean annual isotopic composition of the ice core record and hence the paleo-climate interpretation.

To quantify these drivers we carried out a comprehensive study of surface snow and water vapor isotopes at the new deep drilling site in North-East Greenland, EastGRIP. To balance the water stable isotope budget of the surface snow we combine precipitation and daily snow surface and sub-surface isotope observations with water vapor isotope flux measurements obtained from eddy-covariance and near-surface atmospheric vapor isotope-gradient measurements.

These combined observations document snow fractionation during sublimation resulting in an enrichment of the snow surface isotopes. Further, we observe that the change in the snow surface isotopes during clear-sky days is comparable to the estimated cumulative water vapor isotope flux. This gives us confidence that we can balance the water isotope budget for the snow surface and conclude that post-depositional processes are influencing the deposited mean snow isotopic composition, specifically the second order isotope parameter, the d-excess.
Exploring the Feasibility of a Sea-ice Satellite Simulator

Clara Burgard\textsuperscript{1} (clara.burgard@mpimet.mpg.de), Dirk Notz\textsuperscript{1}, Rasmus Tonboe\textsuperscript{2}, Leif Toudal Pedersen\textsuperscript{3}
\textsuperscript{1}Max Planck Institute for Meteorology, Ocean in the Earth System, Hamburg, Germany, \textsuperscript{2}Danish Meteorological Institute, Copenhagen, Denmark, \textsuperscript{3}Technical University of Denmark, Copenhagen, Denmark

Sea-ice concentration is usually retrieved from satellite by analysing surface passive microwave brightness temperatures. However, different algorithms, based on slightly different assumptions, result in different values for the retrieved sea-ice area. Not knowing which of these retrievals is closest to reality has consequences for both model evaluation and model initialization for seasonal hindcasts.

In our study, we investigate the drivers of sea-ice microwave surface brightness temperatures. This is a first step to assess the possibility to obtain synthetic brightness temperatures from the output of a General Circulation Model (GCM). Ultimately, comparing simulated to observed brightness temperatures could remove the uncertainty introduced by a satellite retrieval algorithm and might hence allow for a more reliable evaluation of both GCMs and retrieval algorithms.

As brightness temperatures are a combination of emissions by different media (sea ice, ocean, snow, atmosphere), we explore the importance of various parameters for simulating realistic brightness temperatures. Using a thermodynamical ice model combined with an emission model, we conduct sensitivity experiments to understand which simplifications of the vertical temperature and salinity profiles in the ice most strongly affect the simulated brightness temperature. First results suggest that simplifying the salinity profiles introduces the largest error into the simulated brightness temperature.
Process-informed Modelling of the Sea Ice Floe Size Distribution

Lettie Roach\textsuperscript{1,2} (lettie.roach@niwa.co.nz), Samuel Dean\textsuperscript{1}, Christopher Horvat\textsuperscript{1,3}, Madison Smith\textsuperscript{4}, Cecilia Bitz\textsuperscript{5}
\textsuperscript{1}NIWA, Wellington, New Zealand, \textsuperscript{2}Victoria University of Wellington, Wellington, New Zealand, \textsuperscript{3}Brown University, Providence, United States, \textsuperscript{4}University of Washington, Applied Physics Lab, Seattle, United States, \textsuperscript{5}University of Washington, Atmospheric Sciences, Seattle, United States

The lateral size of sea ice floes is receiving increasing attention as an important variable for the polar climate system. Sea ice floe size distributions, which can include floe sizes orders of magnitude smaller than the grid resolution, can now be simulated in global sea ice models. This allows inclusion of additional model physics, including alternative sea ice growth pathways and fracture of ice by ocean surface waves. Floe size distributions are difficult to observe at sufficiently high resolution and sufficiently large spatial and temporal scales for global model validation. However, individual model processes can be observationally constrained. Here, we present results from a model-motivated observational study from images captured by wave buoys in the autumn Arctic Ocean.

These results inform our implementation of a joint sea ice floe size and thickness distribution in the Los Alamos sea ice model, CICE, coupled to a dynamic ocean. Our process-based approach to model development allows us to investigate the impacts of each process individually. We find a strong contribution of sea ice growth processes to power-law behaviour in the floe size distribution. A key remaining question is whether such alterations to model physics affect larger-scale sea ice properties. We will present coupled model results that investigate this question, and discuss future possible work that may cause significant impacts on the polar climate system.
Physics of Refreezing Melt Ponds in CICE

Lucia Hosekova1 (l.hosekova@reading.ac.uk), Danny Feltham2, David Schroeder1, Daniela Flocco1
1University of Reading, Department of Meteorology, Reading, United Kingdom

Realistic representation of melt ponds in sea ice models has been demonstrated to have a significant impact on summer melts by enhancing the albedo feedback mechanism. In addition to this effect, it has been shown that melt ponds play a role in delaying the winter basal growth of sea ice during the period of melt pond refreezing. In order to assess the impact of these processes on Arctic variability and predictability in sea ice models, one needs to be able to correctly represent the temperature profile throughout the ice layer during and after the formation and refreezing of trapped ponds. We present a modification of the vertical thermodynamics and melt pond scheme in CICE that allows us to model multiple concurrent phases relevant to melt pond physics (i.e. the refreezing pond, ice beneath the pond, the ice lid) with a goal to realistically account for the heat transfer and heat storage of refreezing melt ponds, and test its ability to provide more skillful sea ice predictions of the summer sea ice extent.
New Insight from CryoSat-2 Sea Ice Thickness for Sea Ice Modelling

David Schroeder¹, Michel Tsamados² (m.tsamados@ucl.ac.uk), Daniel Lee Feltham¹, Andrew Ridout², Rachel Tilling³

¹Reading University, Reading, United Kingdom, ²University College London, London, United Kingdom, ³Leeds University, Leeds, United Kingdom

Estimates of Arctic sea ice thickness are available from the Cryosat-2 radar altimetry mission during the ice growth seasons since 2010. We derive the sub-grid scale ice thickness distribution (ITD) with respect to 5 ice thickness categories used e.g. in the sea ice component CICE of HadGEM3 climate simulations. This allows us both to verify the simulated cycle of ice thickness and to initialize the ITD in stand-alone simulations with the sea ice model CICE. We find that a default CICE simulation strongly underestimates the ice thickness, in spite of doing a reasonable job regarding the inter-annual variability of summer sea ice extent. We can identify the underestimation of winter ice growth being responsible and show that using ice and snow conductivity values on the upper end of the observed range makes sea ice growth more realistic and generally improves the model simulation. Sensitivity studies provide insight on the role of ice strength, momentum and heat turbulent fluxes on the annual cycle of sea ice thickness. We show that the width of ITD plays an important role for the summer lead fraction and basal ice melt. Furthermore, a major discrepancy is revealed regarding the annual cycle of sub-grid scale thick sea ice. According to Cryosat-2 there is a strong formation of thick ice during winter, but hardly any thick ice survives the summer. CICE simulations only show a weak seasonal cycle, indicating that both the formation and the melting of thick is underestimated.
The ice component of the ACCESS-CM2 climate model has been updated in preparation for the CMIP6 experiments with multi-layer ice thermodynamics and pond dynamics that were provided by the UK Meteorological Office Hadley Centre with the Unified Model (UM) upgrade that has been adopted in the atmospheric component of the coupled model. The sea ice model used is the CICE5.1 model from Los Alamos with adaptions to couple to the UK Met office atmospheric model and it is coupled to the MOM5 GFDL Ocean GCM. The Southern ocean has a warm bias which has been reduced over the latest upgrades of UM atmospheric model, however, the ACCESS-CM2 model still does not have extensive enough ice cover in the Antarctic winter, and the ice does not survive the summer season. This is due to the summer ocean mixed layer being too shallow in the MOM ocean model compared to the NEMO ocean model used by the MOHC and we have tested a number of ocean mixing schemes in an attempt to improve our summer ice results. Another sensitivity test we have done is to include the effect of the fresh water land ice flux from the UM in the form of a pseudo iceberg flux which has been implemented as a freshwater and latent heat loss from the ocean in a region of the coast off Antarctica and Greenland though avoiding the key bottom water formation areas. Early results from these tests have allowed the ice to survive through the summer season and gives more realistic autumn ice extents in the model.
A Robust Solver for Viscous Plastic Sea Ice Models in a Finite Element Framework

Carolin Mehlmann¹ (carolin.mehlmann@ovgu.de), Thomas Richter²

¹Universität Magdeburg, Magdeburg, Germany

Subject of this talk are the mathematical challenges and the numerical treatment of large scale sea ice problems. The model under consideration goes back to Hibler (Hibler 1979) and is based on a viscous-plastic description of the ice as a two-dimensional thin layer on the ocean surface.

We present a new efficient Newton solver. The idea of the solver is to combine a fixed-point iteration (Picard solver) with a Newton method. We analytically derive the Jacobian and show its positive definiteness. The positive definiteness guarantees global convergence of a properly damped (e.g. line search) Newton iteration. The Jacobian is split into a positive definite part, which is assumed to give stable convergence and a negative semidefinite part, which might be troublesome. The negative semidefinite part is adaptively damped if convergence worsens and the Newton solver turns towards a Picard iteration. We show the improved robustness of the modified Newton solver and compare it to a full Newton scheme. In every Newton step a linear system of equations must be solved. We introduce a geometric multigrid solver as preconditioner to accelerate the solution of the linear problems.

How Nations Research, Collect and Communicate their Antarctic History

Ursula Rack\(^1\) (ursula.rack@canterbury.ac.nz)

\(^1\)Canterbury University, Gateway Antarctica, Christchurch, New Zealand

This paper will illustrate results from research on how to communicate the past in order to keep the balance among national efforts, the international importance of Antarctic history, and today’s Antarctic activity on the southern continent. The research was made possible due to the New Zealand Winston Churchill Memorial Fellowship 2018, which I was awarded in order to investigate how nations research, collect and communicate their Antarctic history. The Fellowship award allowed me to work in the USA, the UK and Germany, in order to examine archives and museums, to understand outreach programs to bring awareness of the Antarctic history, so to understand the importance of the Antarctic to each of those nations. Many of the current National Antarctic Programs have their foundations on this history. New countries are now participants in the Antarctic research community, and there is a need for them to be aware of their own history in that regard. The wider public too plays a role, as, often, the general public are not conscious of their own history. Museums play a great part in education and in communicating the past so that people can understand developments in the present. Personal stories, sometimes collected in oral history programs, diaries, photos and artifacts are a great resource that can be used to connect with the wider public.
Doing research in Antarctica turned out to be a difficult task. We started using a sailing boat (the 47-feet ketch *Callas*) in 1994. It was quite an adventure. Still, the size of the sailing boat did not allow us to take the necessary equipment on board. Our aim was finding the sunken and abandoned ships of whalers that sailed around the Antarctic Peninsula (Le Maire and Gerlache straits) between 1906 and 1930. We conducted a mapping. Then, we organized other voyages aboard the *Irizar*, an icebreaker of the Argentine Navy. This was equipped with all we needed, but it is so big that we could not approach sites. Then came voyages on tourist icebreakers - the *Academik IOFFE* and the *MIKIEV*. This only served to visit new places. Thanks to a group of businessmen that bought a small icebreaker at Moss (148 feet long), a joint venture was made with the National Naval Museum, the Maritime Museum of Ushuaia, the Antarctic Museum José Maria Sobral, and the Itinerant Museum *Ice Lady Patagonia*. Expeditions were conducted until 2007. The Museum heritage was increased. And now we got the final results involving six partners: a new museum, and cooperation among museums and research institutes resulted in books, TV cartoons, and magazines for students. These engaging materials inspire and educate citizens on polar regions and their issues.
Antarctic Legacy of SA Collaborates to Celebrate South Africa’s Polar Heritage

Anche Louw¹ (anchelouw072@gmail.com)
¹University of Stellenbosch, Botany and Zoology, Stellenbosch, South Africa

In 2017 the Antarctic community celebrated International Polar Week from the 18th to the 24th of September, together with all involved in polar research over the world. South Africans also celebrate our rich heritage in September, whereby we celebrate the various cultures that constitute our heritage. ALSA (Antarctic Legacy of South Africa) saw this as an opportunity and coincided heritage and Polar Week celebrations by creating the slogan ‘Celebrating SA’s Polar Heritage’.

South Africa has a rich Polar Heritage, due to our involvement in Antarctica (SANAE Base) since 1959 and in the sub-Antarctic since 1947 when the Prince Edward Islands became South African territory. ALSA plays a crucial role in archiving this history and was invited to exhibit SA’s Polar Heritage at the Iziko Museum of South Africa in Cape Town in September when we celebrated our Polar Heritage. Celebration efforts was focussed on the Marion Island Exhibition in the Iziko Museum, enabling ALSA to fulfil the role of preserving and promoting South Africa’s involvement in the Polar region.

This presentation will focus on the role of ALSA to collaborate with the Iziko Museums of South Africa in promoting polar heritage and advancing polar science in South Africa.
Polar Lab: Connecting Across Borders

Julie Decker¹ (jdecker@anchoragemuseum.org)
¹Anchorage Museum, Executive, Anchorage, United States

The Anchorage Museum’s Polar Lab program connects across disciplines and across the Circumpolar North. Focusing on people and the environment, the Museum works with artists, designers, scientists, historians, social scientists, Indigenous communities and others to examine a complex and changing landscape. The Arctic region is changing rapidly, in ways that dramatically affect people’s lives and ecosystems. Polar Lab places the museum in the role of a convener, to operate across sectors and disciplines. The Museum brings designers and scholars from Alaska and around the world to the Arctic landscape for long-term, multi-year research projects that connect to scientific research and Indigenous knowledge related to the environment. By supporting non-traditional research, we create new investigations, new collaborations, and new knowledge, that is informed by centuries of adaptation. Current artists, designers and scholars-in-residence through Polar Lab are investigating everything from the global migration of Arctic terns, pingos, place names and language, polar bear dens, food security, changes to Arctic animal species, walruses, timekeeping in remote places, and other areas that enrich our understanding of place and environment. This presentation will explore the role of museums in polar heritage and advancing polar science through non-traditional collaborations and residencies and bold programs that redefine standard museum practice.
The Centre for Arctic Knowledge & Exploration at the Canadian Museum of Nature

Jeffery M. Saarela¹ (jsaarela@mus-nature.ca)
²Canadian Museum of Nature, Centre for Arctic Knowledge & Exploration, Ottawa, Canada

For over 100 years, the Canadian Museum of Nature (CMN) has been a leader in exploring and documenting the natural history and natural science of Canada’s Arctic. Today, the museum's Centre for Arctic Knowledge & Exploration (CAKE) aims to transform people’s understanding of Canada’s Arctic and to position the CMN as a global museum leader in Arctic knowledge and exploration. The CAKE is an interdisciplinary hub dedicated to research, collections development and care, data sharing, public programs, exhibits, galleries, and mentoring of students. Current Arctic research programs focus on Arctic biodiversity in botany, phycology, palaeontology, and invertebrate and vertebrate zoology. A core function of the museum is the collection, preservation, stewardship and curation of natural history specimens, facilitating access to these specimens, and using the collection to engage and educate the public. Among the 14.6 million specimens housed by CMN are about 260,000 Arctic specimens, the largest natural history collection from the Canadian Arctic. These collections represent a substantial component of the global Arctic natural history record. The CMN recently opened the signature Canada Goose Arctic Gallery, comprising sections about Arctic geography, ecosystems, sustainability and climate change, and including the Northern Voices Gallery, which provides an opportunity for Northern communities to share their own perspectives about the Arctic and their relationship with the land.
Museums and other natural history collections (NHCs) worldwide house millions of specimens, contributing to science in a variety of ways. Given the expected environmental changes that will likely affect Antarctica, NHCs of Antarctic organisms will become increasingly important in the future. In order to provide a good service to the scientific community, all the materials stored and curated by Antarctic NHCs should be made accessible and available, virtually leaving 'no jar behind'.

With this idea in mind, at the Italian National Antarctic Museum (MNA, Section of Genoa), the institution hosting all the biological materials collected by the Italian PNRA, we have pinpointed five operational targets to accomplish this mission: i) give a name to all the species/specimens present in our collections (~20,000 units); ii) validate and publish distributional records in form of datapapers (e.g. in Zookeys); iii) publish all the available images in the Antarctic Field Guide (http://afg.biodiversity.aq), iv) provide a freely accessible database of DNA sequences from museum materials and v) publish a synthesis on the “Marine, Terrestrial and Limnetic fauna and flora of Terra Nova Bay” (3 volumes). By following these steps (some of which already accomplished), all the materials stored at the MNA and related information will be made permanently available to the scientific community. The synthesis volumes will summarize more than 30 years of Italian research in the Terra Nova Bay area.
Antarctica has long been considered to be biologically isolated. Indeed, many Antarctic organisms are endemic, found nowhere else on the planet, and many have probably remained and evolved in the Antarctic for millions of years. Yet molecular studies are starting to show some post-Gondwanan biological connections between Antarctica and other parts of the world, suggesting that - at least occasionally - movement into and out of Antarctica has occurred. Recent observations of floating marine organisms drifting on either side of the Antarctic Polar Front also challenge the assumption that the Southern Ocean is an impassable barrier to dispersal.

In this talk, I will present evidence that Antarctica is not biologically isolated - that organisms can, and frequently do, cross the Southern Ocean and reach Antarctica. The unique ecosystems of Antarctica are therefore probably more a consequence of environmental extremes in the region than of isolation. With global warming, we should expect to see successful establishment of numerous non-Antarctic species, even without human-mediated transport of organisms to the region.
Circumpolar assessments of change in the Southern Ocean ecosystem have been advancing over the last two decades. The Census of Antarctic Marine Life during the International Polar Year (leading to the SCAR Biogeographic Atlas of the Southern Ocean) and Southern Ocean GLOBEC made substantial progress in unifying approaches to characterising these ecosystems. The Fifth Assessment Review by Working Group II of the IPCC highlighted that long term observations to measure ecosystem change are a priority. To date, long-term whole-of-system biological observations in the Southern Ocean have been mostly concentrated in the Antarctic Peninsula and Scotia Arc. The scientific communities of IMBER’s ICED program, the Southern Ocean Observing System and SCAR Life Sciences have been designing a program of work to advance these earlier programs to have sustained circumpolar measurements of the Southern Ocean ecosystem for assessing change. A program of co-ordinated circumpolar measurements of the ecological state of the ecosystem in 2022-2023 is to be considered at the MEASO2018 conference in April 2018. The plans arising from these discussions will be summarised in this presentation on behalf of contributors so far, with invitations to participate in further coordination and implementation of the program along with synthesis of results.
Comparing Methods for Ecoregionalisation using Sub-Antarctic Demersal Fish

Nicole Hill¹ (nicole.hill@utas.edu.au), John McKinlay², Scott Foster³, Piers Dunstan³, Skipton Woolley³, Dirk Welsford², Craig Johnson¹
¹University of Tasmania/Institute for Marine and Antarctic Studies, Hobart, Australia, ²Australian Antarctic Division, Kingston, Australia, ³Commonwealth Scientific and Industrial Research Organisation (CSIRO), Hobart, Australia

Understanding the distribution of species and their relationship with the environment is a central goal in ecology. Mapping these patterns also facilitates ecoregionalisation, the delineation of ecologically meaningful spatial units to assist the planning and evaluation of management and conservation options. Statistical models that link sparse biological data with more prevalent environmental data are fundamental in modelling and mapping species' distributions and have successfully been used for key species in the Southern Ocean. However, a suite of recently developed statistical methods identify and model patterns in the distribution of multi-species assemblages; thus facilitating ecoregionalisation. We briefly review these methods, which encompass algorithmic distance-based, machine learning, and GLMs with latent variables. Methods also differ in how they define assemblages and predict into geographic space. We apply a selection of these methods to a sub-Antarctic demersal fish dataset, comparing the resulting ecoregions and their interpretation in light of our knowledge of this region. We discuss the relative dis/advantages of the approaches from a statistical, ecological and pragmatic viewpoint. Taking into account the role of ecoregionalisation in conservation management, we recommend the methods most appropriate to particular circumstances in describing and capturing the relationships between environment and species distributions in the Southern Ocean.
Response of Antarctic Krill to Rapid Regional Warming over the Last 90 Years

Angus Atkinson¹ (aat@pml.ac.uk), Simeon Hill², Evgeny Pakhomov³,⁴, Volker Siegel⁵, Christian Reiss⁶, Valerie Loeb⁷, Deborah Steinberg⁸, Frances Perry¹, Katrin Schmidt⁹, Geraint Tarling², Laura Gerrish⁷, Sevrine Sailley¹
¹Plymouth Marine Laboratory, Plymouth, United Kingdom, ²British Antarctic Survey, Cambridge, United Kingdom, ³University of British Columbia, Department of Earth, Ocean & Atmospheric Sciences, Vancouver, Canada, ⁴Hakai Institute, Vancouver, Canada, ⁵Theunen Institute of Sea Fisheries, Hamburg, Germany, ⁶Southwest Fisheries Science Center, La Jolla, United Kingdom, ⁷Moss Landing Marine Labs, Moss Landing, United Kingdom, ⁸Virginia Institute of Marine Science, Gloucester Point, United States, ⁹University of Plymouth, Plymouth, United Kingdom

Productive, high latitude ecosystems comprise some of the fastest warming marine habitats on the planet. Stenothermal polar species might be sensitive to rising temperatures and loss of sea ice, but solid evidence is still scarce and conflicting. Long-term, temporal-spatial coverage is a key to understanding climate change responses, and Euphausia superba is one of the very few species with the necessary intensity of sampling, due to its role in commercially exploited food chains. Within the KRILLBASE project we have rescued and compiled all available net sampling data on krill spanning the period 1926-2016. KRILLBASE now comprises three databases, on abundance of the larval stages, on postlarval abundance and on postlarval length, sex and maturity stage. This has allowed a comprehensive analysis of long-term trends in abundance, distributional range and body size. We have identified a strong bottom-up control on krill population dynamics, with the Southern Annular Mode (SAM) influential in modulating recruitment across the SW Atlantic sector. This presentation will discuss the implications of the ongoing trends that we are observing, in the context of future access to spawning grounds, linkages to the rest of the food web, biogeochemical cycling and fisheries management.

Climate Model Projections of under Ice Habitats for Antarctic Krill Larvae

Stuart Corney¹, Jess Melbourne-Thomas¹,², Klaus Meiners¹,², Rowan Trebilco¹, Roshni Subramaniam³ (roshni.subramaniam@utas.edu.au), Andrew Constable¹,²
¹Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia, ²Australian Antarctic Division, Hobart, Australia, ³University of Tasmania, Institute of Marine and Antarctic Studies, Hobart, Australia

Overwintering of larvae underneath Antarctic pack ice is an important stage in the life cycle of Antarctic krill. Previous work based on simplified climate change scenarios has demonstrated that simple assumptions for the important characteristics of under ice habitats for larval krill can reveal surprising predictions for available habitat under climate change: reductions in overall ice extent may not necessarily lead to less larval krill habitat. Here we extend that approach using the ensemble of CMIP5 models. Despite variability in future projections (and varying model skill in representing ice), all models project a significant decrease in sea ice cover over the coming century across a range of scenarios. However, even at the resolution of GCMs, reductions in total area do not necessarily lead to reductions in projected habitat. In this presentation, we consider some of the regional differences in projected habitat change, including considering whether strength of dependence of larval krill on winter sea ice may vary between regions of Antarctica. We also discuss limitations to using GCM output for such analyses; specifically, that required variables are not retained from runs of most models. We suggest that better dialogue between climate modellers and ecologists will help maximise the utility of future GCMs for understanding the ecological implications of physical changes.
Sea Ice Dynamics on West Antarctic Peninsula Underlying Ecosystem Alterations

Oscar Schofield\(^1\) (oscar@marine.rutgers.edu), Hugh Ducklow\(^2\), Josh Kohut\(^3\), Deborah Steinberg\(^4\), William Fraser\(^5\)

\(^1\)Center for Ocean Observing Leadership, COOL, Marine and Coastal Sciences, Rutgers, New Brunswick, United States, \(^2\)Columbia University, Lamont-Doherty Earth Observatory, Palisades, United States, \(^3\)Rutgers University, Marine and Coastal Sciences, Rutgers, New Brunswick, United States, \(^4\)Virginia Institute of Marine Science, Gloucester Point, United States, \(^5\)Polar Oceans Research Group, Sheridan, United States

The sea ice of the West Antarctic Peninsula (WAP) has experienced significant change over the last fifty years. Using 25-year spatial time series collected by the Palmer Long Term Ecological Research program, we assess long-term patterns in sea ice, upper mixed layer depth and food web dynamics (phytoplankton, zooplankton, higher trophic levels). Over decadal time scales, the heating on the WAP has been driven by subsurface intrusions of the warm Antarctic circumpolar current onto the shelf that is topographically steered to the coast terminating in regions of abundant penguin colonies presumably fueled by high productivity phytoplankton blooms. Sea ice has steadily declined from the 1980’s until a recent reversal that began in 2008. In the southern WAP, upper ocean mixed layer depth has shallowed significantly and associated with the shallower mixed layer is enhanced phytoplankton carbon fixation. Associated with the recent increases in sea ice has been a large increase in the photosynthetic efficiency in both the northern and southern. Using a decade of glider data, shallower mixed layers appear to promote phytoplankton blooms. There was significant inter-annual variability in phytoplankton blooms, but high chlorophyll years, associated with diatoms, were associated with high krill recruitment suggesting a tightly coupled ecosystem and strong bottom-up control of the food-web. Results demonstrate the close fidelity between the biology and physics on the WAP.
Diisopropynaphthalene in Sediments of Arctic Fjord: Environmental Significance

Neelu Singh¹ (neelu.singh0387@gmail.com), Rajan Sivaramakrishnan², Krishnaiah Chikkamadaiah³
¹National Centre for Antarctic and Ocean Research (ESSO-NCAOR), Vasco da Gama, India, ²Indian National Center for Ocean Information Services, Pragathi Nagar, India, ³Mangalore University, Mangalore, India

This study addresses the tracking of the presence of a synthetic aromatic compound, diisopropynaphthalene (DIPN) in the surface sediments of Kongsfjorden, an Arctic fjord fringing the International Arctic Research Facilities of Ny-Ålesund, Svalbard. Increasing anthropogenic impacts in the form of Persistent Organic Pollutants (POPs), related to human activities and increased use of fossil fuels have been observed at many places along the Arctic regions. Our studies suggest that the source of DIPN to the fjord could be a result of human activities at Ny-Ålesund and its environs. While its present-day concentrations may not be alarming, considering the increasing activities at Ny-Ålesund, it might be prudent to exercise caution to ensure that the levels do not increase over time. This is the first such report of DIPN in the sediments of Kongsfjorden.
Recent data indicate accumulation areas of marine litter in Arctic waters and significant increases on the seafloor over time. Beaches on remote Arctic islands may be sinks for marine litter and reflect pollution levels of the surrounding waters particularly well.

We provide the first quantitative data from surveys carried out by citizen scientists, which participated in sailing cruises around Svalbard in 2016. Litter quantities on six beaches varied from 9 - 524 g m-2 and were similar to those from densely populated areas. Plastics accounted for > 80% of the overall litter, most of which originated from fisheries. Photographs provided by citizens show deleterious effects of beach litter on Arctic wildlife including polar bears (Ursus maritimus), which is already under strong pressure from global climate change. Our study highlights the potential of citizen scientists to provide scientifically valuable data on the pollution of sensitive remote ecosystems. Similar programmes could be adopted in other poorly sampled areas of the world to increase our knowledge base and to stimulate a sense of connectedness with the environment visited.
Perchlorate in Surface Snow along a Traverse Route in East Antarctica

Su Jiang¹ (jiangsu@pric.org.cn), Jihong Cole-Dai², Yuansheng Li³, Chunlei An¹, Guitao Shi¹
¹Polar Research Institute of China, Shanghai, China, ²South Dakota State University, Brookings, United States

Perchlorate in the environment is of significant interest because of potential threat to human health. Recent research suggests that perchlorate is naturally formed in the atmosphere and atmospheric formation constitutes a significantly large portion of perchlorate in the current environment. By virtue of its geographical position and meteorological conditions, Antarctic ice sheet provides chronological records for atmospheric deposition of different substances. Surface snow samples collected along a traverse route from Zhongshan Station to Dome A in East Antarctica were used to assess the spatial variability of perchlorate along the traverse route, to explore possible sources of perchlorate in Antarctic snow and to determine what atmospheric and glaciological factors influence spatial variability of perchlorate in snow. Results show that the perchlorate concentrations vary between 32 and 200 ng kg⁻¹, with an average of 104.3 ng kg⁻¹. Perchlorate concentration profile presents an apparent decreasing relationship with increasing distance inland in the coastal region and a generally increasing trend approaching the dome in the inland region. Perchlorate in Antarctic snow is probably formed in the atmosphere and deposited in snow. Different rates of atmospheric production, dilution by snow accumulation and re-deposition of snow-emitted perchlorate (post-depositional change) are the three possible factors influencing the spatial variability of perchlorate over Antarctica.
High Altitude Lake Environments: Sinks for Chemical Pollutants?

Julia Kleinteich¹ (julia.kleinteich@ifg.uni-tuebingen.de), Sven Seidensticker³, Kurt Hanselmann², Andreas Kappler², Elif Koeksoy¹, Jens Brückmann¹, Maria-De-Lourdes Prieto-Espinoza¹, Maria Schindler¹, Nelly Wang¹, Christiane Zarfl¹

¹University of Tuebingen, Center for Applied Geosciences, Tübingen, Germany, ²ETH Zurich, Microbial Ecology, Zürich, Switzerland

The melting of alpine glaciers mobilizes compounds from anthropogenic origin such as persistent organic pollutants that had been stored in the perennial ice for the last decades. Similarly, hydrophobic polyaromatic hydrocarbons (PAHs), which are potentially carcinogenic and are released by combustion processes, are compounds with the potential for long range transport to remote regions. These compounds that were released decades ago may now be found in glacier ice and glacial streams. Since glacier-fed meltwater often passes through several smaller and larger lakes in alpine glacier forefields, the hydrophobic PAHs can be retained in the sediments of these lakes. We hypothesize that these sites serve as sinks for PAHs. During two field seasons and at three different glaciers we quantified the concentrations of PAHs in sediments of lakes along spatial gradients from the glaciers. We found PAHs in all samples, albeit in the lower concentration range and three orders of magnitude less than in polluted streams in Germany. PAH concentrations decreased with increasing distance from the glacier. Contrary to our hypothesis, we found higher concentrations of PAHs in lakes, which were not directly fed by glacial meltwater but by snowmelt, rain and permafrost. This may be caused by the temporal dynamics of input rates, the age of the lakes, but also due to other biotic and abiotic factors that influence PAH distribution, such as the sediment composition and bacterial degradation.
Air Dispersion Modeling Application for Impact Assessment in the Antarctic

Sergey Kakareka¹ (sk001@yandex.ru), Svetlana Salivonchyk¹
¹Institute for Nature Management, National Academy of Sciences of Belarus, Minsk, Belarus

In the paper modelling results of air impacts of Mount Vechernyaya Belarusian Antarctic station using AERMOD as well as available from Comprehensive Environmental Evaluations (CEE) of construction and operation of the Antarctic research stations are considered. It is shown that emission dispersion models application for impact assessment in Antarctica is limited: from 12 known cases of air impact assessment for CEE no dispersion modeling was done in 6 cases; ICS3 model was applied in 2 cases; SYMOS97, OND-86 and AERMOD were applied in other 4 cases. Among these results both short-term and long-term predicted concentrations were obtained only for two stations: Jang Bogo Station, Korea and Mount Vechernyaya, Belarus. There is a number of reasons of such limited application, first of all high time- and resource-consuming and lack of input data. But more wide application of dispersion modeling in impact assessment in Antarctica is important as it allows to get qualitative estimates of impacts and make projections.

Study have shown that taking into account restrictions it is possible to provide acceptable accuracy of pollution dispersion model results, applying non-standard methods of interpolation of meteorological data. Air dispersion can be combined with geochemical models for analysis of pollutants migration in soils and waters and estimation of critical loads and thresholds. Possibilities of retrospective modelling for estimation of cumulative impacts is also discussed.
This work reports the analysis of 4.5 m pit sampled under ultra-clean conditions on the King George Island ice cap (62°07'42.2"S and 58°36'39.9" W, 700 m a.s.l.), collected in 1997 and representing one year of snow accumulation. We analysed 25 samples for trace elements, ionic content and stable isotopes in a site that suffers intense post-depositional phenomena, with superficial melting, followed by percolation and refreezing. Here we evaluate the anthropogenic and natural contributions for the concentrations in 47 trace elements, determined by ICP-MS at the Laboratoire des Mecanismes et Transferts en Geologie in Toulouse (France). The crustal enrichment factors are low for Al, Si, Ti, V, Cr, Mn, Fe, Co, Ga, Ge, Zr, Nb, Cs, Ba, Ce, Nd, Sm, Tl, Pb, and Bi and the ocean enrichment factors are low for Na, Mg, Cl, K, Br, Sr, and I. The elements Li, C, P, S, Sc, Rb, Ta, and U show mixed source (crustal and oceanic) and contributions of volcanic and/or biogenic source. Ni (129.29 ± 163.48 pg g⁻¹), Cu (93.51 ± 106.26 pg g⁻¹), Zn (214.76 ± 124.14 pg g⁻¹), As (8.93 ± 7.54 pg g⁻¹), Se (63.10 ± 42.37 pg g⁻¹), Mo (10.18 ± 3.63 pg g⁻¹), Ag (6.38 ± 6.79 pg g⁻¹), Cd (399.36 ± 880.65 pg g⁻¹), Sn (17.65 ± 10.99 pg g⁻¹), Sb (4.17 ± 3.51 pg g⁻¹), W (15.74 ± 11.05 pg g⁻¹) and Hg (1.19 ± 0.71 pg g⁻¹) show high enrichment factors, suggesting anthropogenic inputs and/or local contamination.
Fri_8_EN-2_411
PBDEs vs Biological Traits in *Boreogadus saida* from NE Greenland

Alice Marri¹, Kim Præbel², Alessandra Cincinelli¹, Tania Martellini³, Davide Baroni¹, Simonetta Corsolini¹
(simonetta.corsolini@unisi.it)
¹University of Siena, Department of Physics, Earth and Environmental Sciences, Siena, Italy, ²UiT The Arctic University of Norway, Norwegian College of Fishery Science, Tromsø, Norway, ³University of Florence, Department of Chemistry ‘Ugo Schiff’, Florence, Italy

Polybrominated diphenylethers (PBDEs) are flame retardants used worldwide. Their physical-chemical properties allow them to reach the Polar Regions and enter into the food webs. *Boreogadus saida* is a key species in high Arctic marine ecosystems, connecting lower and higher trophic levels in the food web. In NE Greenland *B. saida* forms populations with differentiated life histories in fjords and offshore waters, respectively. The main aim of this study was to elucidate whether PBDEs accumulate differentially in these populations. We collected *B. saida* specimens inside a fjord (Scorebysund Fjord, n=50) and at the NE Greenland continental shelf (n=40) during the TUNU II expedition. We measured biological parameters and 24 PBDE congeners and we correlated PBDEs and biological traits; we calculated Fulton’s condition factor, hepatosomatic index, gonadosomatic index.

The ∑PBDE concentrations were 0.33±0.16 and 0.31±0.08 ng/g wet weight in fish muscle from the shelf and the fjord, respectively. BDE183>BDE47>BDE28 were the most abundant in all specimens, with BDE99 in individuals from the fjord representing the lowest concentration. Positive and significant correlations between PBDEs vs length and PBDEs vs weight were observed in fish from fjord (p< 0.05), while these correlations were negative, but still significant (p< 0.05), for *B. saida* inhabiting the shelf.

To our knowledge, this is the first study on the correlation between contaminants and biological parameters in *B. saida*. 
Numerous studies have shown increases of mercury throughout the environment as a result of increased anthropogenic pollution. As contaminant loads continue to rise, investigations have turned toward monitoring mercury throughout the isolated southern polar region, often using penguins as biomonitors in both the Antarctic and sub-Antarctic region. The utility of penguins as biomonitors of contaminants throughout the Southern Hemisphere has been demonstrated due to their confinement within relatively localized geographic ranges, their widespread distribution, their status as high trophic predators, and their unique simultaneous molt that produces homogeneous feathers. Gentoo penguins (*Pygoscelis papua*) in particular occupy the widest latitudinal breeding range of any penguin species and may be characterized as highly pragmatic biomonitors across both the sub-Antarctic and the Antarctic, however numerous studies have shown Gentoo penguins have high inter-population variability in their mercury burdens. For this study, we investigate mechanisms that generate differences in Gentoo penguin mercury burdens between South America and Antarctica through the use of multi-tissue mercury and stable isotope analyses in contemporary samples. We also reconsider the feasibility of estimating Gentoo mercury exposure trends in relation to the high inter-population mercury variability of this widely distributed species.
Accumulation of Crude oil in Arctic Marine Zooplankton

Mette Dalgaard Agersted¹ (metteagersted@gmail.com), Eva Friis Møller², Kim Gustavson²
¹University of Oslo, Oslo, Norway, ²Aarhus University, Roskilde, Denmark

A future increase in oil and gas activities in the Arctic will increase the risk for accidental oil spills. Due to high lipid content in polar organisms, bioaccumulation of lipophilic contaminants, which are present in crude oil, is more prone to take place. In Disko Bay, West Greenland, we conducted crude oil exposure experiments with three co-existing ecologically important zooplankton species; the lipid rich Arctic copepod Calanus hyperboreus, the smaller and less lipid rich Atlantic copepod C. finmarchicus and larvae of the shrimp species Pandalus borealis, which has the lowest lipid content of the three species. Our results show that lipid rich zooplankton species accumulate heavy hydrocarbon groups, despite that the crude oil they were exposed to mainly consisted of light hydrocarbon groups. Results also indicate that grazing activity in lipid rich zooplankton may be less directly affected by short-term crude oil exposure compared to less lipid rich species. Furthermore, data reveal that elimination rates of crude oil model compounds are minimal and that even short-term exposure may result in long-term bioaccumulation and internal exposure of oil compounds in lipid rich zooplankton. Slow elimination and depuration of oil components indicate a risk for transfer of oil component up the Arctic food web to pelagic fish, seabirds and baleen whales.
Plastic Pollution in the Southern Ocean and its Impact on Antarctic Wildlife

Liliana Keslinka1 (liliana.keslinka@gmail.com)
1Institute of Biochemistry and Biophysics, Department of Antarctic Biology, Warszawa, Poland

The microplastic pollution of the marine ecosystem is a growing issue that is repetitively reported. Antarctica, once believed to be pristine, is also threatened by microplastic pollution, however not enough data exists to estimate the size of the damage and the impact of microplastic on the Antarctic environment, especially Antarctic wildlife.

The aim of the project is to collect and analyze water samples south and north of the polar front in the Southern Ocean in order to establish the extent of microplastic pollution. The samples will be collected at Drake Passage, in the Southern Ocean off the east coast of South America and along the Antarctic Peninsula, north and south of the polar circle, within 100 meter water column, what corresponds to the depths at which gentoo penguins forage. Further, sampling of juvenile gentoo penguin’s digestive systems (carcasses found in colonies) is planned in order to find out, whether at the earliest stage of life parents are feeding the chicks with a) food contaminated by microplastic b) big plastic particles, in order to assess the impact of the plastic pollution on the Antarctic biota. Sampling and analyzes will be conducted according to standardised method scheme provided by the NOAA Marine Debris Program. The surveying will take place on board of mv Ocean Diamond in cooperation with Quark Expeditions Inc. between January and March 2018. The preliminary results and conclusions will be presented in June at the POLAR 2018 conference.
Polybrominated Diphenyl Ethers (Pbdes) in Indoor Environments from Antarctica

América Metzdorff¹ (merirebe@gmail.com), Karla Pozo², José Luis Roscales³, Elena Cerro³, Begoña Jiménez³, Cristóbal Galbán-Malagón⁴, Elisa Bergami¹, Matias Poblete⁵, Rubén Avendaño⁵, Petra Přibylová², Jordi Dachs³, Simonetta Corsolini¹

¹University of Siena, Department of Physical, Earth and Environmental Sciences, Siena, Italy, ²Masaryk University, Faculty of Science, Research Centre for Toxic Compounds in the Environment, Brno, Czech Republic, ³Consejo Superior de Investigaciones Científicas, Instituto de Química Orgánica General, Madrid, Spain, ⁴Universidad Andres Bello, Departamento de Ecología y Biodiversidad, Facultad de Ecología y Recursos Naturales, Santiago, Chile, ⁵Universidad Andres Bello, Laboratorio de Patología de Organismos Acuáticos y Biotecnología Acuícola, Viña del Mar, Chile

Polybrominated diphenyl ethers (PBDEs) are nowadays widely used as flame retardants in electronic components, plastics, textiles and buildings materials. Their commercial mixtures Penta-BDE and Octa-BDE were banned in the European Union because of their toxic effects. Due to their physical-chemical properties, PBDEs can be found in the indoor dust. In this study dust samples were collected from two Antarctic research bases, the Gabriel de Castilla and Prof. Julio Escudero Stations, and a research vessel, the R/V James Clark Ross of the British Antarctic Survey. The PBDE concentrations ranged from 0.1 to 69 ng/g dust. Sample from the Gabriel de Castilla Base showed the highest levels of the ∑PBDEs, 302 ng/g, followed by those from the James Clark Ross Base, 166 ng/g, and the Julio Escudero Base, 80 ng/g. BDE99 was the most abundant congener in the Gabriel de Castilla Base sample (48 ng/g, contributing ~50% of the total BDE burden) followed by BDE47 (41 ng/g, ~40% of ∑PBDEs), and BDE100 (10 ng/g, ~10% of ∑PBDEs).
Glaciers at high-altitude mountains have been receding globally at an accelerated rate in recent decades. The glacial melt-induced release of pollutants (e.g., mercury) and its potential impact on receiving environments has drawn increasing concerns. During 2011-2015, we performed intensive sampling on diverse waters in a typical glacierized basin - Qugaqie Basin (QB), in the inland Tibetan Plateau, to investigate the export and transport of mercury from glacier to downstream environment. The total mercury (THg) concentrations in waters showed a decreasing order of glacier snow, glacier, meltwater, glacial runoff, and wetland. Particulate Hg was the predominant form in all sampled waters except for that of wetland. THg in runoff showed a clear diurnal variation and is closely linked to glacier melt intensity. We estimated that annual Hg exports by the glacier, the upper river basin and the entire QB were 8.76, 7.3 and 157.85 g, respectively, with respective yields of 4.61, 0.99 and 2.74 µg m$^{-2}$ yr$^{-1}$. Unique landforms and significant gradients in mountain regions can promote weathering and erosion, thereby controlling the transport of Hg. In comparison with other glacier-fed river basins globally, QB has a small Hg export yet remarkably high Hg yield, underlining the significant impact of melting alpine glaciers on regional Hg cycles. Such impacts are expected to be enhanced in high altitude regions under the changing climate.
The Impact of Nanoplastics on Antarctic Krill *Euphausia superba*

Elisa Bergami¹ (bergami@student.unisi.it), Clara Manno², Maria Luisa Vannuccini¹, Claire M. Waluda², Simone Cappello³, Ilaria Corsi¹  
¹University of Siena, Dep. of Physical, Earth and Environmental Sciences, Siena, Italy, ²British Antarctic Survey, Cambridge, United Kingdom, ³National Research Council of Italy, Institute for Coastal Marine Environment, Messina, Italy

Under current climate change scenarios, Antarctic krill (*Euphausia superba*) is facing multiple stressors which could affect its abundance and distribution. Microplastics have been recently reported in Antarctic waters, representing an additional potential impact on krill population. In this study we investigated the effects of model nanoplastics (< 1 µm) on krill juveniles through short-term exposure (48h) of polystyrene nanoparticles (PS NPs) with different surface charge. The behaviour of anionic (60 nm PS-COOH) and cationic (50nm PS-NH₂) NPs in Antarctic natural seawater (NSW, 34‰, 2°C) was also investigated by Dynamic Light Scattering. PS-COOH formed nanoscale aggregates (average size of 862nm) in Antarctic NSW, while PS-NH₂ maintained their nominal size. No mortality was observed upon exposure to 2.5µg/ml PS NPs after 48h. However, krill exposed to PS-NH₂ showed lower motility than individuals exposed to PS-COOH and were characterised by significant up-regulation of *cb6* gene involved in new cuticle formation. Similar findings reported for other microcrustaceans have been associated with mortality over long-term exposure. Both PS NPs also accumulated in faecal pellets (FPs), which were characterised by lower density and sinking rate compared to control. Our findings demonstrate that PS NPs are able to affect swimming behaviour, cuticle formation and FPs properties of Antarctic krill, with potential serious consequences on Southern Ocean food web and biogeochemical cycle.
Antimicrobial resistant bacteria are widespread in aquatic environments. The aim of the present study was to obtain information on the occurrence of bacteria with antimicrobial resistance in seawater surrounding Antarctic stations.

*Escherichia coli* strains were isolated from seawater. The samples were collected from sites distributed around the sewage outfalls of six Antarctic stations. Antibiotic susceptibility patterns were determined with the disk diffusion method, using different groups of antibiotics: penicillins, carbapenems, aminoglycosides, quinolones, tetracycline, phenicols, and trimethoprim. *Escherichia coli* ATCC 25922 was used as the control for the tests.

A total of 213 samples were analysed. *E. coli* were detected in 58% of the samples. The highest bacterial counts were found in seawater surrounding the sewage outfalls. However, the bacterial counts decreased rapidly with increasing distance from the outfall. Seventy strains isolated were studied to determine antibiotic susceptibility. The strains studied showed resistant to 16 out of the 18 antibiotics tested. Thirty-seven strains were susceptible to all the antibiotics tested, and 21 showed susceptibility or intermediate susceptibility to Ampicillin. Thirty-three were resistant to at least one antibiotic, and 11 were multidrug resistant.

The presence of bacteria with antimicrobial resistance in the Antarctic environment is indicative of how widespread the global antibiotic resistance situation has become.
Total petroleum hydrocarbons (TPH), pH and nutrients were analyzed in intertidal sediment samples for three years (2014 to 2016). The samples were taken at increasing distances from the discharges of 4 Antarctic stations, located in Bahía Fildes and Bahía Potter.

The maximum average values, considering the three years analyzed, were 1576 and 1180 (mg TPH / kg) for Bahía Fildes and Bahía Potter respectively. The results show that the differences between the years analyzed are not significant, suggesting that the impact of the TPH on the environment remains approximately constant over time. Statistically significant differences are observed between both bays. The points of greatest impact correspond mainly to the places where maneuvers are carried out with boats. In Fildes Bay, these points coincide with the wastewater treated discharges from two stations.

The cluster statistical analysis shows that the samples are grouped according to the activities carried out on the coast, separating the points without human activities in a distinct cluster.

The results of nutrients (nitrogen and phosphorus) in the sediments do not show relationship with the discharges or with the maneuvering sites of boats. These results seem to be more influenced by local situations, such as the presence of backwaters and algae.

This study shows that the maximum pollution detected, with high local values TPH, are confined to places where boat maneuvering and wastewater discharges occur.
Polybrominated-diphenyl ethers (PBDEs) include a class of brominated flame retardants (BFRs) that are added to many products (e.g. plastics, household textiles, etc.) to reduce their flammability. The top predator Greenland shark *Somniosus microcephalus* is an important cold-water species with slow growth and it is also the longest-lived vertebrate known, for these reasons it is vulnerable to bioaccumulation of POPs. PBDE concentrations in the muscle and liver of fifteen Greenland sharks were evaluated and then correlated to the tissue lipid content and age/sex of sharks. $\Sigma$PBDEs ranged from 0.143 to 82 ng/g (mean 20 ± 25) lipid wt in the liver and from 2.49 to 57 ng/g (mean 14.1 ± 15.2) lipid wt in the muscle. The percentage contribution of the PBDE congeners showed the following patterns: BDE-47 > BDE-28 > BDE-154 > BDE-209 > BDE-99 > BDE-100 > BDE-85 > BDE-66 > BDE-153 > BDE-66 > BDE-183 in the liver, and BDE-47 > BDE-99 > BDE-100 > BDE-28 > BDE-209 > BDE-154 > BDE-153 > BDE-66 > BDE-183 in the muscle. Our results showed that sex and age/size may not be the main factors affecting the BDEs bioaccumulation in liver and muscle, since no significant differences were observed between males and females or age groups.
The Atlantic cod *Gadus morhua*, the Greenland cod *Gadus ogac* and the Greenland halibut *Reinhardtius hippoglossoides* are particularly sensitive to persistent organic pollutants (POP) exposure, playing an important role in monitoring the potential effects of these chemicals in Arctic marine ecosystems. DDTs, PCBs, PBDEs and HBCDs were determined in the muscle of five cod and five Greenland halibut specimens collected in the Uummannaq Fjord (NW Greenland). The lipid content ranged 14.5-50% in cod fish and 46-82 in the Greenland halibut. No significant relationship was observed correlating lipid content and POP concentration in these species. The POP contribution to the total residue was PBDEs > PCBs > DDTs > HBCDs in both the cod fish and PCBs > DDTs > PBDEs > HBCDs in the Greenland halibut. The ratio $\Sigma$DDTs/$\Sigma$PCBs was significantly lower than 1 in cods (0.384-0.989 ng/g lw) respect to the Greenland halibut (0.793-1.47 ng/g lw), suggesting a higher POP contribution of industrial and agricultural origin in the two species, respectively, and/or a different inter-specific DDT and PCB bioaccumulation processes. Further investigations are needed since these fish species are commonly eaten by humans and are thus considered an important economic resource.
Source Assessment of Trace Elements in the Polar Regions by Isotopic Analysis

Francisco Ardini1, Marco Grotti1, Andrea Bazzano1,2, Frank Vanhaecke2, David Cappelletti3, Rita Traversi4, Silvia Nava5, Mery Malandrino6

1University of Genoa, Department of Chemistry and Industrial Chemistry, Genoa, Italy, 2Ghent University, Department of Analytical Chemistry, Ghent, Belgium, 3University of Perugia, Department of Chemistry, Biology and Biotechnologies, Perugia, Italy, 4University of Florence, Department of Chemistry Ugo Schiff, Sesto Fiorentino, Italy, 5University of Florence and INFN-Firenze, Department of Physics, Sesto Fiorentino, Italy, 6University of Turin, Department of Chemistry, Turin, Italy

A thorough assessment of the exposure of the Polar environments to contaminants from local and distant areas requires the identification of their sources and transport patterns and the capability to distinguish between natural and anthropogenic inputs. In this context, lead and strontium isotope ratios proved to be very powerful, providing information not easily achievable otherwise. In particular, the $^{208}\text{Pb}/^{207}\text{Pb}$ and $^{206}\text{Pb}/^{207}\text{Pb}$ values differ significantly between crustal and ore Pb deriving from various locations and mining areas, whereas natural variations of $^{87}\text{Sr}/^{86}\text{Sr}$ can be used for tracing the geographical sources of mineral dust.

In the framework of PNRA (National Program for Antarctic Research) and RIS (Research in Svalbard) projects we have developed and have successfully applied novel analytical procedures based on both single- and multi-collector inductively coupled plasma-mass spectrometry, thus obtaining interesting information on the sources and transport pathways of trace elements in various environmental compartments.

Representative results concerning the marine environment of Kongsfjorden (The Arctic), the atmospheric particulate reaching Ny-Ålesund (The Arctic) and Terra Nova Bay (Antarctica), and the surface snow accumulating at Dome C (Antarctica) will be presented and discussed, together with preliminary results of the ongoing SIDDARTA project, the aim of which is studying present-day sources and transport processes of mineral dust to the Antarctic plateau.
Over the past decades, research in Antarctica has built a new understanding of Antarctica, its past, present and future. Human activities and long range pollutants are increasing on the Antarctic continent. Research on Persistent Organic Pollutants (POPs) have been carried out internationally by several countries having their permanent research stations to explain the impact of an ever increasing range of POPs in Antarctic ecosystem. POPs have been detected in Antarctica despite its geographical isolation and almost complete absence of human settlements. Presence of POPs in different abiotic (atmosphere, water bodies, sediments, soil, sea ice) and biotic components (mosses, lichens, krill, penguins, skua etc.) in Antarctica have been studied and documented around for decades and have either been banned or strictly regulated but are still found in the environment. This review focuses on recent research pertaining to sources and occurrence of POPs in Antarctic lake water, soil, sediment, lichen, mosses and other Antarctic marine community. The talk proposes to summarize the current state of research on POPs in Antarctic environment and draw the earliest conclusions on possible significance and impact of POPs in Antarctica based on presently available information from related Antarctic environment.

**Keywords:** Persistent Organic Pollutants (POPs), Biotic and Abiotic Compounds, Ecotoxicology and Antarctic Pristine Environment.
Maritime transport is a globally important source of submicron particulate matter and gaseous pollutants. Ship engines typically combust low-grade fuels without application of exhaust gas after-treatment systems. Hence, they may constitute an important source of air pollution in Polar Regions. The composition of gas phase organic species and the identification of important precursors for secondary organic aerosol (SOA) formed from ship emissions itself remain largely uncharacterized. We investigate the semi-, intermediate- and volatile primary organic carbon (S-/I-/VOC) emitted from a ship engine operated with heavy fuel and marine gas oil. VOC analysis is performed using proton-transfer-reaction mass spectrometry. This is complemented by analysis of sorbent and filter samples using gas chromatography-mass spectrometry. We find a large fraction of aromatic and polycyclic aromatic hydrocarbons in the emissions, present emission factors of those species and an estimated SOA potential providing relevant information also for assessments in Polar Regions.
Characterization of HMW TPH Patterns from Soil at McMurdo Station, Antarctica

McMurdo Station is located in an approximately 4 km² ice free area at the southern tip of the Hut Point Peninsula on Ross Island, Antarctica. The summer population of over 1000 people makes it by far the largest population center on the continent. Human occupation at the site dates back to 1902. Spatial patterns of Total Petroleum Hydrocarbons (TPH) measured in the terrestrial environment surrounding McMurdo Station during the period from 1999 through 2015 as part of a long-term environmental study indicated many areas with little to no impact. There are areas with elevated TPH which are found associated with helicopter operations, refueling operations, vehicular usage and near parking/vehicular maintenance operations. Petroleum hydrocarbons in impacted McMurdo Station soils are characterized by a low molecular weight (LMW) gasoline/JP5/AN8, residual weathered petroleum TPH signature and a HMW signature that has not been characterized. The LMW TPH pattern suggests relatively freshly released petroleum in surficial soils with n-alkanes resolved on an unresolved complex mixture hump. The high molecular weight compounds are spatially-linked and generally restricted to vehicular operations such as historical roadways and parking areas. However, the actual composition of this HMW component has not yet been explored. This research explores the composition of this HMW pattern using GCxGC TOF/MS and Ion Mobility Q-TOF LC/MS which should provide better insight into its origins.
Inputs of Halobenzenes to Ice Cores at Svalbard and Antarctica

Mark Hermanson¹ (markhermanson@me.com), Elisabeth Isaksson², Camilla Teixeira³, Derek Muir³

¹Hermanson & Associates LLC, Minneapolis, United States, ²Norwegian Polar Institute, Tromso, Norway, ³Environment & Climate Change Canada, Burlington, Canada

Inputs of industrial organic contaminants were measured at Holtedahlfonna, Svalbard, and Site M, Antarctica. The Holtedahlfonna core was drilled in 2005 and covered 52 years from 1953 - 2005, and at Site M in 2004 and covered a 47-year period from 1957. Both cores were analyzed by the same lab for 15 halobenzene compounds, including 10 chlorobenzenes, 2 bromobenzenes, 2 chloromethoxybenzenes, and pentachloroanisole (PCA). These compounds are all highly volatile and, in general, would not be expected to condense except under extreme cold conditions, or under situations where the atmospheric concentrations are very high. The Antarctica results show flux and core burden dominated (70%) by 1,3-dichlorobenzene (1,3-DCB), hexachlorobenzene (HCB), 1,2,4-trichlorobenzene, 1,2,3,4-tetrachlorobenzene, and 3,4,5-trichloromethoxybenzene. PCA was not detected. Holtedahlfonna is dominated (90+) by 3 DCBs (1,4-, 1,3-, 1,2-), PCA and HCB. Quantitatively, all 15 contaminants in Antarctica contribute 30.8 ng, or 0.66 ng yr⁻¹, while at Holtedahlfonna, 1894 ng, or 36.4 ng yr⁻¹. The difference appears extreme because Holtedahlfonna is dominated 80% by 1,4-DCB, and without that contribution, the total is 363 ng or 7.0 ng yr⁻¹. The halobenzene input at Holtedahlfonna is at least 10 times greater than Site M during this period. This result is consistent with investigations of organic contaminants in Svalbard glaciers suggesting Eurasian sources that do not exist at Antarctica.
Anthropogenic Impact on Soil Prokaryotic Communities of Fildes Peninsula

João Pereira Santos¹, Hugo Ribeiro¹, António Gaspar Gonçalves Sousa¹,² (antonio.sousa@ciimar.up.pt), Ana Padeiro³, João Canário³, Catarina Magalhães¹,²
¹CIIMAR – Centro Interdisciplinar de Investigação Marinha e Ambiental, Universidade do Porto, Matosinhos, Portugal, ²FCUP - Faculdade de Ciências, Universidade do Porto, Porto, Portugal, ³CQE, Instituto Superior Técnico, Universidade de Lisboa, Lisboa, Portugal

The Antarctica continent is characterized by its extreme environmental conditions and low anthropogenic pressures. However, throughout the year’s many research stations have been implemented in the few ice-free regions of the continent. One of these areas is on the Fildes Peninsula (King George Island). The human footprint in the region has led to the increase of pollution issues around the area such as elevated levels of heavy metals and persistent organic pollutants. In this study, we aim to understand how these human activities are shaping the soil prokaryotic communities of these regions. We collect a total of 20 soil samples along a transect with decreasing human impact at Fildes Peninsula. At a preliminary stage, the structure of bacterial communities was achieved through automated approach for ribosomal intergenic spacer analysis (ARISA), and based on the community fingerprinting profile of ARISA, nine samples were chosen to sequence massively the V4-5 region of 16S rRNA gene to capture all the prokaryotic diversity. The structure of the prokaryotic communities was correlated with the heavy metal contents and persistent organic pollutants measured for each site. Strong relations were identified between the prokaryotic communities and the pattern of distribution of the contaminants analyzed in the present study, alerting us to the risks that anthropogenic activities pose on this pristine environment.
Soil Contamination at Impacted Sites in the McMurdo Dry Valleys

Andrew Klein¹ (klein@tamu.edu), Stephen Sweet², Terry Wade², José Sericano², Terence Palmer³

From 1999-2015, an environmental monitoring program has characterized spatial patterns and temporal trends in anthropogenic contamination of the local terrestrial near McMurdo Station. Soil samples were also collected annually at control sites in areas experiencing minimal human impacts and were analyzed for Total Petroleum Hydrocarbons (TPH) and selected metals. TPH concentrations at the control sites were generally at near background levels and show no evidence of changing significantly over the study period. Trace metals concentrations are similarly low though the impacts of varying parent material among sites are evident. In 2013 and 2015, the monitoring program was expanded to encompass established field camps at Lakes Bonney, Fryxell and Hoare and a temporary campsite in the Meirs Valley within the McMurdo Dry Valleys. Samples were also collected at sites of suspected contamination in the Barwick and Balham Valleys Antarctic Specially Protected Area. This research synthesizes this sampling along with historical sampling conducted as part of operational environmental operations by the United States Antarctic Program to characterize typical levels of contamination at impacted sites in the McMurdo Dry Valleys in comparison to levels found at the well-characterized control sites. It also proposes effective sampling design strategies for characterize soil contamination to inform management decisions in the McMurdo Dry Valleys Specially Managed Area (ASMA).

Effect of Copper Contamination on SOD Activity of Polar & Tropical Chlorella sp

Emienour Muzalina Mustafa1,2 (emie@umt.edu.my), Siew Moi Phang2, Siti Aisah Alias2, Peter Convey3, Stephen Coulson4,5, Ben Matthew Wallis6

1Universiti Malaysia Terengganu, School of Fisheries and Aquaculture Sciences, Kuala Terengganu, Terengganu, Malaysia; 2University of Malaya, Institute of Ocean and Earth Sciences, Kuala Lumpur, Malaysia; 3University of Cambridge, British Antarctic Survey, Cambridgeshire, United Kingdom; 4Swedish University of Agriculture Sciences, Swedish Species Information Centre (ArtDatabanken), Uppsala, Sweden; 5University Center in Svalbart (UNIS), Department Arctic Biology, Longyearbyean, Norway; 6Ocean-expeditions.com, RV Australis, - Ormond St, Bondi Beach, Australia

Environmental conditions affect many aspects of cellular metabolism. Superoxide dismutase (SOD) is the most important enzymes in the front line of defense against oxidative stress; where SOD catalyzes dismutation of two superoxide anion into hydrogen peroxide & molecular oxygen. Algae are notable bioindicator species in environmental pollution studies. In view of this, efforts are made to investigate the use of SOD activity, DNA damage level, growth responses and biochemical composition as biomarker for evaluation on how microalgae responses and adapt to copper contamination occurred at Arctic, Antarctic & Tropical region. Results showed that the carbohydrate, protein, lipid and AP-site content decreased with increasing concentration of copper. The SOD activity in the exposed algae increased with increasing copper concentration until the threshold, beyond which the cells lost their resistance and died. Levels of these SOD enzymes; DNA damage, growth, biochemical composition in microalgae & correlation with physical-chemical characteristics of water quality at Polar and Tropical region measured; will allow the establishment of baseline data that will be used for developing a monitoring programed. The findings of the present study may contribute to the understanding of how the Arctic, Antarctic and Tropical algae respond to environmental stress, and to use SOD enzymes levels to monitor the impact of climate change and increased contamination of the polar and tropical habitats.
Comparative Analysis of Pollutants in Polar, High- and Low-altitude Cryoconites

Ramya Bala Prabhakaran¹ (pramyabala@gmail.com), Gael Le Roux²
¹EcoLab, Université de Toulouse, CNRS, INPT, UPS, Toulouse, France

Rapid industrialization in the Asian countries is one of the greatest contributors of anthropogenic pollutants such as Black Carbon (BC). These pollutants accumulate on the surface of glaciers and in lake ice. Microbes glue these pollutants together with dust in the form of cryoconites in a process called biological darkening, accelerating the melting of glaciers, snow and ice-caps. The Himalayan Mountain range is the second largest ice mass after the Polar region. Anthropogenic fossil fuel combustion and production of non-ferrous metals, leading to bulk release of trace metals such as, As, Cr, Cu, Ni and Zn into the atmosphere, have an adverse impact on the Himalayan ecosystem. There have been very few studies on the Himalayan cryoconites with the first one in 2017 showing high As levels; an element of concern for downstream human populations. Cryoconites in other regions, such as the Hans glacier, reveal high concentrations of anthropogenic Pu, Cs, Sr while those in Alpine glaciers are heavily enriched in artificial radionuclides. Simultaneous monitoring and comparison of various pollutants in polar, high- and low-latitudes will be important in understanding pollutant cycling. With this intent, we are undertaking a multidisciplinary assessment of the mineral, organic and biological components of cryoconites from the Arctic expedition, the Pyrénées and the Himalayas with a special focus on inorganic micropollutants such as artificial radionuclides, Hg and other trace metals.
Fri_31_EN-2_2343

Environmental Relationships of the Heavy Metals in a Periglacial Landscape

Marcio Rocha Francelino¹ (marcio.francelino@gmail.com), Elpidio Inácio Fernandes Filho², Adriano Luis Schunemann³, Martin Meier¹, Carlos Ernesto Schaefer¹

¹Universidade Federal de Viçosa / INCT da Criosfera, Solos, Viçosa, Brazil, ²Universidade Federal de Viçosa, Soil, Viçosa, Brazil, ³Universidade Federal do Pampa - UNIPAMPA, São Gabriel, Brazil

Although only 8.8% of King George Island are ice-free areas, they represent key hot spots where biodiversity is maximum, and greater anthropogenic impacts occur. In the Admiralty Bay of King George Island, four research stations are located, and generate local environmental impacts to different degrees. The objective of this work was to identify the relationship between heavy metal contents and environmental and anthropogenic covariates in Keller peninsula, where the Brazilian station is located. Soil sites located far away from the station were used as control for serving as reference for comparison between anthropogenic and non-affected soils. Categorical covariates such as landforms, lithology, soils and morphometric covariates (from a digital elevation model with spatial resolution of 1 m) were used. Soil samples were collected in 57 points distributed in grid form, in two depths (0-10cm and 10-20cm). The samples were analyzed by X-ray fluorescence spectrometry and the contents of zinc, copper, nickel, cadmium, mercury cobalt, arsenic and chromium were determined. We used the functions “findCorrelation” and “recursive feature elimination”, both using the R software. The model with the lowest number of variables was chosen, which obtained 97%, the highest value of Kappa. This interpretation was very useful to illustrate the general behavior of heavy metals in Antarctic landscapes.
Plastic Debris in Antarctic Marine Organisms: First Results of PLANET Project

Ilaria Corsi1, Elisa Bergami1 (elisa.bergami4@gmail.com), Martina Grattacaso1, Lisa Vaccari2, Silvia Olmastroni1,3
1University of Siena, Physical, Earth and Environmental Sciences, Siena 1, Italy, 2Elettra-Sincrotone, Trieste, Italy, 3National Museum of Antarctica ‘F. Ippolito’, Siena, Italy

For decades plastic debris accumulated in the world’s oceans and recently their presence and impact has been documented in one of the most remote and pristine region on Earth as Southern Ocean around Antarctica. Increasing local human impacts (fishing, tourism and scientific bases) and transportation from transboundary sources will differentially affect occurrence, spatial patterns and biological impact of plastic debris in Antarctic waters. The PLANET project (PLastics in ANtarctic Environment) launched in 2015 by the Italian Antarctic Research Programme is an international network of researchers sharing the common aim to address the impact of plastic pollution on Antarctic marine organisms with particular regard to the smallest debris as micro (< 5mm) and nanoplastics (< 100 nm). An initial monitoring study in 2016 revealed the presence of microplastic in several marine species from the Ross Sea. They resulted more abundant in scallops and fish than in phytoplankton, krill and blood and faeces of seabirds (penguins and skua). Rayon fibers of a size below 100 µm (µ-FTIR) were the most present thus raising concern in terms of toxicity since approaching the nano-scale but also chlorinated polyethylene, poly(butylene terephthalate) and melamine/alkyd resin were identified. Cross-contamination underline the need to standardize protocols for sample handling, digestion and polymer identification in order to properly assess micro and nanoplastic occurrence in Antarctic biota.
Antarctica is considered a pristine ecosystem; nevertheless it is influenced by Persistent Organic Pollutants (POPs), mainly driven by long-range atmospheric transport. Antarctic ice-free areas, where rare lakes are located, are influenced by such sources. In this work, we determine polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbon (PAHs) and pesticides (banned and still in use) in water and sediment samples of 7 shallow lakes in Northern Victoria Land during the austral summer season.

POPs concentrations in lakes resulted low and rather similar across the sites despite their distance. There is always a higher presence of low molecular weight PAHs both in comparison between the various expeditions, and comparing water and sediment of the same campaign. Phenanthrene is the predominant compound in all the sampled sites (single PAHs concentration is in the range 0.1-0.4 ng/L). The 6 PCBs marker (28, 52, 101, 138, 153, 180) are quantifiable and comparable (single PCBs concentrations are in the range 0.01-0.3 ng/L).

Among the pesticides, simazine is most represented for the azine class, especially in aqueous matrices. Endosulfan sulfate is present in all samples often at high concentrations. p, p'-DDT isomer is the most concentrated isomer, but we have found also o,p-DDT and their metabolites. Hexachlorobenzene and BHC-γ (Lindane) are present in most samples. Iprodione is present in most of the aqueous analyzed samples, while in sediments it is less represented.
Using DGT to Assess the Risk of Metal Contaminants in Polar Environments

Darren Koppel\textsuperscript{1,2,3} (djk146@uowmail.edu.au), Merrin Adams\textsuperscript{2}, Catherine King\textsuperscript{3}, Dianne Jolley\textsuperscript{2}

\textsuperscript{1}University of Wollongong, School of Chemistry, Wollongong, Australia, \textsuperscript{2}Commonwealth Scientific and Industrial Research Organisation (CSIRO), Land and Water, Lucas Heights, Australia, \textsuperscript{3}Australian Antarctic Division, Human Impacts, Kingston, Australia

Metal contaminants, such as those that leach from historical Antarctic waste, are known to cause toxicity to a wide-range of organisms. The development of environmental quality guidelines will help environmental managers to understand the risk of contaminants. However, a lack of environmental toxicological data and environmental monitoring tools is limiting the development of guidelines. Diffusive Gradients in Thin-films (DGT) have been established as a robust method for analysing the biologically-available contaminants in situ and is well-positioned to assess the toxicity of metal contaminants.

This study uses DGT to assess the toxicity of Cd, Cu, Ni, Pb, and Zn singly and in mixtures, to two common Antarctic marine microalgae, \textit{Phaeocystis antarctica} and \textit{Cryothecomonas armigera}. DGT devices were optimised for use in Antarctic conditions by determining metal diffusion coefficients and quantifying the DGT's metal-binding capacity. Preferential binding of metals was observed prior to reaching the metal-binding capacity with Cd, followed by Pb, and Zn, outcompeted by Cu and Ni. DGT measurements were then used to predict toxicity to two algal species exposed to a mixture of the metal contaminants. This research demonstrates the applicability of DGT to identify contaminated sites which may pose a risk to Antarctic organisms.
PANGAEA® - Data Publisher for Earth and Environmental Science

Stefanie Schumacher¹ (stefanie.schumacher@awi.de), Amelie Driemel², Hannes Grobe², Rainer Sieger¹

¹Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, PANGAEA, Bremerhaven, Germany

PANGAEA - Data Publisher for Earth & Environmental Science (www.pangaea.de) is an Open Access data-library aimed at archiving, publishing and distributing georeferenced data from earth and environmental science. The development of the system started with the beginning of the Internet and since then offers data curation services to national and international projects, institutes and individual scientists. The World Data Center PANGAEA is member of the World Data System (WDS) of the International Council for Science (ICSU). Observational and analytical data files are stored together with their metadata in a relational database. Each data set includes a bibliographic citation and is persistently identified using a Digital Object Identifier (DOI). Data are archived as a supplement related to an article or as an independent citable data-publication. PANGAEA is a recommended repository for supplements in several hundred journals related to earth system research.

PANGAEA currently provides more than 368 000 data set, consisting of >12 billion data points. This includes important collections from international Antarctic and Arctic research programs, e.g. the Cape Roberts Project, ANDRILL, EPICA project, and data of the first and last International Polar Year (IPY 1882-1883 and 2007-2008). Additionally, the full data amount of combined high and low latitude research projects, e.g. JGOFS, WOCE, DSDP/ODP/IODP and German expeditions are archived and published.
How, what, where, when: Expedition Metadata and Data Collection

Jenny Thomas¹ (jenny.thomas@epfl.ch), Carles Pina Estany²
¹Swiss Polar Institute, Lausanne, Switzerland, ²ACE Foundation, Lausanne, Switzerland

Three months of data and sample collection on the Antarctic Circumnavigation Expedition during the southern summer of 2016/17 required a system to collect metadata and data during the research cruise. A network was established on board the R/V Akademik Tryoshnikov, to automatically store data streams from ship-based instruments, access the local intranet and allow for communications on board. An intranet with event-logging and data-entry system was prepared to allow scientists and data managers on board to record the cruise metadata, database ship-based data streams and perform in-situ checks on the generic data streams being collected during the expedition. This allowed extensive checking of metadata and completion of metadata records of raw data sets whilst on board. This presentation will describe the system used as well as the particular advantages and disadvantages of the systems used on a multi-disciplinary research cruise.
Over 30,000 samples and 30 TB of data were collected during the Antarctic Circumnavigation Expedition. ACE was a unique expedition to the Southern Ocean, sub-Antarctic and Antarctic islands during the austral summer of 2016/17. The scientific potential of resulting data sets depends on good data management and investment in methods to ensure the integrity of these data sets, as well as careful data processing and checking. In addition, once initial analyses have been done on the quality assured data sets, there is huge potential to combine them in new ways and apply data science and machine learning techniques to explore the vast linkages between disciplines.

This presentation will explore the potential of the ACE data sets, from the basis of their archiving, the extent of the data sets and how they will be made available to all. Finally, we will discuss how data science methods will be used as part of the project, "Delivering Added-value To Antarctica", ACE-DATA, to explore air-sea interactions.
Polar data are valuable, unique research assets that are acquired under substantial and expensive logistical effort. Historically, data management for the US Antarctic Program (USAP) has made use of existing disciplinary data centers. However, disciplinary repositories do not exist for all USAP generated data types and often it is unclear what repositories are appropriate, leading to datasets being served locally from scientist’s websites or not available at all. The USAP Data Center (www.usap-dc.org) contributes to the broader preservation of data acquired with funding from NSF’s Office of Polar Programs by providing a repository for diverse Antarctic data. In Spring 2016, USAP-DC and the NSIDC began a new collaboration to consolidate data services for Antarctic investigators and to integrate the NSF-funded glaciology data at NSIDC with the collection hosted by USAP-DC. Investigator submissions for NSF’s Glaciology program now make use of USAP-DC’s web submission tools, providing a uniform interface for Antarctic investigators. The tools have been redesigned to collect a broader range of discovery and preservation metadata. Each data submission is reviewed and verified by a specialist from the USAP-DC/NSIDC team depending on disciplinary focus of the submission. A recently updated web search interface is available to search data by title, NSF program, award, dataset contributor, large scale project (e.g. WAIS Divide Ice Core) or by specifying an area in map view.
Providing High-quality Long-term Data Management at the McMurdo Dry Valleys LTER

Renée F. Brown¹ (rfbrown@unm.edu), Byron J. Adams², John E. Barrett³, Peter T. Doran⁴, Adrian J. Howkins⁵, Diane M. McKnight⁶, Rachael M. Morgan-Kiss⁷, John C. Priscu⁸, Cristina D. Takacs-Vesbach¹, Michael N. Gooseff⁶
¹University of New Mexico, Department of Biology, Albuquerque, New Mexico, United States, ²Brigham Young University, Department of Biology, Provo, Utah, United States, ³Virginia Tech, Department of Biological Sciences, Blacksburg, Virginia, United States, ⁴Louisiana State University, Department of Geology and Geophysics, Baton Rouge, Louisiana, United States, ⁵University of Bristol, Department of History, Bristol, United Kingdom, ⁶University of Colorado, Institute of Arctic and Alpine Research, Boulder, Colorado, United States, ⁷Miami University, Department of Microbiology, Oxford, Ohio, United States, ⁸Montana State University, Department of Land Resources and Environmental Sciences, Bozeman, Montana, United States

Established in 1993, the McMurdo Dry Valleys Long Term Ecological Research Program (MCM LTER) is an interdisciplinary effort focused on the long-term study of aquatic and terrestrial ecosystems in a cold desert region of Antarctica. The McMurdo Dry Valleys are located on the western coast of the McMurdo Sound, forming the largest relatively ice-free region on the Antarctic continent. MCM represents one of twenty-eight sites in the United States (U.S.) LTER Network funded by the U.S. National Science Foundation (NSF). Like all LTER sites, MCM is a data-intensive endeavor with a diverse set of monitoring and experimental studies that span temporal and spatial scales. Data generation largely occurs through the intensive laboratory analyses of biogeochemical parameters and biotic composition of field-collected samples. Additional high-frequency datasets are obtained using automated technologies that include environmental sensor networks and satellite imaging. MCM data standards and access policies are set by the U.S. LTER Network in accordance with NSF guidelines, and were recently revised in the spirit of open science to promote enhanced data quality, visibility, and accessibility.

Here, we describe the complete data life cycle at MCM, focusing on both the technological and human aspects of collecting, curating, and preserving high-quality, publicly available long-term datasets for use by researchers, educators, and policy-makers alike.
Liberating Arctic Botanical Biodiversity Data at the Canadian Museum of Nature

Jennifer C. Doubt\textsuperscript{1}, Lisa C. Gualtieri\textsuperscript{1}, Cassandra M. Robillard\textsuperscript{1}, Lyndsey A. Sharp\textsuperscript{1}, Paul C. Sokoloff\textsuperscript{1}, Jeffery M. Saarela\textsuperscript{2} (jsaarela@mus-nature.ca)
\textsuperscript{1}Canadian Museum of Nature, Centre for Arctic Knowledge & Exploration, Ottawa, Canada

Core to the polar research information spectrum are the millions of biological and geological specimens in natural history collections. These specimens represent biodiversity data documenting the distribution of species in time and space; they serve as vouchers for the datasets that underpin scientific conclusions, allowing future workers to confirm or revise identifications; and they are sources of new data, such as genetic information. Most natural history museums face the massive “big data” challenge of databasing and imaging their collections, allowing them to be widely discovered, shared, used and reused in research and outreach. Many also possess backlog material: specimens collected and stored, sometimes many decades ago, that have never been accessioned or prepared for long-term use, and that are consequently not discoverable or available for study. The Canadian Museum of Nature houses over 300K Arctic specimens - the largest Arctic natural history collection in Canada - but data for only a subset are currently accessible online. To correct this, the National Herbarium of Canada is engaged in a project to digitize, georeference and image its Arctic plant, moss and lichen specimens, according to global standards that facilitate collection data sharing and integration. We are also processing important Arctic backlog material, including 3025 Canadian Arctic specimens collected in the 1970s to the 1990s at great expense that were never mounted or formally acquired.

Developing a Metadata Portal for Researchers

Marten A Tacoma¹ (marten.tacoma@nioz.nl), Taco F de Bruin¹
¹NIOZ Royal Netherlands Institute for Sea Research & Utrecht University, Den Hoorn Texel, Netherlands

One of the challenges when developing a portal is how to get the researchers to work with it. Scientists complain about the number of systems, being from their home institution, funding agency or international, they are required to provide with information and the amount of time this costs. Time they can’t use to perform research.

For the Netherlands Polar Program (NPP) we developed a portal to provide access to all data and information from the NPP. We worked with the researchers to make it as easy as possible for them to provide information about their projects, data sets and publications. In this talk we will show the tools we created and how easy it is for researchers to add information. The portal was built using open standards and only requires free software to run, this way it can easily be incorporated into other national polar programs. The source code for the portal is freely available to the community via Github.
Recent conferences, workshops and meetings have confirmed that there are many projects and programs that are active in polar data management and stewardship at multiple scale. These initiatives have a mandate or desire to contribute to regional or international coordination of effort and activities. These programs have resources available and are making progress towards an envisioned connected, interoperable polar data system. The international polar data community is eager to improve cooperation and coordination of their efforts.

In the spring of 2018, more than ten active programs and initiatives came together to focus on work planning and coordination of effort. This meeting complemented past workshops and fora (e.g. IPY, Polar Data Forums etc.) that have been effective in defining important community challenges and technical issues. The focus of the meeting was to generate detailed plans on how best to mobilise existing and pending funded activities to develop a particular international data sharing case study.

The meeting was co-led and co-organized by key polar data projects and programs associated with polar science and observing coordinating bodies, international initiatives, regional, national and disciplinary programs, and Indigenous organizations. Here we report details of the planning process, the established case study, established interoperability mechanisms and a discussion of the collaborative process involved in bringing together a diverse group of data.
Using Concept Analysis and Visualization to Mediate Data for Different Audiences

Peter L. Pulsifer¹ (peter.pulsifer@colorado.edu), Colleen Strawhacker¹, Noor Johnson¹, Brendan Billingsley¹
¹University of Colorado, National Snow and Ice Data Center, Boulder, United States

The volume and variety of data available for research, decision making and local, community-driven projects and programs is rapidly increasing. These data may be produced using different methods, epistemologies and overall worldviews. At a more technical level, the data are often stored in different formats using a range of different vocabularies that are specific to a natural language or particular domain.

Drawing on examples from the Exchange for Local Observations and Knowledge of the Arctic, the activities of the Arctic Data Committee, and other related projects, data and information generated from different perspectives and managed using different techniques are analyzed and linked through the analysis of concepts and related categories. The results of the analysis are visualized to provide insights into how disparate data and information might be mediated for use between and among actors from different communities, domains and communities of practice. The challenges of representation using visualization to represent non-spatial concepts are discussed as are possible opportunities.
Biogeographically-linked Resource to Share Polar Microbial & Environmental Data

Alison Murray1 (alison@dri.edu), Anton P. Van de Putte2, Bruno Danis3, Lea Cabrol4,5, Maialen Barret6
1Desert Research Institute, Earth and Ecosystem Sciences, Reno, United States, 2Royal Belgian Institute of Natural Sciences, Brussels, Belgium, 3University Libre de Bruxelles, Laboratoire de Biologie Marine, Brussels, Belgium, 4Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile, 5Institut de Recherche pour le Développement, Institut Méditerranéen d’Océanologie, Marseille, France, 6Université de Toulouse, Ecolab, UMRS245, CNRS, INPT, UPS, Castanet Tolosan, France

The microbial Antarctic Resource system (mARS; mars.biodiversity.aq) is an information system dedicated to facilitating the discovery, access and analysis of molecular microbial diversity and ‘omics (meta)data generated by researchers. Here we report on the expansion of the geographic coverage of mARS to include all polar and subpolar regions. This enhancement is envisioned to facilitate comparative studies between the poles and serve as a collaborative, networking resource for polar scientists. mARS incorporates standardized environmental context data into a custom MySQL database in which users can search by latitude/longitude coordinates, environmental temperature, salinity, depth, or elevation etc., so that studies submitted by other researchers can be discovered which may be relevant for comparative diversity and metagenome or transcriptome studies. Visualization tools have also been created to capture the sequence coverage of different studies, geographic coverage, and in the future, phylogenetic coverage of data sets that are reflected in mARS. The mARS team partnered with the ERANET/LAC-supported METHANOBASE project which has characterized archaea and bacteria in permafrost, wetland and lake ecosystems in subarctic and Antarctic, and sub-Antarctic sites over the past two years. This large project, which collected over 480 samples from diverse ecosystems, served to help improve the mARS infrastructure and its usability by the user community of microbial scientists.

The CCADI Initiative: Advancing Arctic Research with Connected Data

Shannon Vossepoel¹ (shannonv@ucalgary.ca), Julie Friddell², Christine Barnard³
¹University of Calgary, Arctic Institute of North America, Calgary, Canada, ²University of Waterloo, Canadian Cryospheric Information Network/Polar Data Catalogue, Waterloo, Canada, ³Université Laval, Centre d’Études Nordiques, Quebec, Canada

The Canadian Consortium for Arctic Data Interoperability (CCADI, http://ccadi.ca) is an emerging initiative to advance collaboration, nationally and internationally, through the development of an integrated Canadian Arctic data management system that will facilitate information discovery, establish metadata and data sharing standards, enable interoperability among existing data infrastructures, and provide accessible data to a broad audience of users, from researchers to the general public.

Importantly, the Consortium aims to connect a broad variety of information types ranging from bibliographic records and research licenses, to metadata and raw data sets. Connecting these various kinds of data grants users the ability to build a holistic view of research, from inception and throughout the data lifecycle, and provides enhanced opportunities to recreate scientific studies and review them from different angles. It also provides countless opportunities to compare and link data, both qualitative and quantitative, across disciplines.

The CCADI also aims to include Inuit Knowledge and is working with regional Inuit organizations and Inuit Tapiriit Kanatami to ensure that indigenous data is included ethically, with full Inuit involvement in the design of systems, and in the management and use of their data.

The CCADI is composed of six Canadian universities, two Canadian federal agencies, two Inuit organizations, and three non-profit partners.
Two sediment cores retrieved, one each from lake GL-1 of Schirmacher Oasis and lake L-12 of Larsemann Hills, East Antarctica were investigated at 2 cm interval for sedimentological and geochemical parameters viz. grain size, total organic carbon, total nitrogen, total phosphorus, biogenic silica and bulk metal concentration. High sand content (>72%) in the major portion of the cores revealed predominant mechanical weathering process, which resulted in coarse-grained material from the rocks in the catchment area of the lakes. Relatively, higher biogenic silica along with high total organic carbon associated with high clay in the upper portion of both the lakes indicated deposition of finer particles from suspension in recent years which facilitated high primary productivity due to exposure of the lakes to the ice-melt water influx. C/N ratio for both the lakes was found to be < 10 which indicated that the major source of organic matter was autochthonous. However, N/P and N/Si ratios were lower than Redfield ratio indicating N and Si were limiting elements in the lakes. In these lakes, TOC and TN exhibited a poor correlation indicating their different source. Cd in both the lakes was found to be of mainly biogenic origin, whereas Pb in these lakes was found to be of lithogenic origin. Silt and organic matter in core GL-1 and organic matter along with the Mn-oxide in core L-12 regulated the distribution of metals.
Long-term Growing Season Dynamics Inferred from Birch Leaf Cuticle

Fabian E Z Ercan¹ (f.e.z.ercan@uu.nl), Wim Z Hoek¹, Daan Blok², F Wagner-Cremer¹
¹Utrecht University, Physical Geography, Utrecht, Netherlands, ²Lund University, Department of Physical Geography and Ecosystem Science, Lund, Sweden

A significant lengthening trend of the Northern Hemisphere growing season increasingly affects vegetation dynamics. Growing season length data, however, are currently restricted back to 1982, when satellite based vegetation monitoring began. All forward modelling of potential consequences to date are restricted to this short reference period. Sound evaluation of positive or negative effects for ecosystem performance requires longer time-series data to place ongoing changes into a broader temporal context. Palaeobotanical investigations provide a tool to generate long-term growing season records beyond the short-term satellite records. Our novel growing season length proxy is capable of accurately reconstructing past growing degree days and spring onset data. In this study, micro-phenological data from modern and fossil leaf cuticles are tested against historical meteorological data, and validated by field climate manipulation experiments. Growing season signals from historical and fossil leaves are subsequently used to estimate spring thermal properties over the past century. We here focus on Disko Island, Greenland and Kevo, Finland, both extremely sensitive to seasonal temperature changes. The generated time-series records of spring dynamics will support the understanding of ongoing climate change on time scales beyond the instrumental record.
Adelie penguin carries pebbles to rookery during summer breeding season, so pebbles deposit thickly year by year with relics such as feces, egg shells, feathers and bones. Prior to the start of summer nesting of Adelie penguin, I excavated sediments of rookery of Adelie penguin that existed around the Lutzow-Holm Bay in Antarctica, and described the sections of feces, bones, feathers and eggs from the basement to the surface layer, and took the radiocarbon dating and nitrogen isotope measurements.

In this research, based on this result, I examine the following four contents: 1) Geographical distribution of Adelie penguin rookery and their formation history, 2) History of change of the sea level change and Antarctic ice sheet, 3) Penguin’s food content, and discuss Holocene environmental change around the Lutzow-Holm Bay region.
Diatom Variation Reconstructed from Two Lake Sediment Cores from East Antarctica

Mahesh Badanal¹ (mahe687@gmail.com), Abhilash Nair², Anish Kumar Warrier³, Rahul Mohan²
¹National Centre for Antarctic & Ocean Research, Antarctic Science Division, Vasco da Gama, India, ²National Centre for Antarctic & Ocean Research, Antarctic Science, Vasco da Gama, India, ³Manipal University, Department of Civil Engineering, Manipal, India

Biogenic proxies such as diatoms retrieved from sedimentary deposits are a good tool to decipher and understand climate changes in the cold environments of Antarctica. The use of diatoms as a paleoclimate indicator in lacustrine systems of Antarctic ice free areas is well documented. In this study, we report diatom abundance and species variation for two sediment cores collected from two freshwater lakes viz., Mochou Lake (ML) and LH-73 of Broknes Peninsula in Larsemann Hills, East Antarctica. The cores were collected at different elevation (ML: 2 m & LH-73: 22 m asl) and distance (ML: 350 m & LH-73: 250 m) from the coast. The ML core spans the last 28.6 kyr while the LH-73 covers the last 25.8 kyr. In the time-series, the appearance of diatoms was recorded at 15.63 ky BP in ML record while it appears at 19 ky BP in LH-73 records wherein the deglaciation in Antarctic ice-core records is at 19 ky BP. This suggests that the lakes became ice-free after the deglaciation in Antarctica aiding growth of diatom community though at different times. This difference is most likely due to the geographical setting of both the lakes. The late-Holocene records higher diatom abundance as compared to the down-core indicating a favorable condition for the diatom community to flourish. The most abundant species in both the records is Stauroforma inermis followed by Planothidium quadripunctatum, Amphora veneta, Diadesmis australis and Psammothidium abundance.
A Land Mammal Tibia from the Eocene of Marambio/Seymour Island, West Antarctica

Javier N. Gelfo1,2 (jgelfo@fcnym.unlp.edu.ar), Marcelo Reguero1,2,3
1CONICET, Buenos Aires, Argentina, 2Universidad Nacional de La Plata, División Paleontología Vertebrados, Museo de La Plata, La Plata, Argentina, 3Instituto Antártico Argentino, San Martín, Argentina

Despite Antarctica is the only continent without terrestrial mammals, in the past it played a key role in the evolutionary history of Southern Hemisphere mammalian communities. Sometime between the Late Cretaceous and the latest Paleocene, before the complete break-up of Gondwana, West Antarctica functioned as a land bridge for the dispersal of metatherians and monotremes, from Southern South America to Australia in the first case, and in the other way round in the last. Fossil land mammals in Antarctica are mostly constrained to the dental remains from the Eocene of La Meseta and Submeseta Formations in Marambio Island. Here we described and discuss the implications of the first mammalian long bone, represented by an almost complete right tibia (MLP 94-III-15-6). The remain came from the lower conglomeratic shell bed from Cucullaea l Allomember at La Meseta Formation (Telm 4) in the locality DPV 2/84. The minimum length of the tibia is approximately of 230 mm; the prominent cnemial crest and most of the proximal epiphysis are cracked and with most of its surface were reconstructed. Proximally, the medial condyle is broken as well as most of the tibial malleolus. The distal third of the bone is the best preserved, particularly the astragalar articular surface. The distal moiety of the shaft resembles some Proterotheriidae litopterns for being more trihedral and less oval in section suggesting Sparnotheriodontid affinities.
Anthropornis, described more than a century ago, is one of a fascinating species of fossil penguins. The robustness and massiveness of its bones caught the attention of Carl Wiman in 1905, and made him worthy of the name Anthropornis, which means “man-bird”. Both species of this genus were only known through isolated bones (tarsometatarsi), until a few years ago, when the reinterpretation of some articulated bones Only isolated bones were described for both species of this genus until that new articulated skeletons from the Antarctic Eocene allowed the reinterpretation and assignment of associated limb remains to Anthropornis sp. A new skeleton found in Priabonian levels of the Submeseta Formation, Marambio (Seymour) Island, Antarctic Peninsula, constitutes the first specimen with a complete tarsometatarsus (that allowed the assignment to Anthropornis grandis), and the cranium, besides many fragments of other bones. The importance of this finding is that it is the first fossil cranium of Antarctica that can be assigned to any of the known species of penguins since all findings of cranial elements constitute isolated remains. Anthropornis grandis has an extremely elongated and slender bill and a small neurocranium, compared to modern penguins. Dimensions of the occipital condyle and the foramen magnum, however, are congruent with a large cranium and neck. These proportions seem to be the rule among large and giant penguins during the Paleogene.
Reconstructing Temp in Antarctica over the past Based on Water Stable Isotopes

François Klein1, Nerilie J. Abram2, Mark A. J. Curran3, Hugues Goosse1 (hugues.goosse@uclouvain.be), Sentia Goursaud4, Valérie Masson-Delmotte4, Raphael Neukom5, Anaïs Orsi4, Jesper Sjolte6, Nathan Steiger7, Barbara Stenni8, Martin Werner9

1Université catholique de Louvain (UCL), Louvain-La-Neuve, Belgium, 2Australian National University, Canberra, Australia, 3University of Tasmania, Hobart, Australia, 4Laboratoire des Sciences du Climat et de l’Environnement, Gif-sur-Yvette cédex, France, 5University of Bern, Bern, Switzerland, 6Lund University, Lund, Sweden, 7Columbia University, New York, United States, 8Ca’ Foscari University of Venice, Department of Environmental Sciences, Venice, Italy, 9Alfred Wegner Institute, Bremerhaven, Germany

Full title: Reconstructing air surface temperature in Antarctica over the past millennium based on water stable isotopes. Last millennium temperature changes over Antarctica are still relatively uncertain. This has several origins:

1) The number of high resolution ice cores is small, in particular on the Antarctic Plateau;
2) The instrumental records are short which limits the calibration period for reconstructions and the assessment of the methodologies;
3) The link between isotope records from ice cores and local climate are usually complex and dependent on the spatial and time scales investigated.

Here, we assess the potential of statistical reconstructions methods and data assimilation-based methods to obtain better understanding of last millennium temperature changes over Antarctica. This is first achieved in a pseudo-proxy framework. A long simulation performed with an isotope-enabled model is sampled at the same spatial and temporal resolution as existing data to provide the pseudo-data of surface temperature over the recent past and of stable oxygen isotopes over the past millennium. The performance of the statistical and data assimilation reconstructions based on those pseudo-data is then assessed by comparing the reconstructed temperature with the simulated one. In a second step, the data assimilation method tested and improved in this idealized framework is applied to real data and the results compared to available reconstructions based on statistical methods.

Hunting for Dansgaard-Oeschger-type Variability in the Earliest Pleistocene

Rebecca Parker1 (rp501@exeter.ac.uk), Deborah Ray1, Anieke Brombacher2, Stephen Obrochta3, Paul Wilson2, Ian Bailey1
1University of Exeter, Penryn Campus, Camborne School of Mines, College of Engineering, Mathematics & Physical Sciences, Penryn, Cornwall, United Kingdom, 2University of Southampton, Waterfront Campus, National Oceanography Centre Southampton, Southampton, United Kingdom, 3Akita University, Graduate School of International Resource Science, Akita, Japan

Geological studies indicate the Earth’s climate system is capable of undergoing abrupt and profound change when surface temperature is cooler than present (Dansgaard et al., 1993). It is now known that these co-called Dansgaard-Oeschger (DO) events likely occurred during a range of intermediate ice-volume states for the past 1.3 million years (Birner et al., 2016). Yet, it remains unknown when DO-events were first a feature of North Atlantic climate during the Quaternary. To shed new light on this issue, we present new suborbital palaeoceanographic records that track variability in surface and intermediate water properties of the northeast North Atlantic Ocean during the onset of major Northern Hemisphere glaciation, 2.5 million years ago. Birner, B., Hodell, D.A., Tzedakis, P.C. and Skinner, L.C (2016), Similar millennial climate variability on the Iberian margin during two early Pleistocene glacialis and MIS 3, Paleoceanography, 31, 203-217
Subdecadal Holocene Climate Reconstruction of Byers Peninsula (Antarctica)

Santiago Giralt, Dermot Antoniades, Ignacio Granados, Emma Liu, Sergi Pla-Rabes, Manuel Toro, Marc Oliva

1Institute of Earth Sciences Jaume Almera (ICTJA-CSIC), Barcelona, Spain, 2Centre d’Études Nordiques, Université Laval, Québec, Canada, 3Parque Nacional Sierra de Guadarrama, Centro de Investigación, Rascafría, Spain, 4University of Bristol, Bristol, United Kingdom, 5Centre de Recerca Ecològica i Aplicacions Forestals (CREAF-CSIC), Bellaterra, Spain, 6Centro de Estudios Hidrográficos (CEDEX), Madrid, Spain, 7University of Barcelona, Barcelona, Spain

Byers Peninsula (Livingston Island, South Shetland Islands) is one of the few glacier-free areas in Antarctica that allow the high-resolution characterization of Holocene history based on paleolimnological studies. Several lakes on the peninsula with sedimentary infills up to 5 m of thickness provide excellent opportunities to conduct multidisciplinary environmental reconstructions. The complete sedimentary infill of five lakes was retrieved in 2003 and 2008 (Limnopolar) and November 2012 (Chester, Escondido, Cerro Negro and Domo). Sediments ranged from nearly completely mineral to an alternation of mosses and mineralogical layers. The age model of these five sedimentary records was built using 53 AMS 14C and 4 TL dates covering the last ca. 8,000 cal years BP. Past climate and environmental changes are here inferred using the results obtained with an X-ray core scanner and x-ray diffraction analysis. Our results are related to the main Holocene climate fluctuations in this area. However, the comparison of the obtained reconstructions for each lake allowed for distinctions between local ontogenic processes controlled by the catchment and lake internal dynamics and those caused by regional climate fluctuations.
New Wet Extraction Technique to Measure CH₄ and N₂O Mole Fractions in Ice Cores

Loïc Schmidely¹ (schmidely@climate.unibe.ch), Michael Bock¹, Christoph Nehrbass-Ahles¹, Jochen Schmitt¹, Hubertus Fischer¹, Thomas Stocker¹

¹University of Bern, Physics Institute & Oeschger Centre for Climate Change Research, Climate and Environmental Physics, Bern, Switzerland

Reconstructions of past greenhouse gases (GHG) concentrations from polar ice cores are highly valuable to study the coupling between GHG and the climate system. A detailed understanding of their past natural variability and feedback mechanisms with temperature is crucial to constrain the future evolution of the climate.

We present a new gas extraction technique coupled to a gas chromatograph. It is characterized by a continuous vacuum extraction of the gases during the ice melting and subsequent collection on an active charcoal adsorber. Our efforts are currently devoted to the reduction of possible sources of contamination connected with desorption and/or outgassing phenomena connected to the ice extraction line.

The goal is to provide precise measurements to increase the temporal resolution of the EPICA Dome C Antarctic CH₄ and N₂O records. Our new data will allow for a better quantification of the phasing between CH₄, N₂O and CO₂ during rapid climate changes along with better estimates of the magnitudes and rates of change of these GHG fluctuations.
Recent changes to the strength and latitudinal range of the Southern Hemisphere Westerly winds (SHW) have highlighted their importance in regulating atmospheric CO₂, sea ice extent, and the stability of Antarctic ice shelves. Despite their critical role in global climate and mitigation of anthropogenic climate impacts, little is known about their long-term natural variability. Here we present efforts to reconstruct past SHW intensity and associated late Glacial and Holocene climate variability from two islands in the Cape Horn Archipelago, Isla Hermite (55º50'S, 67º40'W), the westernmost in the archipelago, and Isla Hornos (55º56'S, 67º16'W), the southernmost. Combining peat and lake records from a suite of low-lying, westerly-facing sites on Isla Hermite, and a lake sediment record from a headwater cirque lake on Isla Hornos, we aim to reconstruct past aerosol deposition and westerly wind intensity using a novel diatom- and geochemistry-based multiproxy approach. Here we present our latest radiocarbon age-depth models, diatom reconstructions, and micro-XRF scanning results from the cores. These records form part of a larger project to reconstruct late glacial-Holocene SHW intensity from sedimentary records from the sub-Antarctic islands, in an effort to understand past migration and changes in intensity to the SHW, and ultimately how these variations affect CO₂ sequestration on multi-millennial timescales.
**Fri_60_EN-6_1453**

**Diatoms as Indicator of Regional Climatic Variability in Antarctica**

Anna Oaquim¹,² (oaquim.bia@gmail.com), Gleyci Moser³, Heitor Evangelista²

¹Federal Fluminense University, Chemistry, Niterói, Brazil, ²State University of Rio de Janeiro, Biology, Rio de Janeiro, Brazil, ³State University of Rio de Janeiro, Oceanography, Rio de Janeiro, Brazil

The use of diatoms as micropaleontological indicators has been used in the last decades, once these organisms that are sensitive to environmental changes, having their frustules preserved in the sediments which enables paleoclimatic reconstructions. In this context, the present study reconstruct regional climatic variations in the west coast of the Antarctic Peninsula, using fossil records of diatoms in a sedimentary corer with 50 cm sampled at the Glubokoe Deepe Lake, King George Island. 25 layers (period 2013 to 1737) was submitted to qualitatively analysis where 19 taxa was considered as frequent and there relative abundance was correlated with environmental variables to established three reconstruction models. The first reconstruct the temperature in Antarctica Peninsula based on the relative abundance of *Brachysira minor* and *Pinnularia* sp. and presented an associated error of 13%. The second reconstruct the energy of cyclones occurring between 50 ° and 70 ° S based on the relative abundance of *Nitzschia cf. Kleinteichiana*, *Pinnularia borealis*, *Gomphonema* sp. and has an average error of 2%. And the last one reconstruct the ozone content in the atmosphere using *Planothidium australis*, *Pinnularia borealis*, *Gomphonema* sp. and *Humidophila tabellariaeformis* relative abundance with a mean associated error of 11%. The results corroborate with other models proposed thereby allowing to concluded that diatom assemblages can be used as paleoclimatic reconstructors for this region.

Pliocene-Pleistocene Paleoproductivity on the Wilkes Land Margin, Antarctica

Grace Duke¹ (grace.duke@otago.ac.nz), Christina Riesselman¹², Briar Taylor-Silva¹
¹University of Otago / Te Whare Wananga o Otago, Geology Department, Dunedin, New Zealand, ²University of Otago / Te Whare Wananga o Otago, Marine Science Department, Dunedin, New Zealand

Although the East Antarctic Ice Sheet (EAIS) is considered relatively stable, the Wilkes Land Margin (WLM) is susceptible to global warming because its marine-based glaciers are at risk of contact with warm mid-depth waters. Unstable ice sheets cause sea-level rise and threaten coastal communities, but our understanding of ice variability and response to climate change is poorly constrained due to a lack of data. We present a Plio-Pleistocene biogenic silica (wt% BSi) stratigraphy, diatom assemblages, and bulk sedimentary stable isotope data from a marine sediment core collected from IODP site U1361A, located on the WLM continental rise. Characterizing Southern Ocean conditions from 1.8 - 3.8 Ma allows us to examine the shift from the warm Pliocene, which is an analog for future warming conditions, to the cooler Pleistocene, and may improve the parameterization of EAIS response to climate forcings. High wt% BSi intervals are interpreted to reflect interglacial episodes of elevated diatom productivity, while lower wt% BSi intervals are interpreted to reflect glacial episodes of decreased productivity and/or increased terrigenous input. Diatom assemblages from mid- and late-Pliocene interglacial intervals indicate the onset of cooler interglacial surface ocean temperatures around 3.3 Ma, punctuated by short-lived warm water incursions. Work is underway to extend this reconstruction into the early Pleistocene.
Preliminary Study on the Geochemistry and Diatom of Core Sediments in Ross Sea

Younho Noh¹ (ss112@kopri.re.kr), Ho Il Yoon¹
¹Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of

The paleoenvironments, XRF, biostratigraphy, and age dating of the piston cores (RS14-GC04) collected from Ross sea Strait, Antarctica are studied by the micropaleontological studies based on diatoms. As a result of dating, the age of the core represents about 6,000 years. The variation of sediment core including diatoms were analyzed from the drilled core which was obtained from the Ross sea for the purpose of reconstruction of the environmental variations during the Holocene. A total of 25 species and varieties belonging to 58 genera are identified from the Core RS14-GC04. The range of diatom valves per gram of dry sediment was approximately $0$ to $26.3 \times 10^7$ g in quantitative diatom assemblage analysis. The diatom assemblages from RS14-GC04 are dominated by _Fragilariopsis curta_, _Thallassiosira antarctica_ cold type, _Eucampia Antarctica_ var, _recta_. A minor species appeared as _F. obiquecostata_, _F. turgiduloide_, _proboscia alata_, _Rhizosoleni styliformis_ and _Stellarima microtrias_. Ba is a good correlation with TOC, suggesting their relation to biogenic debris, precipitation from seawater, or hydrothermal input.
Implications of Biogenic Sulfur Species from GV7 Firn Core, East Antarctica

Sangbum Hong¹ (hong909@kopri.re.kr), Joo-Hong Kim¹, Seong-Joon Jun¹, Yeongcheo Han¹, Jangil Moon¹, Chang-Kyu Lim¹, Chae-Won Chang¹, Jung-Ho Kang¹, Soondo Hur¹, Seong-Joong Kim¹, Roberto Udisti², Silvia Becagli², Rita Traversi², Mirko Severi²

¹Korea Polar Research Institute, Incheon, Korea, Republic of, ²University of Florence, Florence, Italy

The concentrations of ionic species in conjunction with stable isotopes were measured from firn core drilled in the austral summer of 2014 at the GV7 site (70° 41´S, 158° 52´E, 1950m a.s.l.) conducted as a scientific cooperation between ENEA from Italy and KOPRI from Korea. This study presents the snow chemistry of a short firn core covering a time period of at least 35 years (1979-2013). The concentration variations of biogenic sulfur species were studied in detail to investigate their implications as proxies to indicate the long-term perspective on the change of oceanic environmental in the past. The seasonal concentrations of methanesulfonic acid (MSA) were determined according to the age-depth relationship based on the annual layer counting using the variations of oxygen isotope ratio, nssSO₄²⁻, Cl/Na⁺, and Pinatubo volcanic record. The correlation analyses with satellite-derived sea ice area and firn core MSA were systematically conducted. Variations of MSA during austral summer season were found to be positively correlated with sea-ice area (~60-65°S) between the 150°E and 150°W sector during spring season and the correlation between them at each 10° sector was strongest at 180° (p< 0.05).
Controls affecting the morphology and surficial lithology of a confined outwash fan of the Waldemar River (NW Spitsbergen, Svalbard) were analysed on the basis of geomorphological and sedimentological researches which indicate multiple correlations between the shape of distributary channels and textural features of fluvial deposits. The statistical techniques were used to find relations between the morphological and sedimentary features of a confined outwash fan developed in High Arctic conditions. The ability of these techniques to detect relationships was analysed and threshold values for changes in relations between fan slope, channel morphology, sediment distribution and confined outwash fan width were detected. The results of our research indicate that the morphology and surficial lithology of the confined outwash fan developed under High Arctic conditions are closely related to the existence of permafrost. Changes in the confined fan slope, width and rate of sediment supply (as a result of lateral, mechanical and thermal erosion and degradation of the uppermost part of permafrost) control the distributive channels bed lithology. Thus, the evolution and determination of the rate and dynamics of transformations of confined outwash fans in High Arctic regions, affected by climate warming, can be considered as an indicator of polar environment changes resulting from climate fluctuations. This also will help us to understand the outwashes evolution during the Pleistocene.
The Arctic area is responding more rapidly to global warming than most other areas on our planet. The Kveithola Trough located in the NW Barents Sea has an interesting sedimentary record due to its geographical conditions and its dynamic glacial history formation. Its location allows the input and interaction of two of the main water masses, the cold, fresh Arctic Water coming from the north and the warm, salty Atlantic Water flowing from the south.

Four sediment cores collected in the Kveithola Trough area during the oceanographic cruise EUROFLEETS2-BURSTER were analysed with regard to benthic foraminiferal assemblages and sedimentological parameters in order to elucidate past variability of the water masses, the organic matter flux and oxygen concentration to the sea floor during the last decades. The foraminiferal assemblages composition and taxonomic abundance allow inferring significant environmental differences between the evolution of the inner and outer shelf areas. The dominant foraminiferal species recurrent in the study area may indicate that during the last 45 years a higher influence of warm water and an increase in the anoxic conditions has been established along of the Kveithola Trough area. These evidences need to be confirm by further multidisciplinary analysis including biological, sedimentological and chemical data.
Species communities of marine molluscs from two geochronologically identical early Holocene sites with different positions in the northern part of Billefjorden were compared. Kapp Ekholm (KE) site is situated in the main fjord and the terrace surface lies at ~25 m a.s.l. Mimerdalen 1 (MD1) site has a terrace surface at 28 m a.s.l. and is situated in a valley, which represented a shallow cove. Although both sites are identical in morphostratigraphy and geochronology, they bear species compositions, which correspond to different biostratigraphical levels according to classical concept. The species community on KE is correlated to the morphologically highest, i.e. the oldest Holocene terraces. On the contrary, species composition on MD1 is correlated with morphologically lower and younger terraces. This diversity is caused by different palaeodepths on both sites. According to the sediment architecture, the depth of the sea floor inhabited by studied organisms was ~20 m on KE and ~5 m on MD1. The results indicate that past species communities do not have to correlate necessarily with the morphostratigraphy of terraces. They depend more on the palaeogeographic position within the fjord than on chronostratigraphic position within the early Holocene. Species-poor community does not indicate only temperate conditions shortly after the LGM, but can also occur later in connection with ecological conditions at specific locations.
Reconstruction of Sedimentary Environment in Western Ross Sea Since Early LGM

Xibin Han1 (hanxibin@sio.org.cn), Panpan Long1, Linggang Tang2, Lehui Song3, Geng Liu1
1Second Institute of Oceanography, State Oceanic Administration, Key Laboratory of Submarine Geosciences, Hangzhou, China, 2South China Sea Institute of Oceanology, Chinese Academy of Sciences, Guangzhou, China, 3Nanjing University, Geographic and Oceanographic Sciences, Nanjing, China

The Western Ross Sea is an important drainage channel for the Ross Ice Shelf (RIS) and paleo-ice sheet, and its sedimentary records reflect the retreat history of the RIS and the changing processes of the local ocean circulation. The lithologic feature, internal structure, physical characteristics and organic molecular geochemistry of the gravity sediment core ANT31-JB03 in the Central Basin, western Ross Sea revealed that two stage sedimentary environmental change: (Phase I) and (Phase II) in the early Last Glacial Maximum (LGM) and since the Holocene with the boundary of 78cm depth below sea floor. The missing sediment matter during the two stages maybe eroded by the glacial drift flow during the Last Deglaciation followed the LGM. The sedimentary environment of Phase I was glacial-marine sediment still under RIS extension, with two age reversal events which means that the sediment on the Ross Sea shelf were prone to slide migration and mixing effected by ice shelf drainage flow because of sea water temperature rise or the ice-sea interacts strengthening with each other weak reducing-reducing environment. Since the Holocene, with the rising of the sea level, and the retreating of RIS, the sediments grainsize became thinner, the biological activity increased, the productivity increased, the source of organic matter increased, and the influence of ocean circulation increased gradually. In the meanwhile, three events with increased density and reduced porosity.
In this research, we present high resolution record of Al, As, Ba, Cd, Co, Cr, Mn, Mo, Pb, Rb, Sr and V from Greenland NEEM ice core samples covering the period from 1710 to 1970. To our knowledge, long-term trends of these elements except Cd and Pb have never been reconstructed from Greenland ice cores at such a high resolution. The ice core records of the trace metals concentrations are characterized by large fluctuations. The ratios between maximum and minimum concentrations range from 69 for Sr to 1596 for As indicating a stark variation in concentration with depth. To help understanding long-term changes in atmospheric trace metals, individual data points were averaged for a decadal period. The main features of long-term changes are all categorized into three groups. Al, Ba, Mn, Rb, Sr and V show no distinct peaks in their concentrations over the whole period. Meanwhile, Co, Cr and Mo concentrations are largely peaked from the mid-1830s to the mid-1850s and steadily increase for the 20th century. For As, Cd and Pb, two concentration peaks are appeared around 1800 AD and 1900 AD. The different patterns in the periods reaching peaks in concentrations are likely due to the primary anthropogenic sources for the different element. Our first comprehensive and reliable time series for various trace metals from Greenland NEEM ice core provide valuable insights into significant enrichments of these elements due to human activities from the early-19th to the mid-20th century.
Atmospheric nuclear explosions during the period from the 1940s to the 1980s are the major anthropogenic source of plutonium (Pu) in the environment. In this work, we analyzed fg g⁻¹ levels of artificial Pu, released predominantly by atmospheric nuclear weapons tests. We measured 351 samples which collected a 78 m-depth fire core at the site of GV7 (S 70°41´17.1", E 158°51´48.9", 1950 m a.s.l.), Northern Victoria Land, East Antarctica. To determine the Pu concentration in the samples, we used an inductively coupled plasma sector field mass spectrometry coupled with an Apex high-efficiency sample introduction system, which has the advantages of small sample consumption and simple sample preparation. We reconstructed the firn core Pu fallout record for the period after 1954 CE shows a significant fluctuation in agreement with past atmospheric nuclear testing. These data will contribute to ice core research by providing depth-age information.
Anthropogenic Contaminants in the Last Hundred Years of Antarctic Ice

Stefania Giannarelli1 (stefania.giannarelli@unipi.it), Roger Fuoco1, Sandro Francesconi1, Chiara Tiribilli1
1University of Pisa, Department of Chemistry and Industrial Chemistry, Pisa, Italy

The deposition of contaminants, transported by the aerosol, occurs mainly through snowfalls and therefore the ice-cores represent an archive of notions of the variation of trace chemicals. From the stratigraphy of the ice cores, the ice-layers can be temporally related. Antarctica is the ideal site to perform basic studies on contamination: it provides an atmospheric environment free of local sources or anthropogenic contamination, giving a low background of native-pollution which is essential for transportation studies. As the ice compartment represents a reservoir of historically deposited POPs, quantification of concentrations in Antarctic continental ice is particularly relevant in order to predict the possible future POP re-emission into the atmosphere and oceans through ice melt.

In this work we investigated the presence of Organo Chloride Pesticides (OCPs) in a 50-m deep snow firn core, collected at the peripheral site GV7 in East Antarctica during the 2013-2014 XXIX Italian expedition, to elucidate historical deposition rates of OCPs. The concentration depth profile was obtained on the basis of the total concentration of twenty-two OCPs individually detected by GC-MS QqQ.

SOCPs showed linear and constant trend from 1890 till 1960 (with an average value of 0.01 ng/l), then an increase, in the period 1960-2010, from about 0.01 to 0.20 ng/l (200% increase).
The aim of our study was to assess variability in the soil organic carbon pool from the peatlands and bog soils in taiga and tundra zones along the latitudinal transect in Arctic West Siberia (Russia).

The taiga research site is located in discontinuous permafrost zone (N65º18´, E72º52´). The average active layer thickness was 163±8 (August 2015). The CO₂ efflux from the peatlands was low (202 ± 37 mgCO₂/m²hr). The upper horizons of the peatland soils statistically differed from those of the bog in the contents of the total, labile and microbial carbon.

The tundra research site is located in continuous permafrost zone (N 67°48; E 76°69'). Soils of this research site are characterized by low active layer thickness, CO₂ efflux and content of microbial carbon (August 2016). The spatial distribution of CO₂ efflux and content of water-extractable organic carbon are strongly correlated with hypsometric levels ($r = -0.33$, and $r=-0.42$ respectively, $p$-level $< 0.05$) in tundra ecosystems.

Despite the wide array of changes in both physical (soil temperature, soil moisture) and biological conditions (vegetation composition, content of labile and microbial soil carbon), our results showed that soil CO₂ flux did not vary significantly throughout transect (taiga- tundra). But depth of permafrost table differed significantly. It explains the necessity of adequate assessment of the spatial variability on the active layer thickness as a significant factor influencing regional CO₂ emission.
Fire Effects on Greenhouse Gas Emissions on Wetlands in the YK Delta, Alaska

Darcy L. Peter¹ (darcy.peter@akijp.org), Emily M. Bristol², Paul James Mann³, John D. Schade⁴
¹Alaska Institute for Justice, Research and Policy, Anchorage, United States, ²University of Alaska Southeast, Sitka, United States, ³Northumbria University, Tyne, United Kingdom, ⁴National Science Foundation, Alexandria, United States

Climate change is increasing both fire frequency and fire intensity, especially in Arctic regions. Fire leads to increased soil temperature, which increases the likelihood of permafrost thaw. Permafrost soils in northern latitudes store large amounts of carbon, and thawing of this permafrost will alter carbon cycling processes, which may substantially impact ecosystem processes in aquatic ecosystems. One potential consequence of altered aquatic ecosystem processes is changes in carbon emissions resulting from altered carbon inputs from thawing permafrost. Aquatic ecosystems are known to be hotspots of greenhouse gas emissions, so changes in greenhouse gas fluxes from them may have important impacts on global climate. In this work, we focused on CO₂ and CH₄ fluxes from plateau and lowland ponds, fens and bogs in the Yukon-Kuskokwim (YK) Delta in southwest Alaska. The YK Delta experienced unprecedented fires in summer 2015, presenting an opportunity to assess the impacts of permafrost thaw on greenhouse gas fluxes from aquatic ecosystems. We sampled in sites that had burned in 2015 as well as from similar sites where there have been no recorded fires in the past 75 years. We found little difference in gas flux between aquatic sites in burned and unburned sites, with the exception of channel fens, which showed substantially higher CH₄ and CO₂ flux in burned sites. Results may indicate the response of aquatic ecosystems to fire may lead to positive feedbacks on climate change.
Estimating pCO2 in Cambridge Bay Nunavut Using an Autonomous Sensor Platform

Patrick Duke¹ (pjduke@ucalgary.ca), Brent Else¹, Richard Dewey², Kim Juniper², Lisa Miller¹, Akash Sastri², Oksana Schimnowski³, Helmuth Thomas⁵

¹University of Calgary, Geography, Calgary, Canada, ²Ocean Networks Canada, Victoria, Canada, ³Department of Fisheries and Oceans Canada, Sidney, Canada, ⁴Polar Knowledge Canada, Winnipeg, Canada, ⁵Dalhousie University, Halifax, Canada

Continuous monitoring platforms contribute to our understanding of long term ocean change, offering increased temporal resolution and ability to resolve variability compared to occasional measurements. We will present pCO2 time series data from on-board an Ocean Networks Canada cabled seafloor platform at sub-tidal depth in Cambridge Bay, Nunavut. The platform, which supports a Pro-Oceanus sensor for measuring pCO2 and instruments for measuring temperature, salinity, ice thickness, oxygen, chlorophyll, current velocity, and pH was deployed from August 2015 to August 2017. We will quantitatively distinguish influencing oceanographic processes on pCO2 daily, seasonally, and annually for this unique marine biogeochemical time series. This work contributes to quantifying pCO2 cycling in the Arctic Ocean, influencing climate modelling and future projections of the Arctic Ocean carbon cycle. We will also review the performance of the pCO2 sensor operating in near continuous subzero seawater.
Mercury (Hg) is a global pollutant of great concern for human and ecosystem health. The Arctic is particularly vulnerable because of the high dietary exposure of indigenous populations to Hg in fish and mammals. Atmospheric Hg deposition to Polar Regions has been extensively studied in coastal zones with the goal to better understand the nature and relevance of halogen-driven atmospheric mercury depletion events (AMDE’s). Little attention has been given so far to the interior, continental Arctic. We will present a comprehensive Hg stable isotope mass balance of the arctic tundra made at Toolik Field station, AK and compare our findings with extensive terrestrial - atmosphere Hg₀ flux measurements conducted at the same site. The Hg stable isotope results agree well with micro-metrological flux measurements. Both independent approaches suggest that vegetation uptake of gaseous elemental Hg represents the dominant Hg flux between the atmosphere and Arctic tundra soils. The Arctic tundra thus represents a globally important sink for anthropogenic Hg emissions. Changes in environmental conditions, such as warming and thawing of permafrost due to climate change or could however lead to a remobilization of a large Hg pool stored in Arctic tundra soils to the Arctic Ocean.
Tracing the Iron Cycle in the Southern Ocean during the ACE Voyage

Michael Ellwood¹ (michael.ellwood@anu.edu.au), Christel Hassler², Samuel Jaccard³, Tim Conway⁴, Julie Janssens⁵, Maureen Soon⁶, Roger Francois⁶, David Jenssen⁷, Matthias Sieber⁷, Damien Cabanes², Phillipe Arpagaus², Derek Vance⁷, Nolwenn Lemaitre⁷, Gregory de Souza⁷

¹Australian National University, Research School of Earth Sciences, Canberra, Australia, ²University of Geneva, Geneva, Switzerland, ³University of Bern, Bern, Switzerland, ⁴University of South Florida, St Petersburg, United States, ⁵University of Tasmania, Hobart, Australia, ⁶University of British Columbia, Vancouver, Canada, ⁷ETH Zurich, Zurich, Switzerland

Incubation and mesoscale enrichment experiments demonstrate that iron is a key micronutrient limiting the growth of phytoplankton in Southern Ocean waters. It is the size of the bioavailable iron pool that shapes the phytoplankton community and hence their draw-down atmospheric carbon dioxide.

During project 15 of the Antarctic Circumnavigation Expedition (ACE) we collected trace metals samples from Indian, Pacific and Atlantic sectors of the Southern Ocean. Preliminary results reveal that the dissolved iron concentration in open ocean waters is sub-nanomolar in concentration. Near continental features such as the Kerguelen Plateau, iron concentrations are elevated which is consistent with continental supply. In contrast, there was latitudinal surface gradient in the concentration for dissolved zinc, copper, nickel and cadmium. Concentrations for these elements were high in surface waters south of the Antarctic Polar Front consistent with a deep-water supply whereas concentrations declined as surface waters are advected northward in the Subantarctic zone. Using this data, our goal is to develop a mechanistic understanding of the role iron, zinc, copper, nickel and cadmium play in regulating plankton communities in the Southern Ocean.
Photosynthetic production of particulate organic carbon (POC) by marine phytoplankton is a key mechanism for the uptake of carbon dioxide that enters the surface ocean, which is then cycled through the complex marine food web. Sinking of POC from surface waters to the deep ocean represents a major pathway in the long-term storage of carbon. However, only a small fraction of the surface POC is sequestered in the deep ocean. We examined the fate of POC throughout the water column in the Dalton, Mertz and Ninnis polynyas in the Southern Ocean towards the end of the summer bloom. POC concentration in surface waters (2-10m) of coastal polynyas are higher (162 to 274 mg m$^{-3}$) than the Antarctic open water reference station (114 mg m$^{-3}$). Compared to the Dalton where POC concentration decreased with depth, POC concentration in the Mertz and Ninnis polynyas increased (>300 mg m$^{-3}$) between 10-50m before decreasing. Background POC in the twilight zone was also higher within the polynyas. Large fraction of the organic carbon in the sinking particles is subjected to a range of processes such as bacterial remineralisation, abiotic disaggregation and fragmentation into smaller, slower sinking particles by the zooplankton community during its transit through the water column. Seawater ammonia concentrations suggest active bacterial remineralisation in surface seawater. Biologically productive polynyas are hotspots for elevated surface POC, and could play an important role in carbon export.
Microbial communities in supraglacial ecosystems like cryoconite holes and surface snow strongly influence nutrient cycling in these environments. In order to understand carbon flow within these systems, we carried out in-situ measurements of primary (PP) and bacteria production (BP) in cryoconite holes and surface snow at Larsemann Hills, East Antarctica during 2016-17 season. The rates of PP and BP in six cryoconite hole water samples were 0.09±0.03 µgCl⁻¹d⁻¹ and 10.26±7.18 ngCl⁻¹d⁻¹, respectively, with higher rates observed in the sediment (PP=5.88±3.77 µgCl⁻¹d⁻¹; BP=138.40±86.25 ngCl⁻¹d⁻¹), suggesting that sediments play a crucial role in the carbon cycling of the cryoconite holes ecosystem. In snow, mean rate of PP was 0.08±0.02 µgCl⁻¹d⁻¹ whereas BP was below detection limit. To understand the photochemical and microbial transformations of dissolved organic matter and ionic constituents associated with snow and cryoconite holes, in-situ field experiments were carried out in the presence of: microbes under dark, microbes+light and only light (no microbial activity) conditions. Significant changes in DOC and major ions (Na⁺, Cl⁻, Mg²⁺, Ca²⁺, SO₄²⁻, K⁺, NO₃⁻, Ac⁻, Fo⁻, Oxy²⁻ and HCO₃⁻) concentrations were observed after 30 days incubation. Observations made in this study are crucial for an improved understanding of the nutrient cycling in supraglacial ecosystems of polar regions.
Microelements in Soils of Oases of Thala Hills, Enderby Land, East Antarctica

Tamara Kukharchyk¹ (tkukharchyk@gmail.com), Sergey Kakareka¹, Yuri Giginyak², Vladislav Myamin²
¹Institute for Nature Management, National Academy of Sciences of Belarus, Minsk, Belarus, ²The Scientific and Practical Centre for Bioresources, National Academy of Sciences of Belarus, Minsk, Belarus

The paper is devoted to the studies of spatial and temporal patterns of microelements content in soils of Vecherny oasis (Thala Hills, Enderby Land) and their connections to human impact. The paper is based on the results of soils investigation during Belarusian Antarctic Expeditions in 2011-2017.

General description of soils features of the oasis in comparison with others oases of Enderby Land is provided. It is shown, that the most developed soils with profile up to 50-60 cm can be found at bottoms of hollows; such sites are usually partially covered by lakes or snowfields. Their area varies from less than 1 m² to several hundred meters. Soils are acidic or slightly acidic, characterized by low humus content and low sorption capacity; soils properties and intensity of radial and horizontal microelements migration are highly impacted by the hypsometric level of a site location.

Certain connections of microelements content in soils with human impacts in this area is found. Among microelements sources are: erosion of old mechanisms, constructions, waste fuel oil barrels as well as fuel leaks. Generally, detected levels of microelements content can be considered as not very high. No common area of soils contamination was found due to high level of soils fragmentation.

The results of soils study will be used for model of heavy metals migration in soils parametrization to provide the forecast of soil pollution taking into account climate change and human activities.
A large suit of inorganic analytes was determined in water collected from six shallow Antarctic lakes of Terra Nova Bay (Northern Victoria Land, Antarctica), as well as in algae, mosses and suspended particulate material (SPM). The sampling campaigns took place between 2007 and 2012 (and one in 2002) within the framework of the Italian National Program of Research in Antarctica (PNRA). The purpose of this work was to gain insight into the natural processes regulating species distribution, define natural background values and detect possible present or future local and/or global anthropogenic contamination.

The results were processed with multivariate chemometric techniques. Lake water composition was found to be mainly influenced by marine spray and meltwater input, i.e. natural phenomena. The obtained results were compared with older literature data from the same lakes. A considerable variability was observed in metal concentrations, but no clear trend was identified; no evidence of an increase of metal concentrations over time was found for water or vegetation samples. Seasonal variability was also evaluated for each analyte, and explained considering the natural transport processes involving each species. Higher element concentrations were found in SPM than in water, suggesting that weathering plays an important role on the chemistry of these lakes. The exam of the SPM samples with a SEM showed the presence of many diatoms belonging to different species.

Understanding how the climate change affects the microbial community in the Arctic Sea and the ongoing heating results in cascading effects on the earth delicate climatic equilibrium is an important challenge of recent research performed in vulnerable ecosystems such as the Svalbard Islands. Within the UVASS (Unmanned Vehicles for Autonomous Sensing and Sampling) project, an unmanned marine vehicle (PROTEUS, Portable RObotic TEChnology for Unmanned Surveys), equipped with an automatic water multisampler, designed and built by ISSIA-CNR and IAMC-CNR respectively, were exploited to study the response of planktonic communities, particularly prokaryotes, in the extreme environment of Kongsfjorden. In June 2017 seawater samples were collected by those automatic systems along three transects extending from glaciers fronts to the open sea. The samples were analyzed for nutrients, organic matter and its utilization by microbial activity using Biolog-Ecoplates™ and extracellular enzymatic activity rates (leucine aminopeptidase, beta-glucosidase and phosphatase activities). Richness and Shannon-Weaver index and Principal Component Analysis were used to depict differences in the microbial catabolic potential. Variations in organic matter distribution and in functional diversity of microbial assemblages were observed. Freshwater runoff from ice melting was found to increase the amount of terrestrial organic matter to the fjord and microbial processes allowed organic matter decomposition.
**Fri_82_EN-7_1201**

**Sediment Transport in the Northwestern Laptev Sea**

Stefan Buettner¹ (s buettner@ecology.uni-kiel.de), Jens Hoelemann², Markus Janout²

¹Christian Albrecht University of Kiel, Institute for Ecosystem Research, Kiel, Germany, ²Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany

Arctic summer sea ice extent is continuously declining, affecting the hydrography and biogeochemical cycles on the seasonally ice-free shallow Siberian shelves. The prolongation of the open-water season during summer causes higher sediment resuspension and coastal erosion due to larger wind fetch and wave heights. This impacts the optical properties of the water column and hence biological productivity in this region. In order to link changes in sediment distribution with ecosystem consequences under a warming climate, detailed studies of sediment transport and pathways are required.

On the central and eastern Laptev Sea shelf, suspended particulate matter (SPM) transport is mainly characterized by two nepheloid layers, originating from bottom resuspension, erosion of thawing permafrost coasts and the input of turbid river water from the Lena River. In the northwestern Laptev Sea, SPM dynamics and transport mechanisms from the Kara Sea through Vilkitsky Strait and into the Eurasian Basin remain largely unknown due to the inaccessibility of the region. Nevertheless, several ship expeditions and deployments of long-term oceanographic observations were carried out in the western Laptev Sea from 2013 until 2015 to investigate year-round SPM distribution and dynamics. This study presents first results of year-round SPM distribution, obtained by combining optical backscatter data, ADCP echo intensity data and filtration measurements from summer expeditions.
Antarctic Derived Dust in the South West Ross Sea

Cliff Atkins¹ (cliff.atkins@vuw.ac.nz), Gavin Dunbar¹, Juliet Sefton²
¹Victoria University of Wellington, Wellington, New Zealand, ²Durham University, Durham, United Kingdom

Dust in the SW Ross Sea Region is transported by katabatic winds from ice-free areas, offshore onto ice shelves and sea ice where it is released into the ocean. The dust contributes sediment to the Antarctic shelf and is one source of iron (Fe) involved in triggering vast phytoplankton blooms which regulate the oceanic biological pump, drawing down atmospheric CO₂. However, the source, distribution and impact of the dust is still poorly constrained. Although some modelling studies suggest that the McMurdo Dry Valleys is an important source of dust, our field data indicate that most of the dust flux comes from relatively small areas around the coast, in particular an area of unconsolidated debris on the McMurdo Ice Shelf.

We present new major element X-ray florescence analysis from a comprehensive suite of samples from potential source areas in Victoria Land as well as samples from extensive areas of sea ice and ice shelves fringing the coast and also from sea floor grab samples from across the SW Ross Sea. The results shows clear compositional patterns suggesting that dust can be geochemically traced from various onshore sources to offshore Ross Sea sink. This provides constraints on the modern dust flux, transport processes and impact on sedimentation and biogeochemical cycling in the Ross Sea. The data will contribute to the new international High Latitude and Cold Climate Dust Network database, www.hlccd.org.
Dissolved organic matter (DOM) exists ubiquitously in water and is involved in various biogeochemical processes. In Antarctica, most of DOM is considered to be originated from lower plants. This unique feature of Antarctica is ideal to unveil structural properties and functionality of DOM, which depend on the source materials and environmental processing. In this study, we present the diversity in the properties of DOM obtained from various lakes and streams at Soya Coast, East Dronning Maud Land, East Antarctica (n = 81). Water samples were collected from streams, and the center or shore of lakes. They were filtered with a pre-combusted glass fiber filter (< 0.3 µm), and the absorbance and excitation emission spectroscopy (3D-EEM) were measured immediately. Some portion of water samples were stored in a glass bottles and transferred to Japan, where DOM in the samples were fractionated into humic substances (HS) and non-HS. Optical indices such as SUVA254, S275-295, FI, BIX, and HIX were calculated from the absorbance and 3D-EEM data to elucidate the structural properties and origin of DOM. We further analyzed 3D-EEMs by parallel factor analysis (PARAFAC) to deconvolute them into distinct fluorescent components. It was suggested that Antarctic DOM increases its molecular weight, aromaticity, and degree of humification along glacier melt-lake water-pore water spectrum, and these changes are attributed to be driven by the activity of primary producers.
Iron (Fe) availability and its influence on phytoplankton community structure and nutrient cycling has been recognized in the Ross Sea. This region is one of the most productive of the Southern Ocean, thus significantly contributing to the CO₂ sink. The most investigated source of Fe is sea ice melting, but recent studies in the Central and Southern Ross Sea also identified the importance of the CDW intrusion and the glacial melt water. The Fe input evaluation due to glacial melt water in the western Ross Sea is one of the goals of CELEBeR (CDW Effects on glacial melting and on Bulk of Fe in the Western Ross sea) project. To this purpose, CELEBeR carried out ship measurements during a cruise in the austral summer 2016-17, as part of the Italian National Program of Research in Antarctica (PNRA). Dissolved and particulate Fe data were collected in 18 stations sampled in Terra Nova Bay polynya together with physical, chemical (O₂, H₂¹⁸O/H₂¹⁶O ratio, nutrients, CO₂ system variables) and biological (phytoplankton and prokaryotic biomass, characterization of bacteria at DCM) parameters. Water mass characterized by temperature below the surface freezing point and associated with Fe contribution was detected in the intermediate layers of the water column. Particulate Fe concentrations were on average an order of magnitude higher than those of dissolved Fe. The Fe distribution will be discussed taking into account the chemical, physical and biological characteristics of the area.
Dissolved Organic Matter (DOM) and Microbial Enzymes in the Ross Sea

Antonietta Specchiulli¹ (antonietta.specchiulli@ismar.cnr.it), Gabriella Caruso², Pasqualina Laganà³, Lucrezia Cilenti¹, Pasquale Castagno⁴, Paola Rivaro⁵, Maurizio Azzaro²

¹CNR, National Research Council, Institute of Marine Sciences, Lesina (FG), Italy, ²CNR, National Research Council, IAMC Institute of Marine and Coastal Environment, Messina, Italy, ³University of Messina, Messina, Italy, ⁴Parthenope University, Napoli, Italy, ⁵University of Genova, Genova, Italy

In the Ross Sea the dissolved organic matter and the role of culturable heterotrophic microbes in its degradation are almost unknown. In the carbon cycle, dissolved organic carbon (DOC) concentration and its optically significant fraction, the chromophoric component (CDOM) are important for DOM budget estimates. Within the CELEBeR project [Circumpolar Deep Water (CDW) Effects on glacial MELting and on Bulk of Fe in the Western Ross sea - PNRA], DOC and CDOM, culturable heterotrophic bacteria and the enzymatic activities, expressed by bacterial isolates, were examined in the Ross Sea during the austral summer 2017, in relation to CDW contribution. The covered areas were the Drygalski Ice Tongue and the nearby Terra Nova Bay polynya (A) and the continental Shelf Break area near Cape Adare (B). Within the area A, the lowest DOC (38.33 µM), CDOM (α₂₈₀ of 0.27 m⁻¹) and SUVA₂₅₄ (0.54 L mg⁻¹ m⁻¹) were measured at 225 m (CDW); the highest DOC (63.29 µM), CDOM (α₂₈₀ of 1.39 m⁻¹) and SUVA₂₅₄ (1.6 L mg⁻¹ m⁻¹) were recorded at the northernmost area B (DCM), also characterized by the lowest spectral slopes (SR= 1.37). Heterotrophic bacteria ranged from 5.0x10¹ (CDW) to 7.0x10³ CFU/ml (DCM); aminopeptidase and alkaline phosphatase were the most expressed enzymes. Based on microbial cells counting, the distribution of heterothrophic bacteria seems to be not affected by DOC concentration and its composition, as highlighted by the lack of correlations between the two variable sets.
The microbial community uses extracellular enzymatic activities (EEA) to initialize degradation of high molecular weight organic matter in all the ocean.

The intrusion of the warm Circumpolar Deep Water (CDW) into the Antarctic shelf area is one of the recognized drivers of ice shelf melting, playing an important role on the shelf physical and biological processes. The investigated areas covered: a) the Drygalski Ice Tongue and the nearby Terra Nova Bay polynya; b) the coastal area between the Mariner and Aviator glaciers; c) the Antarctic continental Shelf Break area near Cape Adare (North Victoria Land).

During an oceanographic cruise performed in the framework of the CELEBeR (CDW effects on glacial melting and on bulk of Fe in the Western Ross Sea) project (funded by Italian PNRA), the EEA distribution was studied in order to investigate the spatial and depth patterns in the Ross Sea. In particular rates of leucine-aminopeptidase -LAP, β-glucosidase -GLU and alkaline phosphatase -AP were measured. The contribution of free enzymes fraction in some stations was also determined and the relationships with the main environmental parameters were analyzed.

Results suggested the potential capability of the microbial community to decompose proteins, carbohydrates and organic phosphates. In the Shelf Break area LAP values showed higher values than Terra Nova Bay at surface. The decreasing trend with increasing depth was confirmed. Hydrology had also effect on EEA distribution.
Drivers of Phytoplankton Biomass in Three East Antarctica Polynyas

Sebastien Moreau1,2 (sebastien.moreau@hotmail.com), Julie Janssens1, Peter Strutton1, Lavenia Ratnarajah1, Delphine Lannuzel1
1University of Tasmania, Institute for Marine and Antarctic Studies, Hobart, Australia, 2Norwegian Polar Institute, Tromso, Norway

In the Southern Ocean, polynyas have the highest primary productivity rates and represent one of the largest CO2 sinks. As a consequence, top predators favour these biomass rich areas. Three contrasting polynyas were visited in East Antarctica in January 2017: the Dalton, the Mertz and the Ninnis polynyas. The average phytoplankton biomass was ~ twice as high in the Mertz and Ninnis (411 and 466 mg Chl-a m$^{-2}$) than in the Dalton (266 mg Chl-a m$^{-2}$) Polynya. Sea surface $\Delta$O$2$/Ar was also significantly higher in the Mertz and Ninnis (5 to 12%) than in the Dalton (-8 to 8%) Polynya. These strong regional differences were further explored using physiological and physical parameters. First, the maximum yield of photosystem II was not significantly different and > 0.4 in all the polynyas. The higher productivity in the Mertz and Ninnis could be due to higher stratification and iron-rich sea-ice meltwaters. This scenario is supported by the significantly lower surface salinity in the Mertz and Ninnis (33.18 ± 0.33) than in the Dalton polynya (34.01 ± 0.33). In contrast, the major driver of primary productivity in the Dalton Polynya seemed to be the outflow of Ice Shelf Water from the neighbouring Moscow University Ice Shelf. Alternative hypotheses included a trophic cascade due to less top predators in the Dalton and differences in the phytoplankton composition of the three polynyas. Our study highlights the role of cryosphere-ocean interactions on carbon cycling in Antarctic polynyas.
Variations in stable chromium isotopes ($\delta^{53}\text{Cr}$) may serve as a useful tool for understanding biological and physical processes in the modern and past oceans. For example, the redox activity of Cr and the isotope fractionation and solubility changes associated with Cr redox transformations have led to the use of Cr for inferring the paleoredox state of seawater. Additionally, recent data showing the scavenging of dissolved Cr onto growing phytoplankton suggests that $\delta^{53}\text{Cr}$ in marine sediments may yield constraints on changes in marine biological productivity in the past.

To help assess $\delta^{53}\text{Cr}$ as a productivity proxy and better understand the as yet poorly constrained marine Cr cycle, samples for dissolved Cr concentration, redox speciation and $\delta^{53}\text{Cr}$ were collected during the Antarctic Circumnavigation Expedition (ACE) as a component of project 15. These samples, collected across strong gradients in macro- and micronutrient concentrations and in primary productivity, will provide insights into the relationship between Cr speciation, $\delta^{53}\text{Cr}$ and primary production in varying oceanographic regimes and will help determine the potential of the proxy in modern and paleoceanographic settings. Additionally, the samples will add significantly to the global body of $\delta^{53}\text{Cr}$ data and help to further a mechanistic understanding of Cr cycling in the global ocean.
Automatic Sampling Near an Arctic Glacier: First Microbial Results

Maurizio Azzaro1 (maurizio.azzaro@iamc.cnr.it), Rosabruna La Ferla1, Giovanna Maimone1, Filippo Azzaro1, Gabriella Caruso1, Anderson S. Cabral2, Rodolfo Paranhos2, Ermanno Crisafi1, Massimo Caccia3, Roberta Ferretti3, Angelo Odetti3, Giuseppe Zappalà1, Gabriele Bruzzone3

1CNR-IAMC, Messina, Italy, 2UFRJ, Institute of Biology, Rio De Janeiro, Brazil, 3CNR-ISSIA, Genova, Italy

In the frame of the ARCA project (ARctic: present Climatic change and pAst extreme events) aimed at studying the hydrological cycle in the boreal hemisphere, a first prototype of automatic equipment was specifically designed to perform discrete sampling of waters in the area close to a glacier. The Shark USSV (Unmanned Semi-Submersible Vehicle), designed and built by CNR-ISSIA, was the first to reach and autonomously collect samples of water near the front of a glacier, the Kronebreen in the Kongsfjorden. Shark towed, through an adequate rope, a small catamaran carrying an Automatic Water Multisampler built by CNR-IAMC. In June 2015, surface water samples were collected by the automatic Multisampler along a transect subdivided into 9 sampling stations and extending from the glacier front to the open sea. This research reports the results of the first in situ application of this device related to the study of the distributions of prokaryotes, virus-like particles and nutrients. Viral and prokaryotic abundances were significantly correlated with each other and their spatial distributions resulted not to be affected by the presence of the glacier. A low viruses abundance was found compared to the other marine ecosystems and it might be explained by adsorption on particles. The low virus/prokaryotes ratio suggested a lysogenic phase of virus. High nutrient concentrations were detected but they appeared to be not linked to microbial patterns.
Biogenic Matter in Surface Sediments of the Weddell Sea Continental Shelf

Enrique Isla (isla@icm.csic.es)
1Institut de Ciències del Mar-CSIC, Marine Geosciences, Barcelona, Spain

The organic carbon (OC) and biogenic silica (bSi) contents in the upper 5 cm of the seabed were investigated in more than 60 sediment cores from several regions along the continental shelf of the Weddell Sea and the northern Antarctic Peninsula. The results showed that the shelf on the western flank of the Filchner Trough has the lowest contents in OC, 1.2 mg g⁻¹, in contrast to the northwestern Weddell Sea where values of up to 16 mg g⁻¹ were found. In the case of bSi the lowest values were also observed in sediment from the western flank of the Filchner Trough, 5 mg g⁻¹, whereas the highest concentrations were measured in samples from the Bransfield Strait, 114 mg g⁻¹. The lowest values corresponded to regions where sea ice distribution drastically reduces primary production at the sea surface and consequently there is a relatively small export flux of biogenic matter such as in the cases of the western flank of the Filchner Trough and the Larsen A, B and C continental shelves. In contrast, in regions where the typical ice-free seasonal summer conditions take place, such as Bransfield Strait and the northwestern Weddell Sea at the vicinities of the Antarctic Peninsula and the eastern Weddell Sea off Kapp Norvegia, the biogenic matter contents in the sediment are higher. Ongoing climate change directly affects sea ice distribution and most likely will transfer this signal to the chemical characteristics of the seabed sediment.
The Greenland Ice Sheet (GRIS) creates large amounts of fine-grained mineral particles by bedrock erosion. This glacial rock flour (GRF) is transported to the ocean via a series of intermediate environments: pro-glacial river valleys, lakes, estuaries and fjords. GRF in estuaries of meltwater rivers is very fine-grained as exemplified by Ilulialik in West Greenland: D90=24, D50=4, D10=0.7 (microns).

The migration of GRF from land to open ocean is accompanied by export of dissolved carbon and alkalinity, nutrients, trace elements and isotopes, and by change in turbidity and ocean albedo. GRF behaviour is highly dependent on its fine grain size, which allows high-residence time in the water column before settling, and high reactivity in aqueous solutions. We report experimental results on GRF reaction rates in freshwater and saltwater in order to develop a predictive model quantifying these effects and to determine the ultimate fate of glacially derived rock particles during transit through the photic layer in Arctic marine environments.

We propose that the export rate, settling velocity and reactivity of GRF affects the primary productivity and CO2 drawdown capacity of Greenland near-shore environments, and potentially the whole North Atlantic region. Increased melting of GRIS has caused increased sediment export (Bendixen et al., 2017: Nature 550, 101-104: doi:10.1038/nature23873). We address some of the potential effects of this increase on the Arctic marine environment.
Black carbon (BC) is derived from the incomplete combustion of biomass and fossil fuels and can enhance glacial recession when deposited on snow and ice surfaces. Here we explore the influence of environmental conditions and the proximity to anthropogenic sources on the concentration and composition of dissolved black carbon (DBC), as measured by benzenepolycarboxylic acid (BPCA) markers, across snow, lakes, and streams from the global cryosphere. Data are presented from Antarctica, the Arctic, and high alpine regions of the Himalayas, Rockies, Andes, and Alps. DBC concentrations spanned from 0.62 µg/L to 170 µg/L. The median and (2.5, 97.5) quantiles in the pristine samples were 1.8 µg/L (0.62, 12), and non-pristine samples were 21 µg/L (1.6, 170). DBC is susceptible to photodegradation when exposed to solar radiation. This process leads to a less condensed BPCA signature. However, DBC from the Greenland Ice Sheet (GRIS) had a highly-condensed BPCA molecular signature. This could be due to recent deposition of BC from Canadian wildfires. The high concentration measured in supra-glacial melt on the GRIS also suggests DBC can be mobilized across ice surfaces. Overall, variation in DBC appears to be driven by a combination of photochemical processing and the source combustion conditions under which the DBC was formed, and was found to persist across the global cryosphere in pristine and non-pristine areas.
Composition and Transformation of Dissolved Organic Matter in Antarctic Snow

Runa Antony1 (runa@ncaor.gov.in), Amanda S. Willoughby2, Amanda M. Grannas1, Rachel L. Sleighter2, Meloth Thamban1, Patrick G. Hatcher2

1National Center for Antarctic and Ocean Research, Goa, India, 2Old Dominion University, Virginia, United States, 3Villanova University, Pennsylvania, United States

The processing of dissolved organic matter (DOM) in glacier systems is an important part of the global carbon cycle. We applied ultrahigh-resolution mass spectrometry and other chemical and biological approaches to understand the molecular composition of DOM along two coast to inland (up to 300 km from the sea) transects in East Antarctica. We also carried out in situ field incubations to understand photochemical and biological (photo-biochemical) transformation of DOM on the ice surface. DOM composition in Antarctic snow was mainly related to autochthonous production by resident microbial communities, with significant inputs from marine and long range atmospheric transport. We present strong evidence of extensive photo-biochemical alteration of both autochthonous and allochthonous DOM on the coastal Antarctic ice sheet surface, resulting in major shifts in the composition and bioavailability of nitrogen, sulfur, and phosphorous bio-molecules. In some cases, photo-biochemical processing appears to result in altered compounds that are photo- and bio-labile. The opposite is also observed, converting some components of the DOM to photo- and bio-resistant forms. Thus, the biogeochemistry of DOM is highly complex and closely connected with microbial and photochemical processes. The new insights on the interactions between microbes, light and specific DOM molecules highlight the need for focused studies on supraglacial carbon biogeochemistry and its response to a changing climate.
Carbon Export by the Mackenzie River during Spring Freshet

Melissa Sophia Schwab1 (melissa.schwab@erdw.ethz.ch), Robert G. Hilton2, Negar Haghipour1, Timothy Ian Eglinton1
1ETH Zürich / Geological Institut, Zürich, Switzerland, 2Durham University / Geographic Institute, Durham, United Kingdom

Rapid ongoing warming and accompanying hydrological changes in the Arctic influence the mobilization and fate of terrestrial organic carbon transported along the land-to-ocean continuum, with implications for regional and global carbon cycles. The Mackenzie River is the largest supplier of sediment and particulate organic carbon to the Arctic Ocean, with a majority of the annual sediment load being exported during the spring freshet. However, thus far, relatively few studies have attempted a comprehensive quantification and characterization of organic carbon exported by the Mackenzie during the spring freshet.

We collected water column samples for analysis of dissolved inorganic and organic carbon, and depth profiles of suspended particulate matter, as well as bank and channel sediments from the main channel of the Mackenzie River, the Peel River and the Arctic Red during the spring freshet in 2017. We present a comprehensive data set comprising sedimentological characteristics (grain size, mineralogy mineral-specific surface area), bulk geochemical properties (e.g., %OC, δ13C-OC, δ14C-OC) and molecular signatures (i.e. long-chain n-alkanes and fatty acids) to constrain sources and derive fluxes of terrestrial organic carbon during the freshet. We compare these data from the 2017 freshet with complementary information available from previous studies in order to assess potential temporal changes in the nature of materials exported by the river system.
Modern Sediment Distribution and Composition in Kongsfjorden, Svalbard

Stefano Miserocchi1, Leonardo Langone1 (leonardo.langone@ismar.cnr.it), Alessandra D’Angelo1,2, Fabrizio Del Bianco1, Federico Giglio1, Tommaso Tesi1, Stefano Aliani4
1CNR-ISMAR, National Research Council, Bologna, Italy, 2Università degli Studi di Siena, Siena, Italy, 3Proambiente Scrl, Bologna, Italy, 4CNR-ISMAR, National Research Council, La Spezia, Italy

The Kongsfjorden is a small fjord located in western Svalbard. 12 short sediment cores were sampled in 2011 to describe modern sediment distribution and geochemical composition. Core locations were chosen based on a high resolution seismic survey in order to delineate surficial seismostratigraphic features. Based on the different acoustic response, seismic reflectors are continuously or irregularly laminated, transparent-chaotic, or continuous and highly reflective. Maximum sediment thicknesses (~10 m) were recorded close to the calving line of ice tongues.

Sedimentation rates, based on seismic and radionuclide profiles, resulted in high values (up to 10 cm/y) in the laminated fine mud near the glaciers, and lower sedimentation rates (0.2-0.6 cm/y) in the bioturbated muddy sediment of the outer fjord.

Organic carbon content of surface sediments showed values decreasing toward the inner fjord, reflecting the higher accumulation rates and the lower biological production in the turbid water near glacial fronts. High Br/Cl in outer fjord sediments reveals the presence of organic matter of marine origin consistent with the bulk organic carbon data.

High Ca/Ti ratios measured in inner fjord sediments prove the deposition of Ca-rich sediments supplied by the catchment of Kronebreen-Kongsvegen glaciers. In contrast, Ca/Ti is lower in the outer fjord. However, the down core distribution suggests the occurrence of past events during which the glacier influence extended further seaward.
Changes in Ocean Chemistry from 6 Year Time Series in Arctic Outflow Waters

Melissa Chierici\textsuperscript{1,2} (melissa.chierici@imr.no), Agneta Fransson\textsuperscript{3}, Paul Dodd\textsuperscript{3}, Mats Granskog\textsuperscript{3}, Colin Stedmon\textsuperscript{4}, Svein Kristiansen\textsuperscript{5}

\textsuperscript{1}Institute of Marine Research, Oceanography and Climate, Tromsø, Norway, \textsuperscript{2}University Centre in Svalbard (UNIS), Longyearbyen, Norway, \textsuperscript{3}Norwegian Polar Institute, Tromsø, Norway, \textsuperscript{4}Danish Centre for Marine Research, Copenhagen, Denmark, \textsuperscript{5}The Arctic University of Norway, Tromsø, Norway

The Fram Strait is the main gateway for the exchange of warm and saline Atlantic water and the cold and fresh outflow waters from the Arctic Ocean. For six years, we collected data on the chemical (carbonate chemistry, nutrients) and physical (salinity and temperature) data along a section at ~79 °N across Fram Strait from 2011 to 2016. In this study, we focus on the change of the outflow waters in the top 400 m on the NE Greenland shelf between 12°W and 4°W. The largest variability and change in physical-chemical characteristics were observed in the top 100 meters, where temperature and salinity generally increased in the study period. Except for in 2012, total alkalinity (AT), total dissolved inorganic carbon (DIC) and CO\textsubscript{2} (fCO\textsubscript{2}) showed a clear increase in the whole water column throughout the period. Simultaneously, pH and calcium carbonate (CaCO\textsubscript{3}) saturation decreased, and we found indications of a deepening and spread of the lower aragonite saturated waters. This confirms recent findings in the Arctic Ocean that the low CaCO\textsubscript{3} saturated waters are spreading horizontally at depth. The study shows that even a relatively short time-series such as six years gives important information on the present changes in the chemical and physical environment in the Arctic Ocean. We discuss and compare results from previous studies and discuss possible causes for the observed changes in the carbonate chemistry and ocean acidification state.
Effects of Arctic Sea-ice and Biogeochemical Drivers on Under-ice Water $f$CO$_2$

Agneta Fransson$^1$ (agneta.fransson@npolar.no), Melissa Chierci$^2$, Ingunn Skjelvan$^3$, Are Olsen$^4$, Philipp Assmy$^1$, Algot K Peterson$^5$, Gunnar Spreen$^6$, Brian Ward$^7$

$^1$Norwegian Polar Institute, Tromsø, Norway, $^2$Institute of Marine Research, Tromsø, Norway, $^3$Bjerknes Centre for Climate Research, Uni Research Climate, Bergen, Norway, $^4$Geophysical Institute, University of Bergen, Bergen, Norway, $^5$Geophysical Institute, University of Bergen, Tromsø, Norway, $^6$Institute of Environmental Physics, University of Bremen, Bremen, Germany, $^7$School of Physics and Ryan Institute, National University of Ireland, Galway, Ireland

The ice cover in the Arctic Ocean has decreased during the last decades, manifested in particular as an extensive transition from thicker multiyear ice to thinner first-year ice. As the summer sea-ice cover is decreasing, larger areas with open water will be exposed to the atmosphere. This will have implications for the carbonate chemistry and sea-air carbon dioxide (CO$_2$) exchange. We present measurements of CO$_2$ fugacity ($f$CO$_2$) and estimates of the effects biogeochemical processes in the under-ice water, driving the sea-air CO$_2$ fluxes. The data was obtained from January to June 2015 during the Norwegian young sea ICE (N-ICE2015) expedition, where the ship drifted with four different ice floes and covered the deep Nansen Basin, the slopes north of Svalbard, and the Yermak Plateau. This unique winter-to-spring data set includes the first winter-time under-ice water $f$CO$_2$ observations in this region. The observed under-ice $f$CO$_2$ was undersaturated relative to the atmospheric $f$CO$_2$. Although the sea ice partly prevented direct CO$_2$ exchange between ocean and atmosphere, frequently occurring leads and breakup of the ice sheet promoted sea-air CO$_2$ fluxes. In winter, the main drivers of the change in under-ice water $f$CO$_2$ were dissolution of CaCO$_3$ (ikaite) and vertical mixing. In June, in addition to these processes, primary production and sea-air CO$_2$ fluxes were important.
Navarino Island (55° S) is the southernmost territory of the sub-Antarctic Magellanic ecoregion, which is a part of the world where ecosystems have been understudied and from which methane cycling and emissions in lakes have never been reported before. The Island is populated by less than one inhabitant per square kilometer. This pristine environment is dominated by evergreen Magellanic forest, peat bogs with various species of sphagnum moss, and peatland ponds which are the prevailing aquatic ecosystem of the region. In the present work we characterized, for the first time, the methane cycle of two characteristic peatland ponds located close to the northern coast of the Island. Both studied ponds, of 17,900 and 7,600 m², were bordered by forest on the north and south shores while large sphagnum bogs were present at the east and west sides of the ponds. Our study included winter and summer quantification of methane and carbon dioxide concentrations. In addition, several physicochemical parameters were measured together with methane oxidation (methanotrophy) activity. The results indicate that peatland ponds were net sources of methane to the atmosphere with a relatively low seasonal variation. These results will be discussed in a global context.
Soils and Landforms of Elephant Island, South Shetland Islands

Daniela Schmitz1 (danni_schmitz@hotmail.com), Carlos Schaefer2, Antônio Pereira3, Roberto Michel4, Flávia Ferrari1, Luca Aquino1
1Universidade Federal de Viçosa/ INCT da Criosfera, Departamento de Biologia Vegetal, Viçosa, Brazil,
2Universidade Federal de Viçosa/ INCT da Criosfera, Departamento de Solos, Viçosa, Brazil, 3Universidade Federal do Pampa - UNIPAMPA, NEVA, São Gabriel, Brazil, 4Universidade Estadual de Santa Cruz / INCT da Criosfera, Departamento de Ciencias Agrárias e Ambientais, Ilhéus, Brazil

Elephant Island geology is basically metamorphic rocks (gneiss, schists) from Meso-Cenozoic subduction complex, great contrast with the volcanic nature of Shetland’s Archipelago. Soil formation in different geomorphic settings following the Holocene glacial retreat at Stinker point was analyzed. Twenty-three pedons were selected dug, sampled and analyzed. Soil pH, exchangeable nutrients and soil texture were determined.

Soils from till and glacial deposits can be separated by age of exposure: older soils are skeletic, shallow depth, acid reaction and moderate contents of P, SOC and base saturation; recently exposed till have soils with moderate depth, alkaline reaction and very high base saturation. Soils at the mid platforms are shallow, coarse, skeletic textured, with elevated P contents, low pH Ca and Mg. Soil weathering is controlled by the foliation of parent material. The ornithogenic influence is variable, but there are either recent or abandoned areas of bird influence. Soils from the present day beaches are alkaline, very coarse with no horizon differentiation, whereas soils on Holocene beaches are acid and nutrient rich due to the or past influence of the fauna (seals, penguins). Soils from Stinker point are generally shallow, skeletic and strongly related to the geomorphological position on the landscape.

Compared with South Shetlands soils, soil development is less pronounced, due metamorphic nature parent material with greater resistance to weathering.
The Importance of Aeolian Dust Inputs into Oligotrophic Lakes in West Greenland

Joanna E. Bullard¹ (j.e.bullard@lboro.ac.uk), N. John Anderson¹, Suzanne McGowan², Amanda O'Byrne³, Clay Prater¹, Michael J. Watts⁴, Erika J. Whiteford⁵

¹Loughborough University, Physical Geography, Loughborough, United Kingdom, ²University of Nottingham, Nottingham, United Kingdom, ³University of Amsterdam, Amsterdam, Netherlands, ⁴British Geological Survey, Keyworth, United Kingdom, ⁵Nottingham Trent University, Nottingham, United Kingdom

Biogeochemical cycling in aquatic environments is strongly tied to elemental inputs from terrestrial sources. However, while most previous work has focused on nutrient delivery via hydrological inputs, the effects of atmospheric dry deposition are comparatively understudied. This paper examines the influence of aeolian derived elements on water and sediment nutrient chemistry of oligotrophic lakes in West Greenland. Estimates of dust elemental composition and seasonal deposition rates are combined with seasonal lake nutrient concentration measurements to establish connections between glaciofluvial dust and lake biogeochemistry of downwind lakes. Further, elemental profiles of lake sediment cores are used to explore historical changes in elemental deposition in this region. Together, these analyses demonstrate the importance of atmospheric dust deposition on lake biogeochemistry in arid high-latitude environments and demonstrate the need to better understand the role of aeolian deposition in cross-system nutrient transport in polar regions.
Vegetation Determines the Fate of Soil Organic Matter on Antarctic Islands

Isabel Prater¹ (i.prater@tum.de), Filip Hrbacek², Lars Arne Meier³, Christina Braun⁴, Daniel Nyvlt², Carsten W. Mueller³

¹TU Munich, Chair of Soil Science, Freising, Germany, ²Masaryk University, Faculty of Science, Brno, Czech Republic, ³Eberhard-Karls Universität Tübingen, Soil Science and Geomorphology, Tübingen, Germany, ⁴Friedrich Schiller University, Institute of Ecology, Jena, Germany

With a low degree of ecosystem interactions and thus unique conditions for soil development, Antarctica offers the opportunity to disclose basic soil biogeochemical processes. We studied soils from vegetation-free and vegetated sites on King George Island (KGI) with a maritime cold climate, and on James Ross Island (JRI) with an arid continental cold climate. The autochthonous vegetation mirrors the climatic differences; while it solely consists of cryptogams on JRI, on KGI vascular plants are also endemic. This permits the study of the complex interplay between soil organic matter (SOM) sequestration and soil structure development with respect to the varying presence of vegetation. Main aim of the study is to decode the mechanisms determining the fate of SOM in maritime Antarctica and to understand how the scarce vegetation drives SOM distribution within specific physical soil fractions and its chemical composition. The distance to vegetation patches was reflected in variations in the distribution of carbon and nitrogen and in a decrease in labile SOM constituents as revealed by 13C-CPMAS NMR spectroscopy, while mineral associated SOM of the clay sized mineral fractions dominated the carbon storage throughout all sites. The ongoing climate change is assumed to significantly alter the vegetation distribution and thus drive the storage and composition of SOM. This will also affect soil microbial activity and land-ocean transitions on the studied islands.
Characteristics of Soils Derived from Olivine-basalts in Antarctica

Mayara P Daher\(^1\), Carlos Ernesto Schaefer\(^2\), Elpidio Inacio Fernandes Filho\(^2\) (elpidio.solos@gmail.com), Andre Thomazini\(^2\), Eduardo O Senra\(^2\), Marcio Rocha Francelino\(^2\)
\(^1\)Universidade Federal de Viçosa / INCT da Criosfera, Solos, Viçosa, Brazil, \(^2\)Universidade Federal de Viçosa / INCT da Criosfera, Solos, Viçosa, Brazil

It was collected 26 soil profiles distributed through Barrientos Island, Robert Island (Maritime Antarctica) and James Ross Island (Antarctic Peninsula) formed by olivine-basalts. The samples were submitted to chemical and physical analyses such as: texture, pH in water, H+Al, exchangeable bases, phosphorus and total organic carbon (TOC). Clay fraction mineralogy was assessed by X-ray diffraction. Due to the warmer and wetter climate of Maritime Antarctica, permafrost is generally absent in the soils collected and were classified as Entisols. The islands are fully vegetated by mosses and lichens and the presence of bird populations result in physical and chemical changes in soils. The soils have some degree of chemical weathering and leaching bases, with acid pH values and high values of P, TOC and H+Al. On the other hand, the drier and cooler climate of James Ross Island favor the presence of permafrost and soils were classified as Gelisols. The vegetation and bird populations are virtually absent. The soil weathering is predominantly by physical processes. The soils have neutral to alkaline pH values, low values of P and H+Al, and devoid TOC. Meanwhile, the 26 soils pedons have characteristics in common attributed to olivine-basalts and show little transformation in relation to the parent material as the amounts of exchangeable Ca and Mg high, coarse texture (sandy loam) and the clay fraction is mainly composed of feldspar, illite, quartz, kaolinite and vermiculite.
Greenland glaciers play an important role in providing nutrients, dissolved silicon (DSi) in particular, to its coastal area. Given predictions of accelerated melting of the Greenland glaciers, an increase in coastal DSi supply is expected to facilitate production of biogenic opal by Si-precipitating phytoplankton, and the subsequent remineralisation of nutrients at depth will have an impact on the benthic ecosystem. As yet there is little understanding of benthic nutrient fluxes at coastal Greenland, which hinders quantitative examination of the evolving nutrient cycles in the light of enhanced glacial melting. Here, we address this issue through the analysis of sediment pore water and core incubation experiments carried out on a set of mega-cores recently acquired from coastal Greenland. Down-core profiles of pore water DSi concentrations and isotope composition mainly reflect biogenic opal dissolution for the upper ~15cm. Beneath that, precipitation of authigenic Si increases with increasing depth. There is also some evidence of glacier influence which provide greater amount of Si to sites proximal to the coastal fjord. Results from core incubation experiments enable us to quantify the flux of DSi at the sediment-water interface. Together, the new results contribute to the evaluation of benthic Si fluxes at coastal Greenland, which have significant implications in the biogeochemical cycling of Si and other nutrients in the polar regions.
The impact of weathering on atmospheric CO$_2$ depends upon the balance between
(1) alkalinity generation by carbonate and silicate mineral dissolution, and
(2) sulfuric acid generation by the oxidation of sulfide minerals.
In regions of high physical erosion, (e.g., mountainous and glaciated terrains), increased exposure and
oxidation of sulfide minerals, such as pyrite, may change the balance of (1) to (2), leading such regions to
become short term sources of CO$_2$[1].
To test the influence of glacial erosion and permafrost freeze-thaw cycles in high-Arctic environments, we
sampled from the Zackenberg River (NE Greenland), and surrounding tributaries, which individually integrate
different lithologies, and are fed by either glacial rivers, seasonal snowmelt or seasonal permafrost thaw. Major
cation and anion data revealed a major tributary, Aucellaelven, has an extremely high concentration of sulfate
(SO$_4^{2-}$), the highest in the region (>2mmol L$^{-1}$). Here we present coupled sulfur and oxygen isotope data ($\delta^{34}$S$_{SO_4}$
and $\delta^{18}$O$_{SO_4}$) measured in SO$_4^{2-}$ to constrain the source of sulfur to the river system. Determining if the source of
SO$_4^{2-}$ is from either evaporate mineral (sulfate containing) dissolution, or oxidative sulfide weathering, is vital to
determining the importance of sulfuric acid in silicate weathering reactions in terrestrial Arctic environments,
and the impact on inorganic carbon cycling in the region.
The aim of this work was to assess the current chemical regime of sea water and bottom sediments exposed to coastal runoff and glacial melting and an analysis of the possible consequences associated with climate warming (melting of glaciers, permafrost thawing). The work is based on chemical studies of sea water, fresh water, sea ice, fresh ice, glacier, bottom sediments, soil and permafrost, carried out at different intervals within the framework of the Norwegian Research Council POLRES program Norwegian-Russian grants CARSIC (http://www.niva.no/carsic) and POMPA (https://pompaproject.wordpress.com ). Totally there were performed 5 expeditions: in February 2011, in September 2011, in March 2014, in June 2015 and in June 2017. We studies distributions of nutrients, carbonate system parameters, metals, including mercury and methyl mercury, and POPs. Chemical analyses were made in parallel in Norwegian and, when possible, in Russian laboratories. The data received allowed to estimate the characteristic ranges or concentrations of the studied parameters, estimate their seasonal changes, that can be used for the model validations.
Changing Nutrients and Primary Production in the Baffin Bay/Labrador Sea Complex

Jean-Eric Tremblay\textsuperscript{1,2} (jean-eric.tremblay@bio.ulaval.ca), Pierre Coupel\textsuperscript{3}, Igor Yashayev\textsuperscript{4}, Simon Bélanger\textsuperscript{2,5}, Michel Gosselin\textsuperscript{6,7}

\textsuperscript{1}Université Laval, Biology, Quebec, Canada, \textsuperscript{2}Québec-Océan, Quebec, Canada, \textsuperscript{3}Université Laval, Biologie, Quebec, Canada, \textsuperscript{4}Bedford Institute of Oceanography, Fisheries and Ocean Canada, Bedford, Canada, \textsuperscript{5}Université du Quebec a Rimouski, Geographie, Rimouski, Canada, \textsuperscript{6}Institut des Sciences de la Mer de Rimouski, Rimouski, Canada, \textsuperscript{7}Université du Quebec a Rimouski, Rimouski, Canada

The western subarctic Atlantic collects large amounts of water from the North though the Baffin Bay/Labrador Sea complex and is directly affected by changes occurring in the Arctic Ocean (AO) and its remote source waters. Because it carries the cumulated impact of biogeochemical changes in source regions, the nutrient properties of this water can be used to diagnose shifting contributions by different water masses or alterations in micro-algal productivity and microbial processes. These changes potentially impact biological productivity and the contribution of different phytoplankton functional groups, both regionally, through the influence of the Labrador Current along the eastern North American seaboard, and globally though lateral exchange with the subpolar gyre and the central Labrador Sea, where deep convection occurs. Using historical data and time-series of observations collected during ArcticNet, the Atlantic Zone off-shelf Monitoring Program and other program, we present trends in productivity and nutrient concentrations for waters entering Baffin Bay and propagating to the western Labrador Sea, with a focus on probable causes and consequences.
Temporal Variability of Particle Fluxes in Kongsfjorden (Svalbard) in 2010-2017

Leonardo Langone1 (leonardo.langone@ismar.cnr.it), Alessandra D'Angelo1-2, Federico Giglio1, Stefano Miserocchi1, Anna Sanchez-Vidal3, Stefano Aliani4, Tommaso Tesi1, Angelo Viola5, Mauro Mazzola6

1CNR-ISMAR, National Research Council, Bologna, Italy, 2Università degli Studi di Siena, Siena, Italy, 3Universitat de Barcelona, Barcelona, Spain, 4CNR-ISMAR, National Research Council, La Spezia, Italy, 5CNR-ISAC, National Research Council, Roma, Italy, 6CNR-ISAC, National Research Council, Bologna, Italy

Over the last decades, the Arctic has experienced faster environmental changes than any other regions on Earth in response to global warming. The Arctic amplification may be due to feedback mechanisms from loss of sea ice and changes in atmospheric and oceanic circulation.

Kongsfjorden is a small Svalbard fjord whose glaciers are rapidly retreating. However, how the land-to-ocean fluxes of particulate matter are changing in the fjord remains elusive.

Here, we show results from a mooring deployed in the inner fjord since 2010 that collected multiannual time-series to monitor the interaction between the entering Atlantic water (AW), melting glacier water and local winter water.

Thermohaline properties reveal a large seasonal and interannual variability ($\theta = -1.91/6.87^\circ C$, $S = 34.10/35.28$) with greater AW intrusion in November. Middle and bottom water temperatures generally follow the same pattern, although periods of water stratification occur. Bottom temperatures show a consistent increasing trend of 0.16 °C y⁻¹. Currents are generally < 10 cm/s.

The average total mass flux (TMF) is 20 g m⁻² d⁻¹, with higher peaks in summer (~100 g m⁻² d⁻¹) and reduced fluxes in autumn-winters (~7 g m⁻² d⁻¹). Notably, in summer 2013, TMF reached ~330 g m⁻² d⁻¹. Lithics and clastic carbonates by glacier and iceberg melting are the most abundant components. During May-June, higher contents of bSiO₂ and OC with heavier δ¹³C show a higher fraction of marine organic matter by diatom production.
Terrestrial-marine Connections in the Coastal Ross Sea during the Mid-Pliocene

Tirzah Abbott¹,² [tirzah.abbott@northwestern.edu], Justin Dodd¹, Reed Scherer¹
¹Northern Illinois University, Geology and Environmental Geosciences, DeKalb, United States, ²Northwestern University, NUANCE - EPIC, Evanston, United States

Orbital frequencies are well documented in a number of terrestrial and marine climate records throughout the Cenozoic; however, assessing the feedbacks and timing of terrestrial-marine systems on glacial-interglacial timescales is often challenging. This is particularly the case in high-latitude, near-shore environments where traditional proxy records like benthic foraminifera are absent. Here we present a combined oxygen (δ¹⁸O and δ¹⁷O) and silicon (δ³⁰Si) isotope record from marine diatom silica in the mid-Pliocene (3.5 - 4.7Ma) section of the AND-1B core from McMurdo Sound, Antarctica. Diatom silica δ¹⁸O values range between +28.1 and +36.4‰ VSMOW, and have an inverse relationship with the stacked benthic foraminifera δ¹⁸O record. We interpret the diatom δ¹⁸O values as a record of terrestrially-sourced cryogenic brine flux to McMurdo Sound; density-driven transport of these brines from the McMurdo Dry Valleys to the marine coastal environments during the warm mid-Pliocene is a potentially overlooked terrestrial source of hypersaline waters. The δ³⁰Si values range from +0.5 to +2.2‰ and appear to correlate with the benthic stack. The considerable variability in δ³⁰Si values may record large-scale changes in silicon and other nutrient cycling. Combined, these proxies indicate strong terrestrial-marine connections during the mid-Pliocene when sea ice in the Ross Sea was significantly reduced, and serve as a potential analog for future warming and sea ice/ice-sheet retreat.
Mass Budgets of Methylmercury in Kongfjorden, Svalbard

Seunghee Han1 (shan@gist.ac.kr), Jihee Kim1
1Gwangju Institute of Science and Technology (GIST), School of Earth Sciences and Environmental Engineering, Gwangju, Korea, Republic of

Methylmercury (MeHg) is a neurotoxin that bioaccumulates in marine food webs and human can be exposed to MeHg through seafood consumption. While MeHg concentrations in Arctic food webs are relatively higher than lower latitudes, major sources of MeHg in Arctic organisms and seawater remain uncertain. In the current study, we observed the concentrations of total Hg and MeHg using a CVAFS, and the methylation/demethylation rate constants using enriched stable isotope methods combined with MeHg measurement by GC-ICP-MS. Furthermore, the compositions of dissolved organic matter (DOM) in seawater were determined by excitation-emission matrix fluorescence spectroscopy. The average MeHg concentration in seawater was 0.11±0.03 pM (0.053-0.17 pM), and the highest concentration was found to be 0.17 pM at the surface of the inner fjord. The largest source of MeHg was in-situ methylation in the water column and input from stream and glacier discharge was the second largest source, based on the MeHg mass budget estimated using the field observation and incubation data. The result of mass budget agreed well to the spatial distribution pattern of MeHg and DOM components in this region, showing higher concentrations of MeHg and soil humic-like DOM in the surface layer. Overall, an increase of terrestrial organic input, in relation to future climate change, is likely to amplify methylation rates of Hg(II) in Arctic fjord.
The Lambert Glacier area (Mac.Robertson Land−Princess Elizabeth Land) is underlain by a wide range of geological bodies in terms of their age, lithology and tectonic setting. Various models to explain the complex geological composition and protracted tectonic evolution have been proposed but nevertheless it remains the subject of continuing discussion and investigation.

The study region consists of three major crustal provinces, defined by their geological histories and Sm-Nd TDM model ages: the Ruker Province (2.8-3.6 Ga), the Vestfold Province (2.7-3.0 Ga), and the Rayner Province (1.6-2.4 Ga). The Ruker Province comprises the Mawson−Stinear Zone composed of an early Precambrian basement and overlying Proterozoic supracrustal sequences, and accreted the PP Lambert Zone. The Rayner Province comprises: (1) Fisher Inlier composed of mid-MP juvenile arc-related mafic and felsic rocks, (2) Beaver−Prydz (BEAP) Zone comprising late-MP arc(? ) felsic rocks with rare mid-MP inheritance, and (3) South Princess Elizabeth (SPEL) Zone comprising late-MP – early NP felsic rocks of either juvenile or within crust origin. The Fisher Inlier and BEAP Zone include recently discovered PP rocks (India edge? Mawson Continent?) subsequently reworked. Tectonothermal events in the Rayner Province are concentrated in three age intervals: ca 1200–1100 Ma (Fisher Phase), ca 1000–950 Ma (Beaver Phase), and ca 800 Ma (Bolingen Phase). Cambrian reworking affected much of the SPEL and eastern BEAP zone.
Upper Mantle P-wave Velocity Structure Beneath the Terra Nova Bay, Antarctica

Yongcheol Park¹ (ypark@kopri.re.kr), Won Sang Lee², Choon-Ki Lee², Samantha Hansen³

¹Korea Polar Research Institute (KOPRI), Division of Earth-System Sciences, Incheon, Korea, Republic of, ²Korea Polar Research Institute (KOPRI), Unit of Ice Sheet and Sea Level Changes, Incheon, Korea, Republic of,
³University of Alabama, Geological Sciences, Tuscaloosa, United States

The Extreme Geophysics Group (EGG) at Korea Polar Research Intititue (KOPRI) have installed four broadband seismic stations around Mt. Melbourne during the Antarctic summer in 2010-2011 to monitor the activities of Mt. Melbourne. Next summer season, seven broadband seismic stations were installed around the end of David Glacier which is the biggest glacier outlet in the Terra Nova Bay area. The number of seismic station is increasing year by year, and the Korea Polar Seismic Network (KPSN) consists of seventeen broadband stations and one infrasound array. The division of Polar Earth-system Science is focused on the research titled “Characterizing mantle domain beneath West Antarctic Rift System and Antarctic mid-ocean ridges”, and trying to install OBSs (Ocean Bottom Seismometers) in Terra Nova Bay in order to optimize the data usage combining with the data set from the landbased seismic network.

The P-wave upper mantle velocity structure was modeled with the teleseismic events observed on the KPSN and the Transantarctic Mountains Northern Network (TAMMNET) to extend the spatial coverage of the rays. The preliminary results show two separate low velocity anomalies located beneath Terra Rift and the inland area from Mt. Melbourne to the north, respectively in 100 km depth.
The Lambert Glacier area (Mac.Robertson Land−Princess Elizabeth Land) including the Prydz Bay shelf has been subject of long-term multinational and multidisciplinary geological and geophysical research. A huge amount of geological mapping work in the study area has been done and numerous papers published elsewhere, while U−Pb zircon ages were obtained for >350 samples. We present a specific zonal legend which describes the geology of map region. The tectonic grid is dominated by three pre-Cambrian provinces variously overprinted within the Cambrian orogen. Prydz Bay shelf is generally covered by Late Paleozoic to Mesozoic deposits and different stratigraphic units crop out in the sea bottom due to differentiated crustal uplift/subsidence tectonic history and recent ice-sheet erosion.

The basic map units are assigned to two categories: stratigraphic (sedimentary and volcanic including their metamorphosed counterparts) and non-stratigraphic (intrusive bodies, metamorphic or plutonic-metamorphic complexes). High-grade metamorphic and plutonic-metamorphic complexes predominate. They are shown with stripe color patterns, with separate colors indicating protolith age and metamorphic/structural age. We invent a complex format of indices which includes two age components. The first symbol stands for protolith age and the second indicates the age of the main-stage metamorphism and pervasive deformation. Thus at the same time both geological and tectonic features are indicated.

Study of Ice-caves on Melbourne and Rittmann: Results from ICE-VOLC Project

Gaetano Giudice1 (gaetano.giudice@ingv.it), Giovanni Giuffrida1, Marco Liuzzo1, Andrea Cannata2,3
1Istituto Nazionale di Geofisica e Vulcanologia, Palermo, Palermo, Italy, 2Università degli Studi di Perugia, Dipartimento di Fisica e Geologia, Perugia, Italy, 3Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Etnoe, Catania, Italy

Thanks to the interaction between permanent thick ice layers and fumarolic hot gases, Antarctic volcanoes host very peculiar features called ice-caves. These are networks of passages melted into the base of the snowpack where geothermal heat and warm gases are supplied to the ice-rock interface. Recently, Antarctica ice caves have attracted the attention of scientists working on both geology and biology fields, since they can provide precious insights into degassing and heat release from volcanoes, as well as into organisms that thrive in physically extreme conditions inside the caves.

In the framework of the ICEVOLC project (www.icevolc-project.com) funded by the Italian PNRA, several activities focused on the investigation of ice-caves in both Melbourne and Rittmann volcanoes (Victoria Land) were carried out such as:

i) identification of pinnacles and ice-towers, chimney-like ice formations indicating the entrance of the ice-caves;
ii) identification and mapping of unexplored ice-caves on both volcanoes;
iii) sampling of gases released by fumaroles within the ice-caves to get insights into volcano dynamics and its state of health;
iv) thermal survey to investigate ice-cave microclimate and evaluate energy exchanges.
Fri_116_GG-1_162
Cenozoic Tectonic Characteristics of the Adare Basin, West Ross Sea

Qiao Zhang1 (zhangqiao0317@163.com), Jinyao Gao1, Fei Ji1,2, Zhongyan Shen1
1Second Institute of Oceanography, State Oceanic Administration, Hangzhou, China, 2Wuhan University, Chinese Antarctic Center of Surveying and Mapping, Wuhan, China

Based on the geophysical data from the Adare Basin, we employed the F-K filtering method to recover the newly processed dataset with high signal noise ratio and complete seismic event which highly contributes to reveal more detailed geological structures. Combined with glaciation, the associated sedimentary facies were summarized. Our analysis revealed that, at 16 Ma, due to the thermal effect caused by residual magmatism and asymmetric spreading of Adare Basin, surrounding areas of two flanks of the Adare trough were characterized by uplift folds and tilted uplift zone, respectively. The small-scale uplift fold zone was characterized by nearly upright faults and folds and was located in the southern part of the eastern flank, whereas the tilted uplift zone dominated in the corresponding district of western flank that reached the continental margin. By utilizing the contact relationship between igneous rocks and surrounding rocks, igneous rocks can be divided into two periods: early-stage and late Cenozoic igneous rocks. The early-stage rocks are generally located dispersedly in the tilted uplift zone and the age is poorly known. It is suggested that they were related to the residual magmatism. On the other hand, the spatial distribution of Late Cenozoic igneous rocks, formed not earlier 5.5 Ma, almost covered the whole study area, which indicates that they might be affected by decompression melting of the mantle because of the large-scale deglaciation since Pliocene.
Drilling of the Wilkes Land margin of East Antarctica during expedition 318 was designed to provide a long-term record of the sedimentary archives along an inshore to offshore transect of Cenozoic Antarctic glaciation. To develop an understanding of sourcing of these sedimentary archives, geochemical characterization was carried out on the sediments of site U1359 of Miocene age. The prime objectives of this study are to delineate source rock characteristics, degree of chemical weathering, sorting processes and the geochemical behaviour of sediments during transportation and deposition.

The Chemical Index of Alteration shows a variability from ~55% to 65% indicating a moderate alteration index. The chondrite normalized, UCC and shale normalize graphs conclusively show that the sediments depict variable behaviour hence cannot be supplied from single source. The significance of grain size and its role in this particular site was also supported by the La/Th plot and ternary plot of La-Sc-Th.

The sediments source from basic, felsic and metasedimentary provenance interpreted from the heavy mineral population and mineral chemistry is also supported by various ratio plots and ternary diagram (La-Sc-Th). A continental island arc tectonic setting along with few samples from active/passive continental margin is interpreted from the geochemical behaviour of the sediments.

Geological Mapping in the Convoy Range, Victoria Land, Antarctica

Giovanni Capponi¹ (capponi@dipteris.unige.it), Stefano Casale², Chiara Montomoli², Rodolfo Carosi³, Simon Cox⁴, Laura Crispini¹, Laura Federico¹, Salvatore Iaccarino², Andreas Laufer⁵, Giovanni Musumeci², Maria Cristina Salvatore², Marco Scarsi¹
¹University of Genova, DISTAV, Genova, Italy, ²University of Pisa, Dipartimento di Scienze della Terra, Pisa, Italy, ³University of Turin, Dipartimento di Scienze della Terra, Torino, Italy, ⁴GNS Science, Dunedin, New Zealand, ⁵BGR - Bundesanstalt für Geowissenschaften und Rohstoffe, Polar Geology Unit, Hannover, Germany

In the austral summer 2017/18, a three person team performed geological and geological-glacial field mapping in the Convoy Range, at the scale 1/250000. Activity was heli-supported, starting from the Italian Mario Zucchelli Station, with two principal targets: 1) to complete geological mapping for the area between 76° and 76°30’ S, filling a gap existing between the GIGAMAP maps (Pertusati et al., 2016) to the north and the geological maps by GNS Science - New Zealand to the south (Gunn & Warren, 1962; Pocknall et al., 1994); 2) to collect new data (stratigraphic, structural, sedimentological, petrographic and geochronological data) to better characterize the lithotectonic units cropping out in the investigated area.

In more detail, in Antarctica the activity included:
- geological and geological-glacial field mapping.
- photogeological analyses, to support the field work;
- rock sampling.

On return from Antarctica the activity comprised:
- digitisation of the new cartographic data and their integration in the Geomap dataset;
- elaboration of structural data;
- microstructural analyses;
- minero-petrographic analyses of rocks and glacial deposits.

High-resolution Aeromagnetic Imaging of the Lanterman Range, North Victoria Land

Antonia Ruppel¹ (antonia.ruppel@bgr.de), Andreas Läufer¹, Laura Crispini², Giovanni Capponi², Frank Lisker³

¹BGR - Federal Institute for Geosciences and Natural Resources, Hannover, Germany, ²University of Genova, Genova, Italy, ³University of Bremen, Bremen, Germany

The Lanterman Range covers the boundary between the Wilson Terrane and Bowers Terrane, i.e. the two western tectonometamorphic units of the Ross-orogenic basement of North Victoria Land, Antarctica. This boundary is formed by a distinct belt of highly deformed mafic and ultramafic rocks with UHP relicts. It is interpreted as the trace of a former suture zone that formed during continuous accretion at the Palaeo-Pacific active continental margin of East Gondwana in the Early Paleozoic. We report on high-resolution magnetic anomaly data over the Lanterman Range. Preliminary results show two distinct and nearly parallel magnetic lineaments. These magnetic lineaments follow the main strike of the Wilson-Bowers terrane boundary. The western of these lineaments correlates with the boundary zone itself. The eastern lineament cannot be attributed to any exposed rocks so far, which show only rather low magnetic susceptibility values. Similar paralleling magnetic structures occur further to the southeast, where they are apparently offset by a possibly post-Jurassic WNW-ESE oriented left-lateral strike-slip zone. We tentatively propose that the origin of the eastern lineament is due to remnants of the Palaeo-Pacific subducted slab hidden under the boundary zone of the Bowers Terrane and the easterly dominantly turbiditic Robertson Bay Terrane. The western may represent remnants of a closed back-arc basin intermittent between the Wilson and Bowers terranes.
The observed gravity change and GPS uplift rates beneath the Amundsen Sea Embayment in western Antarctica can only be explained by glacial isostatic adjustment (GIA) in the presence of a thin elastic lithosphere and low upper mantle viscosity. Different geological concepts exist to explain the upper mantle structure. The low viscosity might relate to a warm upper mantle, which might in turn relate to the West Antarctic Rift Zone or the previously proposed West Antarctic mantle plume.

To address which of the suggested processes is responsible for the low upper mantle viscosity, we combine a 3D lithospheric scale model with geodynamic modelling of the large-scale mantle structures underneath Antarctica. The 3D lithospheric model is established for the Antarctic continent by combing satellite gravity gradients and seismological data. The geodynamic models are calculated with the mantle convection code ASPECT, an open-source code based on finite elements. It features an adaptive mesh refinement that considerably improves the resolution at regions of interest. Our models focus on West Antarctica and explore how to reconcile a possible plume with the lithospheric structure. Another aspect that is investigated is the importance of the sublithospheric composition and temperature on the upper mantle viscosity structure.
In order to study the effect of axial transport and lateral inputs on sediment characteristics in High Arctic proglacial streams we focused on the sediments of Munindalen in central Svalbard. Muninelva River is ~6 km long; its channel belt is 50-250 m wide and has a valley-train character, which changes into a braided outwash fan at the mouth. The river is dominantly pebble-cobble gravely along the entire stream with predominant sandstone and limestone clasts from two main sources according to their position in respect to the main stream: I) axial head source - Muninbreen Glacier and its terminal moraine-mound complexes; II) lateral sources - colluvial and alluvial fans, terminoglacial outwash fan from a lateral glacier and bedrock in the channel belt banks. Our results show that the axial head source is crucial for the origin of cobble fraction, whereas lateral sources contribute by large amount of pebble material and overwhelms thus the downstream trend in pebble clasts' roundness. On the contrary, the amount of cobbles transported from the lateral sources is smaller; therefore the downstream trend of cobble clasts roundness is not masked by lateral inputs. Pebbles are highly mobile both in river transport and on lateral fans; therefore lateral inputs hides the downstream roundness trend in Muninelva River sediments, which was not found for cobbles. This study emphasized the importance of material sources on sedimentary characteristics in proglacial streams.
Sør Rondane and adjacent regions in eastern Dronning Maud Land are of major interest regarding our understanding of the architecture of crustal fragments that were involved in the amalgamation and breakup history of Rodinia and Gondwana. Approximately 40,000 line kilometre of new magnetic anomaly data were collected to the east and south of Sør Rondane with 10 km line spacing. These data are integrated with exposure information from Sør Rondane, the Belgica Mountains, and the Yamato Mountains. Main emphasis was placed on estimating the spatial extent of the recently discovered Tonian Oceanic Arc Super Terrane (TOAST), which is interpreted as early Neoproterozoic juvenile crustal additions within the East African-Antarctic Orogen (EAAO).

The FMA is interpreted as western extent of the TOAST, whereas evidence for its prolongation is provided by SE-striking parallel positive magnetic anomalies that can be correlated with ca. 1000-900 Ma juvenile rocks in Sør Rondane. New data constrain the southern and eastern minimum extent of the TOAST, which corresponds in size with ca. 500000 square kilometres to at least 5% of East Antarctica. The juvenile Tonian rocks developed outside Rodinia and represent major remnants of the Mozambique Ocean. They resemble rocks of the Arabian-Nubian shield, but are slightly older. Thus, the EAAO is characterised by major Neoproterozoic crustal additions on either ends.
Seismicity of the Eurasian Basin Based on the Data of Polar Seismic Stations

Galina Antonovskaya¹ (galina.antonovskaya@gmail.com), Yana Konechnaya¹, Natalya Vaganova¹, Alexey Morozov¹, Irina Basakina¹

¹N. Laverov Federal Center for Integrated Arctic Research, Russian Academy of Sciences, Arkhangelsk, Russian Federation

On the basis of the N. Laverov Federal Center for Integrated Arctic Research there is an Arkhangelsk seismic network (ASN). Some of seismic stations of the ASN were installed at the Arctic region. There are on the Franz Josef Land and Severnaya Zemlya archipelago and on the coast of the Kara Sea. Main goal is seismic monitoring of the Eurasian Basin.

Seismic information of the Arctic region is not quite complete. For the Eurasian Basin by combining seismic data bases of the NORSAR (Norway), Kola Department Geophysical Survey of RAS (Russian Federation) and ASN a General Seismic Catalog above 70°N was created for 1998-2015 for magnitude above 2.0. We compiled the map of main tectonic elements of the Eurasian Basin and applied on it the seismic information.

Results about the latest seismicity shows tectonic activation in the Arctic Basin caused by rifting, stretching lithosphere blocks and volcanic activity. Areas of the Mid-Arctic Ridge, transition continent-ocean zone and graben sides are the most seismic active regions. The weak seismicity of the Barents-Kara shelf can be explained by ultra-slow speeds of the processes occurring in the lithosphere.

Polar stations record many icequakers associated with formation of icebergs, cracking of glaciers and their movements. First results correlations of icequakers number with meteorological data were obtained, a database was created.
ADMAP-2: The Second Generation Antarctic Crustal Magnetic Anomaly Map

ADMAP-2 is the second generation crustal magnetic anomaly compilation for the Antarctic region south of 60°S. It was produced from more than 3.5 million line-km of airborne and marine magnetic observations collected since the International Geophysical Year 1957/58 through 2013. The data were edited, IGRF corrected, profile levelled and gridded on a polar stereographic projection at an interval of 1.5 km. Microlevelling was also performed on some of the grids from more recent detailed surveys. Data quality was maintained by statistical analysis of the crossover errors.

Given the ubiquitous polar cover of snow, ice and sea water, the magnetic anomaly compilation offers important constraints on the global tectonic processes and crustal properties of the Antarctic. It also links widely separated areas of outcrop to help unify disparate geologic studies, and provides insights on the lithospheric transition between Antarctica and adjacent oceans, as well as the geodynamic evolution of the Antarctic lithosphere in the assembly and break-up of the Gondwana, Rodinia, and Columbia supercontinents and key piercing points for reconstructing linkages between the protocontinents. The magnetic data together with ice-probing radar and gravity information greatly facilitate understanding the evolution of fundamental large-scale geological processes such as continental rifting, intraplate mountain building, subduction and terrane accretion processes, and intraplate basin formation.
Aeromagnetic surveys over Princess Elizabeth Land have revealed extent of continuous accretional orogen characterized by low amplitude, linear NE-trending magnetic anomalies that is extremely unique relative to other regions of the East Antarctic. It can be traced from Clemence Massif to the southern margin of the Vestfold Hills crustal block and further east to 88° E. Positive anomalies associated with the predominantly orthogneiss Pickering Series (Laiba, Kudriavtsev, 2006; Mikhalsky et al., 2013) and negative anomalies with the paragneiss Manning Series. Mafic granulites from the Manning Nunataks show typical characteristics of island arc basalts; whereas felsic orthogneisses have the characteristics of volcanic arc granites (Liu et al., 2014). Geochronological data give protolith ages ranging from 1347 to 1020 Ma for these arc-related rocks, indicating a long-lived magmatic accretion in the Rayner continental arc. The most prominent Robertson anomaly is reflected by amphibolite-facies rocks only occur in Robertson Nunatak where mafic schists and subordinate orthogneiss crop out. Isotopically juvenile rocks from the Fisher Terrane and Robertson Nunatak may represent a small-scale oceanic arc extending eastward across the Lambert Rift. Two fragments of this oceanic arc, displaced for a distance of about 50-60 km along dextral strike-slip system of faults, are most likely related to Cretaceous transtensional tectonics associated with break-up of India and Antarctica.
The new aerogeophysical data collected within the international ICECAP and IceBridge projects (Aitken et al., 2013) allowed us to distinguish spatial characteristics of the Vanderford-Totten (VT) rift over Wilkes Land in East Antarctica. Its length exceeds 400 km and width varies from 50 to 100 km. The VT Glaciers are underlain by distinctive continuous depression with depth up to 2525 m below sea level, their shoulders are extremely steep, suggesting the tectonic origin of the riftogenic structure. In accordance with the results of the local Airy isostatic Moho depth estimations, the axial part of the rift is characterized by an essential thinning of the Earth crust thickness (up to 24-27 km) and it is elevated along entire length of this structure. The potential field modeling indicates more than 3 km of sedimentary infill within the suggested rift. Additional argument for the riftogenic crust beneath the VT Glaciers is significant level of seismicity registered here, more than 30 intraplate earthquakes have occurred to date. Earthquakes magnitude varied from 3.9 to 5.8 and their sources concentrated in upper part of earth crust in a depth range of 8-10 km, although some of them were registered at 33 km depth. By analogy with intracratonic basins of southern Australia, it is suggested Permian age of the rift formation. The VT rift may inherit pre-existing tectonically weak zone between the Albany Fraser orogen’s counterpart in Antarctica and the West Mawson craton.
Fri_127_GG-1_550
Toward a Seismic-based 3D Thermo-mechanical Model of the Greenland Lithosphere

Aurelien Mordret\(^1\) (mordret@mit.edu)
\(^1\)Massachusetts Institute of Technology, Earth, Atmospheric and Planetary Sciences, Cambridge, United States

During the past 120 million years, the Greenland craton drifted over the Iceland hotspot; however, uncertainties in geodynamic modeling and a lack of geophysical evidence prevent an accurate reconstruction of the hotspot track. I image the Greenland lithosphere down to 200 km depth with seismic noise tomography. The 3D shear-wave velocity model obtained using 4-5 years of continuous records from the GLISN seismic network is well resolved for most of the Greenland main island. The crustal part of the model clearly shows different tectonic units. The hotspot track is observed as a linear high-velocity anomaly in the middle and lower crust, most probably associated with magmatic intrusions. In the upper mantle, a pronounced low-velocity anomaly below the East coast might be due to the remnant effect of the Iceland hotspot when it was at its maximum intensity. Thermo-mechanical modeling suggests that this area has higher temperature and lower viscosity than the surrounding cratonic areas and experiences a higher than average surface heat flow. This new detailed picture of the Greenland lithosphere will drive more accurate geodynamic reconstructions of tectonic plate motions and help to better understand the North Atlantic tectonic history. Models of Greenland glacial isostatic adjustment will benefit from the 3D upper mantle viscosity model, which in turn will enable more precise estimations of the Greenland ice-sheet mass balance.
Inferring a Rift-thinned Lithosphere in Princess Elizabeth Land, Antarctica

Devsamridhi Arora¹ (devsamridhiahora@yahoo.com), Naresh Pant¹, Jamin Greenbaum², Martin Siegert³, Sun Bo⁴, Anupam Chattopadhyay¹, Mayuri Pandey⁵, Donald Blankenship²
¹University of Delhi, Department of Geology, Delhi, India, ²University of Texas Institute for Geophysics, Austin, United States, ³Imperial College London, London, United Kingdom, ⁴Polar Research Institute of China, Shanghai, China, ⁵Banaras Hindu University, Varanasi, India

Geophysical surveys including radar sounding, laser altimetry, gravity, and magnetics under ICECAP-2 (International Collaborative Exploration of Central East Antarctica through Airborne geophysical Profiling) program reveal that PEL hosts an assortment of previously unidentified subglacial lakes and complex geomorphology. Presence of a 1,100 km-long system of canyons and two large lakes connecting south of the Lambert Rift to the West Ice Shelf has been confirmed.

Ice free exposures of East Antarctic Shield are available along the ~250 km long coastal fringe of East Prydz Bay. The major outcrop in the east is Archean granulite terrain of the Vestfold hills. The adjacent Rauer Group contains both Archean and Proterozoic components. Further ~70 km west, Brattstand bluff, Larsemann Hills and Bollingen Islands constitute the mid-Proterozoic block with a strong Pan African overprint. ~140 km westwards, Landing Bluff exposes the undeformed granites of Pan African age. A westward younging sequence is evident and the large time gap of >2000 Ma suggests presence of complex geological history and interleaved distinct terrains.

We propose presence of a thinned lithosphere (probably a failed rift) in sub-ice East Antarctic terrain along the detected canyon. Analog modelling related to the Lambert rift is used to demonstrate influence of pervasive mechanical anisotropy of the basement in defining orientation of this rift system and its connection to the Lambert Graben.
The parts of eastern Indian Ocean off Wilkes Land (Antarctica) and Australia include good examples of conjugated hyperextended magma-poor margins. In this research we compare crustal characteristics of Wilkes Land continental margin with those in northern Atlantic (well-studied Newfoundland-Iberia margins) and Indian Ocean (still poorly-studied Enderby Land - Eastern India margins). According to data from the studied pairs of passive margins there are few notable differences which include:
1) character and duration of crustal stretching; 2) width of rifted regions and zone of exhumed mantle (ZEM); 3) pattern of potential fields above ZEM; 4) resolution of Moho boundary beneath ZEM by seismic data; 5) the style/regime/geometry of sea-floor spreading followed rifting and mantle exhumation; 6) crustal (tectonic) prehistory of rifting.

Revealed differences can be explained by rheological conditions of lithosphere, global plate motion, mantle convection, serpentinization process etc.
Ammonites from the Byers Peninsula, Livingston Island, Antarctica

Docho Dochev¹ (dochev@gea.uni-sofia.bg), Vyara Idakieva¹, Marin Ivanov¹, Stefan Velev², Kamen Bonev²
¹Sofia University 'St. Kliment Ohridski', Geology, Paleontology and Fossil Fuels, Sofia, Bulgaria; ²Bulgarian Antarctic Institute, Sofia, Bulgaria

During the field season in 2016, Bulgarian geological team collected ammonite fauna in the southwestern part of the Byers Peninsula, Livingston Island. The cephalopod fauna was obtained at the vicinity of the Devils Point and southern part of the President Beaches areas. The ammonites from this area have already been subject of studies, mainly by Chilean paleontologists (Tavera, 1970; Covachevich, 1976).

From the Devils Point the ammonites come from dark-grey mudstones, intercalated between coarse-grained sandstone beds. From this locality we recognize *Haplophyllloceras strigile* and *Protancyloceras* sp. indet. The first one is characteristic species for the Uppermost Tithonian and/or for the base of the Berriasian (Thomson, 1979; Yin and Enay, 2004).

The sedimentary rocks cropping out in the southern part of the President Beaches are mudstone-dominated with small sand-bodies. The ammonites from this area were obtained from the coarse-grained sandstones. From this locality we identify *Spiticeras* (S.) *spiensis*, *S. bilobatum*, *?Spiticeras tripartitum lovaldesensis* and *Argentiniceras lonchochense*. Based on this ammonite assemblage we assume Late Berriasian age for the sandstone beds exposed in southern part of the President Beaches area.

The biostratigraphic interpretation allowed us to consider late Tithonian-early Berriasian age for the sedimentary sequence of the Devils Point area and late Berriasian age for the sand-bodies of the President Beaches area.
Based on field data we proposed classification of hydrothermal breccias from Hurd Peninsula. They are intruded among sedimentary rocks (medium- to coarse grained sandstones, alternating with mudstones and fine-grained sandstones).

Hydrothermal breccias are classified as magmatic hydrothermal injection breccias (Corbett and Leach, 1998). These kinds of breccias are related to hydraulic breccias and form by injection of mineralized magmatic fluids. Magmatic hydrothermal injection beccias in studied area comprise host rock fragment, set in a hydrothermal matrix, composed of quartz, carbonates and ore minerals (pyrite, chalcopyrite, galena and malachite). These breccias are classified as rotational, mosaic (jigsaw) and fluidized breccias. Rotational breccias are characterized by substantial fragment rotation or transport in association with fluid injection. Mosaic or jigsaw breccias are distinguished by fragments which are separated, but have not undergone substantial transport. Rock fragments in these breccias may be joined back together by removal of the matrix. Fluidized breccias contain milled fragments in a transported matrix, to form dike-like bodies. The formation of the magmatic hydrothermal breccias is an integrated element of the formation and the evolution of the magmatic hydrothermal system. They are formed by the explosive release of overpressured magmatic fluids from the fluid saturated magma.
TRACERS Project: Tephrochronology Study of the Ross Sea, Antarctica

Alessio Di Roberto¹ (alessio.diroberto@ingv.it), Ester Colizza², Paola Del Carlo¹, Andrea Gallerani³, Federico Giglio³
¹Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Pisa, Pisa, Italy, ²Università degli Studi di Trieste, Dipartimento di Matematica e Geoscienze, Trieste, Italy, ³CNR-ISMAR, Bologna, Italy

Marine sediment sequences from the polar regions are crucial archives for paleoclimatic and paleoenvironmental studies. Often, they contain tephra layers produced during large explosive volcanic eruptions. The study of tephra provides significant data and constraints for volcanological reconstructions e.g. the age of eruptions, their recurrence, dynamics, as well as the spatial and temporal evolution of volcanic activity. If geochemically fingerprinted and tied to a known, dated eruption tephra layers became isochronous marker horizons that provide high-resolution time-stratigraphic information. ROSSTEPHRA project, carried out within the Italian PNRA (2010/A2.12), demonstrated that marine sediment of the Ross Sea, Antarctica, contain a number of primary tephra layers (Del Carlo et al. 2015). This project laid down the groundwork for the new multidisciplinary research project TRACERS aimed at the tephrochronology-tephrostratigraphy study of selected sediment cores sampled in Ross Sea, downwind the principal volcanic edifices. Here we present the preliminary results of TRACERS project. The projects have proven the validity of the multidisciplinary approach in polar region to contribute substantially to the improvement of the chronological framework of the area. In addition, their results contribute to gain new knowledge about eruptive history of the Antarctic volcanoes (age, frequency, intensity of eruptions, volume of the material erupted).
Algae Lake Pluton is located in SW part of Banger Hills and its area is around 15 km². This intrusion is formed by different rock types and can be applied to anorthosite-mangerite-charnockite association. However, opx-bearing granites here are enderbites (Pl 70-50%, Afsp 10-15%, Qz 20-15%). Accordingly, rock composition varies from gabbro-diorite to monzonite and monzodiorite on QAPF diagram. Gabbroic and anorthosite-like rocks are concentrated at the edge of Pluton. Central part of Pluton is composed by enderbites. Thanks to their specific geochemistry enderbites and charnockites are essential for reconstruction of geodynamic circumstances of their formation time. Intrusion of enderbite-charnockite magma is supposed to be syn-orogenic event. Geochronology data (U-Pb, zircon) provides that intrusion event happened after the maximum of granulite metamorphism. Obtained geochemical and isotopic data (Sheraton et al., 1991; Tucker et al., 2016, 2017 and our preliminary data) reveal that studied rocks have sufficient crust influence. On tectonic diagrams (Pearce et al., 1984; Whalen et al., 1987) they are within syn-orogenic fields and A-type granites. The source of enderbite-charnockite magma is still under discussion. Data on zircon geochemistry, Sm-Nd system, geochemistry of inclusions in minerals are coming up.
Seismic/Thermal Structures of the Crust and Uppermost Mantle Beneath Antarctica

Since the 1990s, over 200 broadband seismic stations have been deployed across Antarctica. In this presentation, we discuss our recent efforts to build reference crustal and uppermost mantle shear velocity (Vs) and thermal models for continental Antarctica with those seismic stations. First, by combining the Rayleigh wave dispersion maps with P receiver functions, we develop a 3-D Vs model for the crust and uppermost mantle beneath central and West Antarctica to a depth of ~200 km. Second, using this 3-D seismic model to constrain the crustal structure, we re-invert for the upper mantle thermal structure using the surface wave data within a thermodynamic framework. The final product, a high-resolution thermal model together with associated uncertainty estimates from the Monte Carlo inversion, allows us to derive lithospheric thickness and surface heat flux maps for the continent. A variety of tectonic features, including a slower/hotter but highly heterogeneous West Antarctica and a much faster/colder East Antarctic craton, are present in the 3-D seismic/thermal models. Notably, a seismic signature of lithospheric foundering is observed beneath the southern TAMs, and an uppermost mantle compositional anomaly is found beneath the Gamburtsev Mountains. These features from the 3-D models help further investigate the dynamics of Antarctica’s lithosphere and asthenosphere, and provide key constraints on the interaction between the solid Earth and the West Antarctic Ice Sheet.
Carbonate-bearing slope deposits are reported from the upper Cambrian Series 3 Spurs Formation in northern Victoria Land, Antarctica, deposited during the Ross Orogeny. The formation consists of shales interbedded with conglomerates and thin- to thick-bedded sandstone, which overlies the middle Cambrian Series 3 Glasgow Volcanics and coeval volcanioclastic Molar Formation and is overlain by the Furongian sandstone-dominated Eureka Formation. The Spurs conglomerates are composed of granule- to boulder-sized polymictic clasts of shales, sandstones and limestones. Various limestone clasts include thrombolites, dendrolites, oolitic-peloidal packstone to grainstone, and minor lime mudstone. These are collectively interpreted as downslope deposits, in which limestone clasts may have been derived from missing platform margin carbonates, analogous to Cambrian to Lower Ordovician slope successions elsewhere. On the other hand, devoid of thinly bedded lime mudstone in the Spurs slope successions is markedly different, possibly due to subdued lime muds behind the platform edge. It is suggested that the Spurs carbonate platform may have developed within narrow shelf margin area in the volcanic quiescent time until regression with clastic influx. Such small-scale carbonate platform dominated by microbial reefs and coarse-grained carbonates would hint how syn-orogenic carbonates developed in arc-related sedimentary basins along the pacific margin of Gondwana.
Historic Hydrovolcanism at Deception Island (Antarctica): Hazards Implication

Dario Pedrazzi¹ (dpedrazzi@ictja.csic.es), Karoly Németh², Adelina Geyer³, Antonio Álvarez-Valero⁴, Gerardo Aguirre-Díaz⁵, Stefania Bartolini³

¹Consejo Superior de Investigaciones Científicas, ICTJA, Barcelona, Spain, ²Massey University, Palmerston North, New Zealand, ³Consejo Superior de Investigaciones Científicas, Barcelona, Spain, ⁴Universidad de Salamanca, Salamanca, Spain, ⁵Universidad Nacional Autónoma de México, Querétaro, Mexico

Deception Island (DI), the southernmost island of the South Shetlands Archipelago (Antarctica), is characterised by a Quaternary caldera system and a post-caldera succession due to a dispersed (monogenetic), volcanic field. Volcanic activity since the 18th century involved monogenetic small volume eruptions such as scoria cones and hydrovolcanic edifices with estimated VEI magnitude of 2-3. The latest volcanic unrest episodes in the 20th and 21st centuries, demonstrates that the volcanic system is still active and that future eruptions are likely. Magma-water interaction represents a major issue on DI as shown by the 1967, 1969 and 1970 explosive episodes, where the scientific stations on the island were destroyed, or severely damaged. Nowadays, DI is an important touristic destination during the austral summer hosting two temporary military bases as well.

A detailed revision of the historical hydrovolcanic post-caldera eruptions of DI was carried out, to understand the dynamics of magma-water interaction, and to characterise the most likely eruptive scenarios from future eruptions. Crimson Hill (estimated age 1825-1829), Kroner Lake (estimated age 1829-1912) eruptions and 1967, 1969 and 1970 events were characterised by describing the eruption mechanisms related to the island’s hydrovolcanic activity.

The project was partially funded by the POSVOLDEC project (CTM2016-79617-P)(AEI/FEDER-UE). D.P. is grateful for his Beatriu de Pinós contract (2016 BP 00086).
Peculiarities of Ultramafic Alkaline Magmatism in the Lambert Rift Area

Nadezda Suschevskaya¹, Daria Tkacheva² (shunya2004@bk.ru), German Leitchenkov²,³
¹Vernadsky Institute of Geochemistry and Analytical Chemistry of Russian Academy of Sciences, Moscow, Russian Federation, ²VNII Okeangeologia, St. Petersburg, Russian Federation, ³St. Petersburg State University, St. Petersburg, Russian Federation

This research is focused on the study of Mesozoic ultramafic alkaline rocks developed in the north-western flank of Lambert Rift in East Antarctica. The rocks are represented by high- and low-magnesian associations which are akin by lithophils and Nd-Pb ratio. High-magnesian association was resulted from melting of metasomatized continental mantle at T ~1270° and at depths ~130-140 km. Increased Ni/Co ratios in magmatic rocks are close to mantle values and demonstrate the mantle source of magma. Analysis of olivine grains in rock samples shows that liquidus high-magnesian olivines (Fo90-91) from lavas are similar to those of mantle inclusion. The mantle is distinguished by presence of carbonate, minerals of biotite-phlogopite group and volatiles. The ultramafic alkaline magmatism is associated with the melting of the ancient metamorphosed mantle, which is similar with the mantle of the southern Kerguelen Plateau. The plume thermal effect on the continental blocks margins of India and East Antarctica 117-110 Ma led to the melting of the deep parts of mantle enriched with volatile components.
Lateral Variations of Seismic Anisotropy in Grove Mountains

Heng Zhang¹ (zhangheng415@itpcas.ac.cn), Junmeng Zhao¹, Hongbing Liu¹, Changhui Ju¹
¹Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China

We estimate the azimuthal anisotropy in the upper mantle of the Grove Mountains, East Antarctica. The shear-wave splitting technique has been applied to the teleseismic data recorded from the 3-component seismic stations in that region, which were deployed by the Institute of Tibetan Plateau Research (ITPCAS). The patterns of the azimuthal anisotropy, for the stations a little far from the Lambert rift, show that the fast S-wave orientation is nearly parallel to the Lambert rift and their amplitudes are relatively small. However, the orientations and amplitudes of the shear-wave splitting are much more complicated in and around the Lambert rift. The formation of anisotropy beneath the stations away from the rift is possibly related to the breakup of Gondwana, and we attribute the complex results near the Lambert rift to the existence of ancient lithospheric mantle.
The West Antarctic Rift System is one of the least understood rift systems on earth, but displays a unique coupled relationship between tectonic processes and ice sheet dynamics. Geothermal heat flux (GHF) is a poorly constrained parameter in Antarctica and suspected to affect basal conditions of ice sheets, i.e., basal melting and subglacial hydrology. Thermomechanical models demonstrate the influential boundary condition of geothermal heat flux for (paleo) ice sheet stability. Young, continental rift systems are regions with significantly elevated geothermal heat flux (GHF), because the transient thermal perturbation to the lithosphere caused by rifting requires ~100 Ma to reach long-term thermal equilibrium. We discuss airborne, high-resolution magnetic anomaly data from the Amundsen Sea Sector, to provide additional insight into deeper crustal structures related to the West Antarctic Rift System in the Amundsen/Bellingshausen sector. With the depth-to-the-bottom of the magnetic source (DBMS) estimates we reveal spatial changes at the bottom of the igneous crust and the thickness of the magnetic layer, which can be further incorporated into tectonic interpretations.
Precambrian Crustal Architecture in the Gamburtsev Province of East Antarctica

Fausto Ferraccioli¹ (ffe@bas.ac.uk), Wu Guochao², Carol Finn³, Robin Bell⁴
¹NERC/ British Antarctic Survey, Geology and Geophysics, Cambridge, United Kingdom, ²Zhejiang University, School of Earth Sciences, Hangzhou, China, ³US Geological Survey, Denver, United States, ⁴Lamont-Doherty Earth Observatory Columbia University, Palisades, NY, United States

The Gamburtsev Subglacial Mountains are underlain by 50-60 km thick crust and over 200 km thick lithosphere formed during the assembly of a mosaic of distinct geophysical provinces that make up interior East Antarctica. Enhanced magnetic and gravity images, depth to magnetic and gravity sources and 2D models help unveil the crustal architecture of the Gamburtsev Province (GP). Potential field imaging enables us to trace major fault systems that segment the GP into the Northern, Central and Southern domains. Apparent offsets within the Central Domain are interpreted as revealing a transpressional fault system parallel to the previously proposed Gamburtsev Suture. Magnetic and gravity modelling, combined with independent sediment provenance constraints, are interpreted here as revealing arc and back arc terranes of inferred Grenvillian age (1.3-1.0 Ga) in the Northern and Central domains of the GP. Anomalously dense lower crust beneath these domains may reflect widespread magmatic underplating. Distinct magnetic anomalies correspond to older Paleoproterozoic crust of the Lambert Terrane, north of the Gamburtsev Suture. The Southern Domain may represent an extension of the South Pole Province, an inferred Mesoproterozoic (1.6-1.4 Ga?) igneous province.

The Precambrian crustal architecture of the GP is remarkably well-preserved, in spite of proposed reactivation of interior East Antarctica during Pan-African age collision responsible for final Gondwana assembly.
Stratigraphy of the Basal Beacon Supergroup, Northern Victoria Land, Antarctica

Jusun Woo1 (jusunwoo@kopri.re.kr), Changhwan Oh1, Moon Young Choe1, Jong Ik Lee1
1Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of

Regional reconnaissance field works and reviewing previous works on the sedimentary strata of the Beacon Supergroup (BS) in northern Victoria Land (NVL) have showed a new perspective of the initial post-Ross sedimentation in NVL. BS in NVL formed on top of an unconformity developed on the basement of the early Paleozoic in age and the upper boundary of the supergroup is mostly demarcated by Ferrar Dolerite intrusion or Kirkpatrick Basalt, Jurassic in age. The late Paleozoic glacial deposits herald initiation of post-Ross sedimentation; Permian Takrouna (TF), Triassic-Jurassic Section Peak, and Jurassic Shafer Peak formations follow. An outcrop section showing transitional change from the basal glacial deposit into the TF occurs in the Lanterman Range, northern part of NVL. Morozumi Range and Helliwell Hills, west of the Lanterman Range, expose the TF which needs to be tested for the geological age based on new plant fossils. BS at the southern part of the Freyberg Mountains in the north of the Evans Névé, is characterized by basal glacial tillite and overlying TF. Low-relief hills in the west of the Mesa Range expose thin BS on the basement. The Section Peak and Shafer Peak formations near Priestly Glacier occur on topographic highs, directly overlying the unconformity with thin discontinuous diamictite of unknown origin. Difference in the lithology and probable age of the basal part of the BS in NVL might be resulted from tectonically controlled geometry of the basin.
CROSS Program, a detection and research project, will complete the "CROSS" formed transects which cross the South Pole through the Antarctic continent to take comprehensive detection research, which will be lasted by 10 to 15 years. Along the perpendicular two transects such scientific surveys as geology, geophysics, geochemistry, ecology, environment and the atmosphere will be carried out, and the structure and geodynamic processes of the crust, mantle and the core of Antarctic will be revealed systematically and comprehensively. Such problems of the global level as splitting of the Gondwana land, the evolution of Tethys tectonic domain, the hyperplasia of Eurasia continent, the drive mechanism of plates and the asymmetric structure between northern and southern hemispheres will be discussed. This program will study the resources, environment, ecological and atmospheric processes of the Antarctic and its impact on global climate change; this program will also study the genetic relationship between the South Pole and the third pole (Tibetan Plateau), and establish the northern boundary of Gondwana continent, and develop the theoretical system of earth science in the Antarctic continent. At the beginning of the Program, we have installed 30 seismic stations in the eastern part of the Antarctic and the first-term (two years) seismic data have been obtained. By data processing and interpretation, some results have been obtained.
We report on synsedimentary deformation structures in upper Permian deposits of the Takrouna Formation (Beacon Supergroup) exposed at an unnamed spur east of Mt Remington north of Boggs Valley, central Rennick Glacier area, North Victoria Land. In the lower part of this section, the formation consists of fluvio-lacustrine successions of pebbly sandstone, climbing-ripple-laminated sand- and siltstone, and carbonaceous silt- and mudstone rich in plant debris (*Glossopteris* leaves and *Vertebraria* roots). Sand- and siltstone beds in particular are characterized by prominent synsedimentary brittle-ductile deformation structures at the outcrop scale, e.g., sedimentary dikes, thrust, growth microfaults, shear folds, normal faults, laminated convolute beds, and intense slumping. This succession is overlain by about 10 m of barren sand- and siltstone deposits that lack such evidence for synsedimentary deformation, and are instead folded and tilted by post-sedimentary deformations. Our synsedimentary tectonic structures may testify to an active tectonism during the late Permian in northern Victoria Land and give constraints for the changes in paleoclimatic and tectonic conditions of Gondwana during late Paleozoic-Mesozoic transition.
Fault-controlled Ancient Hydrothermal Systems in North Victoria Land, Antarctica

Laura Crispini¹ (laura.crispini@unige.it), Giovanni Capponi¹, Andreas Läufer², Frank Lisker³
¹University of Genova, DISTAV, Genova, Italy, ²BGR - Federal Institute for Geosciences and Natural Resources, Federal Institute for Geosciences and Natural Resources, Hannover, Germany, ³University of Bremen, Bremen, Germany

Northern Victoria Land (NVL) at the Pacific end of the Transantarctic Mountains is a key region for understanding the geodynamics of East Antarctica and provides a window to its crustal architecture. The structural frame of NVL derives from polyphase tectonics and is mainly characterised by NW-SE striking lineaments, which transect the NVL crust and the Cenozoic rift basins of the Ross Sea and which are responsible for the reactivation of inherited Paleozoic - Mesozoic discontinuities.

We present preliminary data on regional scale metasomatic and hydrothermal alterations linked to different exhumed fault systems in NVL. Main hydrothermal alterations are: (i) Mg-Ca- carbonation and silicification of mafic and ultramafic rocks along faults and brittle-ductile shear zones at the boundary between the Wilson and Bowers terranes; (ii) Mg-Ca-Fe carbonation of metavolcanic rocks accompanied by syntectonic carbonate coatings on fault planes, hydraulic brecciation, and quartz-carbonate veining in the Bowers Terrane and at the Bowers-Robertson Bay terranes boundary; (iii) epidote and chlorite indurated gouge and cataclasite in fault cores in granitoid rocks and epidotization of metabasalt in the Lanterman Range and in the Bowers Terrane and in Ferrar Dolerite.

We discuss the fluid-rock interaction during faulting and the relevance of these hydrothermal systems in reconstructing the tectonic history of this sector of the Transantarctic Mountains.
Study of a Syntectonic Au-transporting Fluid in North Victoria Land (Antarctica)

Paolo Stefano Garofalo¹ (paolo.garofalo@unibo.it), Alexander Gundlach Graham², Detlef Günther², Laura Crispini³, Giovanni Capponi³

¹University of Bologna, Bi.Ge.A. Department Geological & Environmental Sciences Section, Bologna, Italy, ²ETH Zürich, Department of Chemistry and Applied Biosciences, Zürich, Switzerland, ³University of Genova, DISTAV, Genova, Italy

We constrain the physical-chemical properties of a hydrothermal fluid linked to the Dorn Glacier shear zone (Crispini et al., 2011) that crosscuts the metabasalts and metasandstone of Sledger Group (Bowers Terrane, North Victoria Land, Antarctica). Fluid constraints derive from the analysis of syntectonic quartz vein and provided by a combination of LA-ICP-TOFMS of fluid inclusions, microthermometric determinations, spindle stage measurements of fluid inclusions, and panchromatic cathodoluminescence imaging of quartz.

The geological framework for these veins is: close occurrence to regional tectonic lineaments; location within a greenschist to low-greenschist metamorphic sequence; mineralogic assemblage made mostly by quartz and carbonates, and low modal abundance of sulphides; carbonate-sericite-albite-sulphide hydrothermal alteration well developed adjacent to the vein and postdating the regional metamorphism. Moreover there is a poorly developed mineral and metal zoning within the veins and is gold mineralized. Our dataset provides informations on the composition and origin of the vein fluid, which formed massive and euhehedral quartz crystals. Assuming P correction of 100-200 MPa, entrapment of massive vein fluid is estimated at 330-400 °C and at 260-320 °C for druse fluid. The very high Sb concentrations in vein fluid could be explained by fractionation of Sb into vapour phase of an orogenic fluid.

The geology of the Transantarctic Basin in the far north of Victoria Land is still poorly known. Joint Korean-Italian-German field work in the central Rennick Glacier area during the 2015-2016 season has yielded exciting new results. Based on lithology and fossil content, we recognize four distinct terrestrial sedimentary units in the area; in ascending order,

(1) the Permian Takrouna Formation (thickness ~300 m) with common glossopterid remains;
(2) a previously unknown unit (thickness 75+ m) mainly of reddish-weathering, commonly tabular-cross-bedded pebbly sandstone with intercalated siltstone and palaeosols, barren of body fossils but rich in trace fossils;
(3) another previously unknown unit (thickness 250+ m) of olive-weathering fine-grained sandstone and thick overbank mudstone with palaeosols and thin coal seams, containing abundant silicified wood (Kyklopylon, Agathoxylon), silicified peat, and plant compressions (e.g., Heidiphyllum, Lepacyclotes) indicating a Triassic age; and
(4) about 15 m of mainly conglomeratic trough-cross-bedded, medium- to coarse-grained quartzose sandstone similar to the Section Peak Formation (Rhaetian to Early Jurassic) further south. Our results reveal a much more complete Permian to Jurassic basin fill in that area than was previously thought; on-going palynological analyses should help clarify the precise stratigraphic relationships to better-known sections elsewhere in the Transantarctic Mountains and in Tasmania.
Satellite gravity gradient data from GOCE provide a new tool to investigate the structure and geodynamic evolution of the Antarctic lithosphere. Here we analyse satellite gravity gradient images and superimpose them on a new estimate of crustal thickness derived from inversion of satellite gravity data, combined with independent seismic estimates. The gradient data clearly image the thinner crust and lithosphere beneath the Cretaceous to Cenozoic West Antarctic Rift System and the Jurassic Weddell Sea Rift System with respect to the thicker Precambrian lithosphere of East Antarctica. Within East Antarctica, the satellite gravity data provide significantly more detail than seen in current passive seismic imaging, including new views into the extent of the Archean to Mesoproterozoic Terre Adelie Craton and the adjacent crust and lithosphere beneath the Wilkes and Aurora subglacial basins.

Thick crust underlies the Transantarctic Mountains, the Terre Adelie Craton, the Gamburtsev Subglacial Mountains and also Eastern Dronning Maud Land, in particular beneath the recently proposed Tonian Oceanic Arc Superterrane sector.

One of the most prominent lithospheric-scale features recognised from satellite gravity gradient data is the Trans East Antarctic Shear Zone, which separates the Gamburtsev Province from the Tonian Oceanic Arc Superterrane. We propose that it represents a major previously unknown Pan-African age suture and/or shear zone related to Gondwana assembly.
Fri_151_GG-1_1933
Crustal Deformation Derived from GPS Measurement Data around Lützow-Holmbukta

Akihisa Hattori¹ (hattori.akihisa@nipr.ac.jp), Yuichi Aoyama¹2, Jun'ichi Okuno¹2, Koichiro Doi¹2
¹SOKENDAI (The Graduate University for Advanced Studies), Department of Polar Science, Tachikawa, Tokyo, Japan, ²National Institute for Polar Research, Tachikawa, Tokyo, Japan

With objective to monitor crustal deformation due to Glacial Isostatic Adjustment (GIA), Japanese Antarctic Research Expedition (JARE) have conducted campaign GPS measurements at nine sites on the outcrop rocks around the Lützow-Holmbukta and in the Riiser-Larsen Mountains areas, Dronning Maud Land (DML), East Antarctica for a maximum of eighteen years.

In this study, we analyzed the data observed at seven sites, Tottsuiki Misaki, Langhovde, Skarvsnes, Skallen, Rundvåghetta, Padda and Syowa Station during 2004-2017, with precise point positioning (PPP) procedure. Consequently, subsidence in the range of 2 to 4 mm/year are found at six sites.

We consider that the subsidence is caused by recent increase of surface ice mass loading on DML.
Fri_152_GG-1_1993
U-Pb Zircon Age Constraints from Prydz Bay Evidence of Late Neoproterozoic Basin

Sandip Kumar Roy¹ (sroy845@gmail.com), Joy Gopal Ghosh², Mohd Sadiq²
¹Geological Survey of India, Polar Studies Division, Faridabad, India, ²Geological Survey of India, Faridabad, India

Prydz Bay area rock broadly classified into basement Sostrene Orthogneiss and overlying metasediments Brattstrand Paragneiss. These rocks bear evidence of two granulite facies, Late Mesoproterozoic-Early Neoproterozoic and Late Neoproterozoic-Early Cambrian. These two granulite events have been likened to collisional tectonics related to Rodinia and Gondwana. The rocks of Prydz bay holds the key towards Rodinia vs Gondwana. New U-Pb Zircon ages (LAICPMS Multicollector) supports presence of a Late Neoproterozoic basin. Samples were from Storness, Wilcock and from Mcleaod Island. Analysis shows large concordant cluster around 810Ma. Considering the array of ages it is opined that the maximum depositional age of this rock is around 550Ma or younger. The bedded sillimanite schist rock from Wilcock is also a part of Brattstrand Paragneiss. A large concordant cluster of zircon from the samples is around 1.1Ga and some prominent smaller clusters are around 550-2550Ma. It is opined that the maximum depositional age of this rock is around 550Ma. Zircons from the meta-arkosic rock rock show a large concordant cluster around 550Ma. This rock is interpreted to be a tuffite and signifies the age of deposition of the basin. The work indicates at least parts Brattstrand Paragneiss in the Stornes Island and in the northern part of McLeod Island formed during 550 Ma. Thus, Pan-African suturing in the Prydz Bay area is thus supported even though its orientation and extent remains conjectural.
The Quaternary volcanism in the Bransfield Basin, northern Antarctic Peninsula region is related to the extension of the back-arc basin and the former Phoenix Plate subduction and roll-back under the South Shetlands Block, combined with the eastward motion of the Scotia Plate along the South Scotia Ridge. The main and more active volcanic edifices are located parallel to the NE-SW basin axe in blocks differentiated by NW-SE strike-slip faults. This work shows new results of recent petrologic, mineralogic, geochemical and paleomagnetic studies in the three most relevant Quaternary volcanic edifices in the region: Deception, Penguin and Bridgeman islands. The evolution of the magma and the paleomagnetic and magnetic fabric signals of these volcanoes are interpreted in the framework of the tectonic and geodynamic evolution of the Bransfield Strait region. Different episodes in the evolution of the mentioned volcanoes are pointed out, including the caldera formation in Deception Island. Signatures related to the magma source, depth of crystallization and crustal influence have been identified, showing differences between the main units in the case of Deception Island.
Fri_154_GG-1_2121
Rittmann Volcano, Northern Victoria Land, a Source of Englacial Tephra

Philip Kyle1 (philipkyle1@gmail.com), Mi Jung Lee2, Jong Ik Lee2, Yeongcheol Han2
1New Mexico Institute of Mining and Technology, Earth & Environmental Science, Socorro, United States, 2Korea Polar Research Institute, Incheon, Korea, Republic of

Northern Victoria Land (NVL) is the home to the “active” volcanoes: The Pleiades, Mt Melbourne and Rittmann volcano. All 3 volcanoes have evidence of recent activity which have deposited tephra in ice cores, blue ice/snow areas and as surficial tephra layers. Although there is a significant area of geothermal activity at Rittmann until now there has been no evidence of any recent eruptive activity. We propose that a tephra layer erupted in 1254 CE and found in ice cores from East and West Antarctica was erupted from Rittmann. We report a new occurrence of the tephra in an ice core from the Styx Glacier in NVL. Ignimbrite samples formed by explosive pyroclastic eruptions from Rittmann have glassy fiamme and electron microprobe analyses of the fiamme have trachytic and phonolitic compositions. Some of the fiamme are identical in composition to glass tephra shards from the 1254 tephra and suggest Rittmann was the source of the eruption. The 1254 tephra is found over 2000 km from Rittmann and is the most significant teprochronological marker in Antarctic ice cores. The eruption of the 1254 tephra is the largest known of any Quaternary volcano in Antarctica and probably resulted in the formation of the current 2 km wide caldera which defines Rittmann volcano. This new discovery and the occurrence of numerous Holocene eruptions from Melbourne volcano show that there is a significant volcanic hazard from these volcanoes especially to aircraft operations.
The Canyon and Isostatic State in PEL

Lin Li¹ (lilin@pric.org.cn), Jingxue Guo¹, Bo Sun¹, Xiangbin Cui¹, Jamin Greenbaum²
¹Polar Research Institute of China, Shanghai, China, ²University of Texas, Austin, United States

Princess Elizabeth Land in East Antarctic has only several ice radar profiles currently. The aerogeophysical exploration project team of CHINARE 32 carries out the aerogeophysical survey by Chinese snow eagle 601 fixed-wing aircraft in PEL. To maximize the accurate ice/rock interface conditions, the result of two-dimensional gravity interface inversion under radar constraints reveals the formation of the canyon in the study area. It proved a big canyon under the ice sheet of PEL, quantitative characterization of the canyon features and analysis the detailed structure. The isostatic gravity anomaly is closely related to the vertical gravity balance compensation movement of the crustal, and the stability of the regional crust can be understood through the isostatic state. PEL is widely distributed in subglacial mountains, which is up to 3000km above sea level. With the area’s huge overlying ice sheet, the isostatic state of the crust has a great impact. We calculated the isostatic gravity anomaly of PEL by the Erie isostatic model and analyzed the crustal isostatic state of this area, the result shows that the region is negative isostatic anomalies, the southern inland negative anomalies are very large, which is most likely due to the ablation of ice sheet produced a strong imbalance force, to promote the crust rising and thicken to supplement the ice loss.
The aero-geophysical survey over Princess Elizabeth Land (PEL) was carried out during the Chinese 32th and 33th National Antarctic Research Expedition based on Chinese first fixed-wing aircraft “Snow Eagle 601”, one purpose of the studies is to reveal the ice sheet processes and glacial history. The platform of “Snow Eagle 601” was equipped with advanced deep ice penetrating radar system (HiCARs radar), it has the advantages of strong ice-penetrating ability, high resolution and rich data information, based on electromagnetic theory and radio-echo sounding technique, will allow studies of internal structure of ice sheet, subglacial environments, as well as ice-sheet dynamics and evolution; The intent of GT -2A airborne gravimeter is also to study the characteristics of the ice sheet, and the geological structure of the earth under the ice sheet. Preliminary findings was on the basis of the data of 29 aerogeophysical lines proved the geophysical characteristics of the ice sheet and bedrock under the PEL. Through the three-dimensional gravity interface inversion method under radar constraints, we invert the subglacial lake and obtain its structural characteristics. The results show that this lake is only part of the narrow subglacial lake, and it is likely to become the second large subglacial lake in Antarctica, which is just after the largest one - Lake Vostok.
The elevated subglacial topography underlying the Marie Byrd Land dome likely has played a crucial role in the inception and evolution of the West Antarctic ice sheet through time. The Marie Byrd Land ice dome hosts a number of subaerial Miocene to recent propagating volcanic chains, but the crust underlying these volcanoes was poorly understood. The volcanic centers, a nearby abundance of high amplitude magnetic centers, and occasional exposures of a ~23 Ma elevated erosion surface have been used to argue for a distinct Cenozoic hotspot underlying this region and lifting topography over time. Other interpretations include that this region represents the collapsed remnant of an ancestral West Antarctic orogeny, or represents a broad region uplifted by subduction driven mantle flow.

In this presentation we review

1) constraints on the evolution of the Marie Byrd Land Dome from subglacial geomorphology;
2) present the results of airborne gravity for the compensation and rigidity of the MBL crust; and
3) integrate these results with observations of basal melt and additional potential fields data.
The record of continent formation in the first half of the Earth's history is obscured by the advent of plate tectonic processes that repeatedly ruptured and reassembled Archean crust into new continents. By the end of the Archean Eon, 2.5 billion years ago (Ga), such processes were already in operation, and continents worldwide contain late Archean orogens produced by the collision of older crustal remnants. The Nain Province of coastal Labrador, on the western margin of the North Atlantic Craton (NAC), was assembled from early Archean and mid-Archean components around 2.7Ga, as indicated by widespread high-T metamorphism and ductile deformation (Kusiak et al., 2018, Chem. Geol.). New evidence from dating of zircon and monazite in high-T metamorphic assemblages and in ductile-deformed granitoids indicate widespread orogenic re-working of the margin of the NAC at ca. 2.5Ga. Similar orogenic ages, recently identified in the conjugate part of the NAC on the western Greenland coast, also indicate dual timing in the late Archean assembly of the craton. Dual metamorphism associated with orogenesis in the late Archean is also known from the Napier Complex of East Antarctica, which also contains early Archean crust (Kelly & Harley, 2005, Contrib. Min. Pet.). These similarities increase the likelihood that both polar terranes were components of a lost supercontinent, which also may have included the North China Craton and the Yilgarn Craton of Western Australia.
One Period Magma Intrusion or More of Landing Bluff Adamellite

Yingchun cui¹² (cuiyingchun@fio.org.cn), Xiaochun liu³, Chenguang liu¹², Jianhui Liu⁴
¹First Institute of Oceanography, SOA, Qingdao, China, ²Qingdao National Laboratory for Marine Science and Technology, Qingdao, China, ³Institute of Geomechanics, Chinese Academy of Geological Sciences, Beijing, China, ⁴Beijing SHRIMP Centre, Institute of Geology, Chinese Academy of Geological Sciences, Beijing, China

Landing Bluff Adammellite was commonly considered as one magma intrusion happened at ca. 500Ma based on the results of granites from Landing Bluff (Tingey, 1981; Sheraton & Black, 1988). Sansom Island located in Sandefjord Bay, one of marginal gulf of Prydz Bay, east Antarctica and are composed of two kinds of undeformed biotite granites, which is part of Landing Bluff Adammellite. these granites were firstly conducted the ion-microprobe U-Pb zircon dating. The zircons of two samples yield two SHRIMP zircon U-Pb concordant ages of 516±5 Ma and 496.5±4.7 Ma, respectively. The results indicate that these granites emplaced at two pulses in Cambrian, and further demonstrated the Pan-African event overprinted this area. These ages reveals that Landing Bluff Granite has the complex magmatism.

The research was funded by the National Natural Science Foundation of China (No. 41530209) and the Chinese Polar Environment Comprehensive investigation & Assessment Programmes (CHINARE2015-02-5; CHINARE2017-04-3).

References:
The area under study belongs to the Ruker granite-greenstone Terrane of the Archaean stabilization. The studied mountain massifs of Rymill and Bloomfield are located in the southern part of the Prince Charles Mountains, in the northern part of the archean Ruker Terrane in the area of its connection with the Reiner province. In the course of isotope-geochronological studies, new data were obtained on the age of protoliths of the ortho- and para-rocks. The zircons of samples of orthogneisses of the Mawson series and of the primary sedimentary rocks of the Menzies series were studied. The southern part of the Mt Rymill is composed of Mesoarchean orthogneisses of the Mawson series whose age of crystallization of magmatic protolith is 3164.2 ± 9.2 Ma and 3163.2 ± 7.8 Ma. The maximum time of deposition of the sedimentary protolith of the Menzies series is estimated at 3.1-3.0 Ga. The rocks of the series form a folded, granite-gneissic, domed structure. A significant degree of recrystallization most ancient rocks of the Mawson series is associated with high-grade metamorphism, whose time is compared with the formation of Meso-Neoarchean granite gneisses with an age of about 2800 Ma. The distribution of the values of the age of detrital zircon in metasedimentary rocks makes it possible to consider the Mawson series as the foundation for the primary sedimentary rocks of the Menzies series, the formation of which is associated with the rifting of the Paleoarchean continental crust.
Brief Introduction of Natural Earthquake Observation in the East Antarctica

Liu Hongbing¹ (hbliu@itpcas.ac.cn), Zhao Junmeng¹, Deng Gong¹, Li Yawei¹  
¹Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China

During the 30th Chinese Antarctic scientific expedition, the Grove Mountains earthquake investigation project completed 10 seismic stations set-up, 5 stations in the Grove Mountains and 5 stations around the Zhongshan Station. The installation of the station has been carefully researched, and the station is powered by 200w solar panels and 6 100ah Gel batteries. The seismometer and recorder were installed in a special Heat insulation box and heated by 4 pieces 3w silica gel heating plate, heated for 30 minutes every 4 hours. After two years of field observation, a total of 48GB of seismic data has been obtained, which achieves the desired observation effect. Especially in the Grove Mountains during the polar night and under low temperature conditions, we obtained 19GB data for the first time. The temperature in the Grove Mountains is as low as 60 degree Celsius below Zero, and under such conditions our seismic instruments record data continuously for up to 572 days, which provided valuable experience for future improvement earthquake observation. The distribution of seismic stations are located in Pu Liz orogenic belt and extending southward in the Grove Mountains. We can get preliminary crustal structure characteristics for the tectonic evolution of this region, by analyzing the recorded seismic data from stations using anisotropy and receiver function method.

Keywords: East Antarctica; Earthquake observation; Seismic data; Crustal structure
The origin and emplacement of the Precambrian/early Palaeozoic Pearya terrane, northern Ellesmere Island, Canada, is still a matter of debate. A suture zone between Pearya and the passive margin of the Franklinian basin is assumed within the Petersen Bay Fault Zone [1]. Within this fault zone, amphibolitic rocks of the Kulutingwak Formation crop out, for which some authors [2, 3] assume an island-arc affinity. During the CASE19 expedition in 2017, amphibolite and metasedimentary rocks of the Kulutingwak Formation were collected within the Petersen Bay Fault Zone west of Kulutingwak Fiord. Preliminary data of selected samples show that the volcanic rocks can be classified as subalkaline andesitic basalt to andesite with tholeiitic to calc-alkaline geochemical signature. Both, amphibolite and metasedimentary rocks indicate an island-arc setting. These first geochemical results in combination with a 450-Ma zircon U-Pb age for the amphibolitic rocks [2] might be an indicator for the existence of an oceanic island arc during Ordovician times and, therefore, an oceanic basin between Pearya and the passive margin of Laurentia, which might be represented by the Kulutingwak Formation. However, further investigation is necessary to constrain these preliminary results and to consider a new assignment of the Kulutingwak Formation.

Neotectonic Deformation in the Southwestern Ross Sea

Terry Wilson\textsuperscript{1} (wilson.43@osu.edu), Will Blocher\textsuperscript{1}, Jie Chen\textsuperscript{1}, Tricia Hall\textsuperscript{1}, Jerome Hall\textsuperscript{1}, William Magee\textsuperscript{1}
\textsuperscript{1}Ohio State University, SES/BPCRC, Columbus, United States

Seismic mapping combined with revised age constraints document the structural evolution of the Terror Rift and superposed Erebus flexural basin in the southwestern Ross Sea. Terror Rift fault-related subsidence was underway in the early Miocene (by at least 18 Ma) and syntectonic stratal growth signatures show that most extension occurred between ~15-5 Ma, but faulting continued through the Pliocene. Ubiquitous normal-sense fault displacement, the strong case for rollover origin of regional folds within the rift, and the absence of flower structures, all support an orthogonal rift model with regional extension in the ENE-WSW direction. Total extensional strain is on the order of < 10%. The eastern margin of Terror Rift is defined by a zone of west-dipping faults projecting to depth with a listric ramp-flat geometry. This border fault zone projects beneath Ross Island and the Erebus Basin formed by Plio-Pleistocene volcanoes. Seismic mapping within western Erebus Basin shows evidence of two discrete sub-basins formed by Mt. Bird loading since 3.8-4.6 Ma and Mt. Erebus loading since ~1.31 Ma. A 3D thin elastic plate model, using the dip angle of seismically mapped reflector surfaces as constraints, simulates flexural basin evolution with a best fit lithospheric effective elastic thickness of 4-5 km.
Two widely distributed granitic vein types are seen in Sverdrupfjella, W. Dronning Maud Land (WDML), Antarctica. The younger generation (P2) comprise 2-mica granites and pink 2 feldspar pegmatites. The older (P1) generation comprises white biotite plagioclase rich pegmatites. The P2 veins dip mostly shallowly (~45-50°) to N and NW and displace the older veins along planes with extensional and compressional top to the south geometries. In contrast, the older P1’s dip mostly ~60° toward the S and SW with no displacements. Similarly oriented local shears show normal displacements to the S and SW. The structures are consistent with late extension toward the S and SW followed by top to the S and SE compression.

SHRIMP zircon ages on the P1’s yield ages of ~520Ma whereas data from the P2’s yield ages of ~490Ma. Radiogenic Sr and Nd data from the two types indicate relatively juvenile sources for the P1’s, in contrast to the P1 granites which were sourced in older crust, similar to Mesoproterozoic TTG gneisses in W Sverdrupfjella. Radiogenic Sr/Nd data from basement gneisses hosting the veins in E and W Sverdrupfjella show differences with W Sverdrupfjella characterised by older evolved crust in contrast to the juvenile basement rocks in E Sverdrupfjella. The two areas are separated by major thrust faulting coincident with strong magnetic anomalies.

The data are inferred to reflect the emplacement of a Kuunga Orogeny mega nappe complex with top to the S geometry.
Palinkas (1990) notes that research into humans in isolated and confined conditions has more frequently taken place in Antarctica, which Suedfeld (1991) explains by the fact that Arctic teams are somewhat more accessible and thus easier to evacuate. This is true but neglects an essential characteristic of Arctic team safety: polar bears. Bears pose a significant threat to human survival in Arctic regions; this means that Arctic teams have to handle large-calibre fire arms on a regular basis (Norwegian Polar Institute, 2005). Levesque (1991, p. 16) describes that an Antarctic team spent some of their wintering time plotting an unpopular crew member’s death. In the Arctic, such behaviour would be even more worrying than in this Antarctic team because the means to murder are ever-present. My research investigates the eleven members of the 38th expedition to the isolated Polish Polar Station, Hornsund, Svalbard (77° N). This study illuminates their lives via mental health questionnaires, cognitive testing as well as interviews. Each participant was interviewed before, during and after polar night. The interviews are a unique approach to understanding how isolated teams feel and why they feel this way. My results show what makes individuals feel poorly or well, and also what makes a good polar explorer in the eyes of other polar explorers. Conclusions about preparation and selection techniques are possible.
Historical reports of different psychiatric afflictions during polar night have always been common, for example Sidney Buddington from the Arctic Polaris expedition (1871) or Sidney Jeffryes from Mawson’s Australasian Antarctic Expedition (1911-1914). Through the past six decades, research has indicated that there are individuals who have required medical evacuations on psychiatric grounds from Antarctica (e.g. Pattarini et al., 2016). During my research with the 38th expedition to the Polish Polar Station, Hornsund, Svalbard (77° N), a participant - Albert - developed severe psychiatric complications in the polar night which eventually resulted in his evacuation. Albert has allowed me to present his case study. The quantitative results will show how his mental health differs from the rest of his team at the station but also from an age-/gender-matched control group in a normal environment (Symptom Checklist-90-Revised and the Profile of Mood States). Albert’s interviews from before and during the polar night illuminate his personal experience. Most important however, is the successful application of Emotional Freedom Techniques (EFT) in order to alleviate Albert’s depression, anxiety and suicidal ideation. EFT helped Albert feel better and should be considered as a preventative technique that can be taught to isolated teams pre-deployment to avoid psychiatric afflictions and possibly, evacuation.
In observation activities in the Antarctic region, evaluation of the injury and disease trends in party members during wintering is indispensable to advance the medical system and research.

A total of 4,233 injury or disease cases in the 1st-39th Japanese Antarctic Research Expeditions were analyzed and reported in Nankyoku Shiryo (Antarctic Record) (2000).

We obtained disease and injury statistics based on the wintering reports by the 40th-56th wintering party members who performed activities from February 1999 to January 2016.

Among a total of 578 members (27 females), 2,604 disease or injury cases (4.5 per member) were observed. The 2,604 cases included cases in the Surgical and Orthopedic (45.1%), Internal Medicine (19.9%), Dermatological (10.2%), Dental (9.8%), Otological (7.8%), and Ophthalmological (5.6%). The period from February, when wintering was initiated, to January of the following year was divided into quarters, and changes in the incidence of diseases and injuries were analyzed. Although results differed among parties, the incidence was low irrespective of the department in the 3rd quarter (August-October) in each party.

Neither severe cases requiring transportation nor deaths were observed. There was no surgery performed under general anesthesia. In the 44th party, peritoneal lavage and appendectomy were performed under lumbar spine anesthesia due to localized peritonitis associated with diverticulitis in 1 case.

The Adaptation of Chinese Expeditioners under the Antarctic Dome A

Chengli Xu1 (xuchengli0425@sina.com), Yanlei Xiong1, Chengyu Jiang1
1Institute of Basic Medical Sciences Chinese Academy of Medical Sciences, School of Basic Medicine Peking
Union Medical College, Beijing, China

Dome A (80°22′S, 77°22′E) has the highest ice peak in Antarctica, with an elevation of 4093m. The average temperature of -54°C with a barometric pressure of 560-590 hpa (January-April). It is among the most challenging environments on Earth, due to poor oxygen availability, harsh weather conditions, dangers related to glaciers and difficult accessibility for transportation. Chinese Kunlun Station was established at Dome A in 2009. We focuses on the adaptation patterns of expeditioners under the hypoxic and cold environment. We firstly identified the association between psychophysical phenotypes and genome-wide gene expression changes in human adaptation at Dome A. A group of genes were found to be strongly related to significant phenotypes. We found 28 genes were potentially involved in the psychological disturbance. A reliable method was developed to search novel genes and mechanisms related to phenotypes. At Kunlun Station, more than half of expeditioners experienced AMS symptoms, among which sleep disturbances were prevalent. Our polysomnography (PSG) study at Dome A suggested that sleep architecture changed and slow wave sleep reduced. Apneas were prevalent, with almost exclusively of periodic breathing. The nocturnal oxygen saturation decreased. The strict physical screening examination and pre-acclimatization training before departure heading Antarctica is necessary.
The Psychological Safety of Workers in Oil and Diamond Productions in the Arctic

Yana Korneeva¹ (amazonkca@mail.ru), Natalia Simonova¹, Tamara Tyulyubaeva¹
¹Northern (Arctic) Federal University, Psychology Department, Arkhangelsk, Russian Federation

The Arctic is very rich in oil, gas and other minerals. An important role in the development of the Arctic is played by attracting and retaining a relatively small number of able-bodied people in these remote regions. For the possibility of prospecting and mining in these hard-to-reach regions with extreme climatic conditions, the shift method of labor organization is used. Despite the development of the problem in this direction, there remain a number of poorly understood questions. What are the psychological features of the employee making mistakes in the workplace, the employees, what position in the oil producing and diamond mining industries has the greatest risk of accidents, what are the components of the psychological safety of these workers in the Far East North and the Arctic. The goal is to identify differences in the psychological safety of workers in oil producing and diamond mining industries under shift work organization in the Far North and the Arctic. As the research result, the models of psychological safety of oil producers and diamond mining companies under the shift work organization in the Far North and the Arctic (including psychological properties, functional states, behavioral characteristics and attitudes to dangerous and extreme factors and conditions of the professional environment) are refined. The role of production factors in the formation of psychological safety and safe behavior of the personnel of extractive companies was determined.
Physiological Stress in Brazilian Antarctic Program (PROANTAR) Participants

Michele Moraes1 (michelemacedo.moraes@gmail.com), Ygor Martins2, Tiago Mendes3, Cristian Espinosa4, Chams Maluf5, Rosa Arantes1

1Universidade Federal de Minas Gerais, Laboratório de Neuro-Imuno Patologia Experimental, Instituto de Ciências Biológicas, Belo Horizonte, Brazil, 2Universidade Federal de Minas Gerais, Laboratório de Fisiologia do Exercício, Escola de Educação Física, Fisioterapia e Terapia Ocupacional, Belo Horizonte, Brazil, 3Universidade Federal do Maranhão, Escola de Educação Física, Pinheiro, Brazil, 4Universidad de Magallanes, Laboratorio de Fisiología, Escuela de Medicina, Universidad de Magallanes, Punta Arenas, Chile, 5Universidade Federal de Minas Gerais, Departamento de Propedêutica Complementar da Faculdade de Medicina, Belo Horizonte, Brazil

From a physiological perspective Antarctica has a very challenging environment since the cold; the wind and the sensory monotony are considered stressful stimuli for the human body. However, acclimatization can attenuate stress responses consequent to sympathetic activation caused by this extreme environment. In addition, the voyage to Antarctica is commonly carried out by ship, which lasts for a long period and represents a confinement stress. The aim of this study is to investigate biological variables (autonomic activity, endocrine and metabolic markers) and humor parameters of progressive adaptation during an Antarctic expedition, including a period of ship confinement and a period in a camp. Ten volunteers from Brazilian Antarctic Program were evaluated during 3 weeks in a ship and 3 weeks in an extreme camp, during Brazilian Antarctic Operation in 2017 summer. Initially, the volunteers performed a maximal progressive exercise and basal data were collected at 3 moments in the ship. After 1 month of ship confinement, the group camped in Antarctic. There were evaluated autonomic balance, by measuring the heart rate variability, mood, by Brunel Mood Scale (BRUMS), and hormonal parameters - samples of blood, saliva and urine were collected to measure TSH and T4, catabolic state (cortisol/testosterone) and catecholamine’s concentration. We will also test the hypothesis that biological parameters of adaptation and humor relates with VO2MAX along Antarctic field stay.
Every year Brazilian researchers and military personnel are sent to the inhospitable Antarctic environment. Expeditions to Antarctica include hiking and staying in camps or research stations, with durations ranging from one season to a year (for a group of wintering military). Considering that participants perform functions in which they need to maintain attention and focus, changes in their mood and cognitive ability may result in errors that compromise their functions and even security in an extreme environment such as Antarctica. In order to prepare the participants of the Antarctic Operations for the conditions faced in the expeditions, the Brazilian Antarctic Program (PROANTAR) promotes Pre-Antarctic Training (TPA) in which researchers and the military participate in activities that simulate the stress experienced in the expeditions, such as the pressure of time for the accomplishment of tasks, the coexistence in restricted groups and strenuous daily physical activities. Thus, it is possible that the mood responses of the participants to a week of TPA predict the expected mood changes in the Antarctic field. We used one validate questionnaire - the Brunel Humor Scale (BRUMS) to compare the mood of researchers and military of PROANTAR at the beginning and at the end of a Week of TPA. We believe that by understanding these responses we can seek strategies to minimize the risks of the Antarctic environment on the physical and mental health of the PROANTAR participants.
Since the very beginning of the scientific presence of Ukraine in the Antarctic biomedical research direction has been developed for the monitoring of individual biomarkers of Antarctic winterers and medical accompaniment Antarctic expeditions. Constant medical supervision (including the possibility of telemedicine) the state of health of Antarctic experts and new technology for monitoring the individual parameters of the functional state of the organism, despite the extreme conditions, allowed to maintain the health and performance of all the participants of 20 Ukrainian Antarctic expedition (over 200). The main success of the Antarctic medicine is to preserve the health of all members of 20 expeditions, the creation of an effective system of medical and psychological selection of candidates, the development of health monitoring methods for winterers at the Antarctic station, using telemedicine, the introduction of innovative technologies for prevention, treatment and rehabilitation. The main achievements of scientific developments in the field of medicine and physiology are to receive new information about human adaptation features to the extreme conditions of Antarctica, clarifying mechanisms of disadaptive, desynchronosis, "Antarctic syndrome" symptoms determine the causes of stress, problems of interpersonal relations in a small team, as well as a significant expansion of knowledge in the field of environmental physiology, extreme and preventive medicine.
The Relationship between the Third-quarter Phenomenon and Medical Statistics

Tetsuya Kawabe1 (kawabe@hs.osakafu-u.ac.jp), Atsushi Ikeda2, Nobuo Naruiwa3, Tomo Shigeta4, Reiji Sasaki5, Nanako Kato6, Asako Sasaki7, Tomoko Kuwabara8, Giichiro Ohno9,10, Kentaro Watanabe10, Satoshi Imura10

1Osaka Prefecture University, Graduate School of Humanities and Sustainable System Sciences, Osaka, Japan, 2University of Tsukuba, Department of Urology, Faculty of Medicine, Tsukuba, Japan, 3Kyoto Koka Women’s University, Faculty of Health Science, Kyoto, Japan, 4Osaka Syoin Women’s University, Osaka, Japan, 5Kyushu University, Graduate School of Human-Environment Studies, Fukuoka, Japan, 6Nara Women’s University, Graduate School of Humanities and Sciences, Nara, Japan, 7Ritsumeikan University, Kyoto, Japan, 8Kyoto University, Graduate School of Education, Kyoto, Japan, 9Tokatsu Hospital, Department of Surgery, Chiba, Japan, 10National Institute of Polar Research, Tokyo, Japan

Psychological states and health conditions are known to change as a result of long periods of stay in Antarctica. The “third-quarter phenomenon” hypothesis suggests that these changes in condition occur in the latter half of long stays. The aim of this research is to analyze the relationship between the third-quarter phenomenon and statistics of disease and injury during ten wintering periods of ten years in Japanese Antarctic Research Expeditions (JARE). An analysis of mood scales (the Positive and Negative Affect Schedule [PANAS] and the Profile of Mood States [POMS]) indicated that seven of ten wintering parties experienced the third-quarter phenomenon (we name these parties the third-quarter (TQ) parties), and the other three parties did not (two parties of three had flat mood scores, and one party had unclear results). We name the three parties the non-third-quarter (NTQ) parties. Subjective complaints of disease and injury were measured by the Subjective Health Complains Inventory [SHC]. The following findings became clear as a result of the investigation. First, the number of consultations with a doctor decreased in the third-quarter for all NTQ parties. Second, the number of consultations regarding surgery and orthopedics decreased by half in the fourth-quarter for only one of the NTQ parties. Third, the members of both the TQ and NTQ parties had almost the same complaints, but the members of the NTQ parties did not consult a doctor very much in the third-quarter.
Japanese wintering members were kept enclosed and isolated in Antarctica. In our post-mission interview, although they underwent considerable stress, they maintained themselves. In Antarctica, it was not easy for them to narrate their psychological problems. We could not determine their maladjustment using standard methods like asking their self-assessment. The main purpose of this research was to investigate their stress by their performance. We used the Uchida-Kraepelin psychodiagnostic (U-K) test as a performance measure. Data have been collected for 30 members of one wintering party at 6 periods during mission. Furthermore, using the Profile of Mood States (POMS), we investigated the relationship between performance by physiological responses and subjective assessment.

The following became clear as a result of the investigation.

1) In U-K test, the score of PF (which shifted from standard value) changed continuously. Especially, many members' score on PF was worse at polar daybreak.
2) In POMS, the score on Tension-Anxiety (T-A) was higher at midnight sun. The result did not correlate much with U-K.
3) Some members rejected this survey. Most of their scores on PF before rejecting were the worst. Their rejection was also interpreted as performance suggestive of their coping.

These results indicated that their performance was the clue that helped to assess members under stress. Therefore, we need various stress assessment methods for providing mental support in Antarctica.
Successive Japanese wintering parties were placed in an isolated environment in Antarctica for durations of about one year. They received few visitors because there were no other permanent research stations nearby. The environment was very stressful. However, all members completed their tasks with very few injuries and few big accidents.

We interviewed the wintering members after they returned to Japan from their expeditions. In our interviews, we hypothesized that the leaders’ management of the party played an important part in their party members’ mental health. The main purpose of our research was thus to investigate what the leaders of wintering parties did to prevent their party members from suffering mental distress and what the leaders considered most important for managing their parties.

We did semi-structured interviews of ten former leaders of Japanese wintering parties. We focused on their regard for their parties and their party members in the period of preparation in Japan and of wintering in Antarctica.

We found that the leaders put careful consideration into selecting a suitable head of each section of the party, respected the specialties of each member, and maintained a sense of distance between themselves and their party members so as to remain unbiased.
In the history of each station in Antarctica, many report were published about infectious disease. You may think there is no pathogen, like bacteria and virus but it’s not true. This is a review of the pathogens we human being fight against. We hope this article will help you to protect from them in Antarctica in the future.
An Introduction to the Korean Society of Polar Medicine (KSPM)

Eojin Yi1,2 (eojinkorea@gmail.com), Han Kyeom Kim1,3, Jong Won Hong1,4, Min Goo Lee1,3
1Korean Society of Polar Medicine, Seoul, Korea, Republic of, 2Yeosu Immigration Office, Yeosu, Korea, Republic of, 3Korea University College of Medicine, Seoul, Korea, Republic of, 4Yonsei University College of Medicine, Seoul, Korea, Republic of

The Korean Society of Polar Medicine (KSPM) is an academic and social organization for Antarctic health care, emergency response, and medical research. Founded on 21st June 2014, it gathered three existing groups about polar medicine: the Korean Society of Antarctic Practitioners, the Korea University Research Group for Polar Medicine, and Korea Polar Research Institute. The day of founding KSPM was a day of Antarctic winter solstice so it has an alias “Antarctic Dong-ji Association”. (‘Dong-ji’ is pronounced same as that of Korean character ‘winter solstice’ and ‘the companion’) The purpose of the KSPM is not only to provide health care for diseases control, but also to investigate and characterize the features of medical specificity occurring in the polar region. So the main contents dealt with by KSPM are
(1) Antarctic Stations,
(2) icebreaker Araon,
(3) medical evacuation,
(4) telemedicine,
(5) psychological and physiological research,
(6) extreme medicine and its medical resource,
(7) medical microbiology,
(8) international cooperation in medicine,
(9) humanities and science: combined research on convergence and integration.
As an well-organized platform, KSPM is an attempt in Korea which is going to be a good 'Agora' for collecting the experiences and opinions of people who were in Antarctica. The outcomes will be valuable for not only the Antarctic field but also the development of various research, and ultimately give benefit to humanity and future generation.
Cosmic Ray Measurements in Antarctica and their Impacts on Human Activities

Guillaume Hubert\textsuperscript{1} (guillaume.hubert@onera.fr)  
\textsuperscript{2}ONERA, the French Aerospace Lab., DPhIEE, Toulouse, France

The primary and the secondary radiation produced in the atmosphere can be a serious issue for the reliability of microelectronics devices embedded in aircraft and this is of a major concern for aircrew member’s dose assessment. Moreover, Polar Region development induces an important issue related to space weather. In the framework of the CHINSTRAP project supported by the French Polar Institute (IPEV), a new cosmic ray induced neutron spectrometer has been installed in December 2015 in the inner Antarctic Plateau, at Concordia station. Atmospheric shower modelling associated to a primary cosmic ray model allows for deducing the proton, muon and electron fields from cascade neutron measurements. Using the fluence to human dose conversions coefficients, the complementarity of measurement and modelling makes it possible to calculate the human dose, but also to extrapolate it for other localization. In the same way, Single Event Effect risk can be determined from electronic devices, which is particularly critical for nanoscale technologies whose sensitivities are increasing with the technological integration. This paper proposes to analyze two-year measurements from December 2015 to 2017, and to investigate the Cosmic Ray impacts on Antarctica activities, in the point of view of human dose and electronic systems. Discussions of this work will be extended to contributions of the cosmic ray knowledge improvement to the space weather and the cosmogenic nuclide dating activities.
Extreme Environment Effects on Human Health in High Altitude in Antarctica

Shinji Otani1 (otanis@alrc.tottori-u.ac.jp), Yoichi Miyaoka2,3, Giichiro Ohno3,4, Kentaro Watanebe3

1Tottori University, International Platform for Dryland Research and Education, Tottori, Japan, 2Hokkaido University, Department of Gastroenterological Surgery I, Sapporo, Japan, 3National Institute of Polar Research, Tachikawa, Japan, 4Tokatsu Hospital, Nagareyama, Japan

Introduction: The Antarctic inland, with average altitude of 2450 m above sea level (a.s.l.), is an extremely cold and dry place with rarefied air. Many inland parties, from various countries, conduct research activities in Antarctica; however, obtaining clinical data is challenging. To improving the safety of members during Antarctic expeditions, we evaluated the impact of extreme environmental conditions of the Antarctic inland on health.

Methods: In total, 33 members of 4 inland parties from the Japanese Antarctic Research Expeditions (JARE) 40, 43, 44, and 46 were included in the study. Dome Fuji Station (Dome F), located 3810 m a.s.l., was the destination of all the parties. We evaluated the impact of the extreme environmental conditions on subjective symptoms, percutaneous arterial blood oxygen saturation (PaO2), and hematological findings.

Results: The correlation coefficients of SpO2 levels and headache/sleep disturbance scores were −0.181 (p < 0.001) and −0.101 (p = 0.007), respectively; both headache and sleep disturbance scores exhibited significant negative correlations with SpO2 levels. Serum erythropoietin concentration increased promptly, and the number of erythrocytes peaked within 6 weeks.

Conclusion: Thus, as is widely alleged, hematological adaptation occurs over several weeks. SpO2 monitoring might be useful for the early detection of acute mountain sickness, prior to adaptation.

Effects of Environmental Conditions from Antarctica on the Human RBCs Viability

Iris Tusa\textsuperscript{1} (iris.tusa@gmail.com), Corina Itcus\textsuperscript{2}, Manuela Sidoroff\textsuperscript{1}, Daniela Bratosin\textsuperscript{3}

\textsuperscript{1}National Institute of Research and Development for Biological Sciences, Bioinformatics, Bucharest, Romania,
\textsuperscript{2}National Institute of Research and Development for Biological Sciences, Arctic and Antarctic Research,
Bucharest, Romania, \textsuperscript{3}National Institute of Research and Development for Biological Sciences, Cellular Dynamics and Flow Cytometry, Bucharest, Romania

Our research analysed human erythrocytes viability in relation to environmental conditions from Antarctica and was conducted two years on three Romanian researchers that participated in two expeditions in West Antarctica, King George Island. We chose to study the RBCs adaptation because under these conditions it is expected that the adaptation of an organism to extreme conditions will be determined by cellular adaptations, especially at the level of RBCs involved in oxygen transport. The methods to investigate cellular changes at erythrocyte level was flow cytometry for morphological changes (FSC/SSC analysis) correlated with scanning microscopy, erythrocytes viability determined with Calcein-AM and the analysis of RBCs apoptosis with Annexin-V- FITC. We also investigated the number of reticulocytes in the circulation. The results were obtained by comparing the data gathered from the explorers before and after three weeks spent in Antarctica. Our investigations have shown a clear decrease of erythrocytes viability in the absence of significant morphological changes and an increasing of reticulocytes number as a result of a greater elimination of RBCs by apoptosis, as a compensatory mechanism. It is difficult to say at the moment what climatic factors have led to the change in the viability of RBCs. Further more we will correlate the results with the climate parameters variations.
Health Problems in a Long Term Stay in Antarctic High Land

Purpose: There is need to study both acute mountain sickness and chronic response during a long term stay in Antarctic high land. We examined medical cases of wintering-over teams at Dome Fuji (S77, E39, 3810 m a.s.l.) and compared them with Syowa station(S69, E39, 29 m a.s.l.).

Methods: Dome Fuji summer operations started in 1995. Wintering-over operations were carried during the 1995-1998 period. The number of wintering-over participants was 9 per year and 27 in total with 243 medical consultations.

Result: Medical consultations occurred frequently at the beginning of wintering-over and polar night. The proportion of medical consultations showed that the largest group were surgery and Orthopedic (82 cases) followed by internal medicine (80 cases), teeth problems (23 cases). The forth is psychiatric problems that totaled 23 cases. Comparing with Syowa station, internal medical and mental problems were dominant with less injury cases. Dome Fuji had more cases of headache, gout, alcohol related disorder, frost bite and insomnia.

We had no fatal case nor major operation in high land. There was one severe case of bradycardia with AV block that occurred in summer. The patient could be airlifted to Japan.

Discussion: During the long term stay at Dome Fuji, we detected some difference of health problems compared with Syowa station. To solve these problems, we need to further study hypoxia, coldness, daylight change, smaller group isolation and work patterns.
Building the International Guide for Online Arctic Ethnographic Collections

Igor Krupnik1 (krupniki@si.edu), Nicholas Parlato2, Chelsi Slotten1
1Smithsonian National Museum of Natural History, Anthropology, Washington, United States, 2University of Northern British Columbia, Geography, Prince George, Canada

The museum practices of collecting objects from indigenous peoples has created a vast and diverse landscape of museum holdings across the world. Through acquisition, trade, scientific expeditions, and government policies, the ethnographic collections held in many museums worldwide have achieved a distinct character in terms of their history, scope, depth of catalog record, and accessibility. Scholarly researchers, indigenous communities, educators, and the public face many challenges in navigating this uneven and uncharted territory of world’s ethnographic museum collections for northern regions. The paper introduces an effort launched at the Smithsonian National Museum of Natural History to produce an international “guide” for Arctic ethnographic collections using individual museum websites and other mostly web-based resources. As of late 2017, the guide covers 15 states, including all polar nations, and over 100 individual museums, with more than 250,000 ethnographic objects total. The paper discusses the rationale and purpose underlying the project, and explains why accessibility is a critical issue for northern ethnographic collections to address the main question: To what degree are museum materials available online to outside researchers, students, and indigenous users?
Promoting the Antarctic Heritage of South Africa with a Digital Museum

Ria Olivier¹ (riaolivier@sun.ac.za)
¹Stellenbosch University, Botany and Zoology, Stellenbosch, South Africa

A museum is devoted to the procurement, care, study, and display of objects of lasting interest or value for a specific subject. The internet and virtual environment create a possibility of digital museums that is a digital footprint of the physical. Physical museums are essential; humans want to relive the experiences of others. This is however not always a possibility for everyone. Therefore, the digitised era of objects is more accessible to a wider audience. A digital museum need to communicate research and exploration to the public, and provide access to their specimens. It involves a location for the collection and a set of digital objects, on a permanent base. Therefore, it is necessary to investigate new ways where museums can work together in a global context to advance research and collections, and engage, inspire and educate the future generations of all countries and especially South Africa. Antarctic Legacy of South Africa's (ALSA) main aim is to preserve our legacy in the Antarctic region by maintaining a digital archive. It is to be a resource for research in history and humanities, and secondary to promote this legacy. ALSA investigate the possibilities of utilizing the digitised material in the archive. This poster will outline the process of creating a digital museum with the digitised material in the archive and highlight the open accessibility of such a museum. A copy in CD Format of the ALSA digital museum will be available during the poster session.
Jeffery M. Saarela¹ (jsaarela@mus-nature.ca)
² Canadian Museum of Nature, Centre for Arctic Knowledge & Exploration, Ottawa, Canada

Natural history museums hold the record of nature over time, including millions of specimens from the Arctic, yet museums have been largely on the periphery of Arctic science and Arctic data discussions. The "Arctic Evidence Eight" is an alliance of eight national Natural History Museums in the eight Arctic Council countries: Canadian Museum of Nature; Finnish Museum of Natural History; Icelandic Institute of Natural History; National Museum of Natural History, Smithsonian Institution; Natural History Museum of Denmark; Natural History Museum, University of Oslo; Swedish Museum of Natural History; and Zoological Institute of the Russian Academy of Sciences. The Arctic Evidence Eight aspire to play a vital role in saving the world with evidence, knowledge and inspiration. Each institution holds substantive collections of Arctic flora and fauna, as well as cultural artefacts and genetic resources, which provide a foundation for creating new knowledge. The Arctic Evidence Eight are engaged in Arctic exploration and discovery, and have research expertise in diverse Arctic disciplines, such as taxonomy and systematics, Arctic ecology, environmental monitoring, climate change monitoring, and Arctic culture, human history and exploration. The Arctic Evidence Eight are engaged in finding ways to better work together and with the broader scientific community to advance Arctic research and collections, and engage, inspire and educate citizens about the global Arctic.
All credible museums conduct research. Natural history museums assemble collections as part of the research done by their staff of experts and in association with a broad network of collaborators. Work in the Arctic occurs as part of regular programs of work to explore the vast polar reaches of our planet. It can also happen opportunistically as part of events that mark significant milestones, for example the International Polar Years, or in this case the 150th anniversary of the Confederation of Canada, a year of celebrations known as Canada 150. One of the feature projects of Canada 150 was entitled Canada C3, a 150-day icebreaker exploration of the entire coastal region of Canada, from Toronto, Ontario to Victoria, British Columbia via the northwest passage. The complex program of activities during the voyage addressed the four themes of Canada 150, the environment, youth engagement, diversity and inclusion, and reconciliation. Canada C3 developed a scientific research program as part of the environment theme that explored marine and terrestrial habitats as the ship moved along its 25,000 kilometer transect around the country. This poster describes how the Canadian Museum of Nature, Canada’s national museum of natural history, participated and lead the program of research.
20th Century Italian Antarctic Exploration: The Ajmone-Cat Collection

Ester Colizza\textsuperscript{1,2} (colizae@units.it), Ioanna Protopsalti\textsuperscript{2}, Gianguido Salvi\textsuperscript{1,2}, Stefano Cirilli\textsuperscript{1}

\textsuperscript{1}University of Trieste, Mathematics and Geosciences, Trieste, Italy, \textsuperscript{2}Museo Nazionale dell’Antartide ‘Felice Ippolito’, Trieste, Italy

The Antarctic National Museum - Trieste Section (University of Trieste) collects and preserves marine geological findings, and preserves archives regarding the history of exploration to present them to the public on a permanent basis. The Museum is divided into two sectors: the Permanent Exhibition and the Sorting Center. Since the end of the 1800s many Italian explorers have organized or taken part in various expeditions to the Southern Seas and by the early 1970s some private expeditions were also being carried out, which are also included in the Permanent Exhibition.

Here we present the collection of Naval officer Giovanni Ajmone-Cat who made two Antarctic expeditions (1969-1971 and 1973-1974) on board the steam motorsailer San Giuseppe Due which had been specially built for the expeditions. He explored Deception Island (South Shetlands), Wiencke and Anvers Islands, and visited Argentine and American Stations in the Antarctic Peninsula. Recently the Italian Navy, in accordance with the wishes of the Ajmone-Cat family, has lent the Captain’s entire collection to the MNA - Trieste Section. The collection consists of photographs, slides, movies, maps, papers and information about these two autonomous trips. These materials are catalogued and we are currently digitizing part of the collection using a laser scanner with photographic overlay to create a 3D model appropriate for long distance access in order to communicate these two Antarctic explorations to the public.
The Italian Museo Nazionale dell’Antartide

Carlo Alberto Ricci¹, Giorgio Bavestrello², Alessio Casagli³, Ester Colizza³, Michele Fernetti¹, Cristiano Landucci², Jacqueline Müller³ (jacqueline.muller@unisi.it), Silvia Olmastroni³, Rosaria Palmeri³, Ioanna Protopsalti⁴, Gianguido Salvi⁴, Sonia Sandroni³, Stefano Schiaparelli², Franco Maria Talarico³, Guido Travaglia⁴

¹Museo Nazionale dell’Antartide ‘Felice Ippolito’, Siena, Italy, ²Museo Nazionale dell’Antartide ‘Felice Ippolito’, Sede di Genova, Università di Genova, Genova, Italy, ³Museo Nazionale dell’Antartide ‘Felice Ippolito’, Sede di Siena, Università di Siena, Siena, Italy, ⁴Museo Nazionale dell’Antartide ‘Felice Ippolito’, Sede di Trieste, Università di Trieste, Trieste, Italy

The Italian Museo Nazionale dell’Antartide (www.mna.it) was established as a consortium of three universities (Genova, Siena, Trieste) in 1996 with the aim to preserve, study, and increase the value of all material collected during the Italian Antarctic expeditions, as well as to promote public understanding of Antarctic science. The specimen repositories host rocks, meteorites, sediment and ice cores and marine and terrestrial flora and fauna, collected by the Italian Antarctic expeditions since 1985. All the material stored in the repositories is described in specific data bases. The museum operates as an infrastructure of the Italian Antarctic programme (PNRA) in support of the national and international scientific community. The storing, classification and distribution of Antarctic scientific material is a peculiar aspect of the Italian Antarctic museum that marks a clear difference to other polar museums. The museum contributes to education, outreach and training by promoting polar knowledge to schools through lectures, guided visits and didactic experiments to all-level students, from kindergarten to PhD level and to the general public through permanent exhibitions in Genova, Siena and Trieste. The museum publishes scientific journals, volumes, and multimedia and is also partner of international initiatives devoted to the dissemination of information of the specimen collections and results obtained by PNRA.
How can a Polar Research Institute convey its history and the historical heritage of its discipline to the public? What kind of role can archives of these institutions play in this matter? How can these archives use records and other materials kept by them for the best effect on the public sphere? How can they combine historical research with the focus on polar research with public relation activities of Polar Research institutes? These questions will be answered during this talk by having a close look on a staged reading on the history of German Polar Research, a result of a collaboration between the Alfred-Wegener-Institute's own Archive for German Polar Research (AGPR) and the project “Aus den Akten auf die Bühne” (AdA) (“Staging Files”), a cooperation between the institute of history at Bremen University and the “bremer shakespeare company”.

To fulfill this task, the talk will initially present both AGPR and AdA with the regard to their history, their task or aims and their work approaches and ways of working. Next, the cooperation between the AGPR and AdA on the history of German Polar Research will be described with respect to its emergence and its work modus. Afterwards an overview of the project product, the stage reading, will be given with regard to its contents, structure and theatrical means. Finally, since the staged reading started in May 2018, a first evaluation of the project will be presented.
Climate change is no longer a theory to be debated but rather an indisputable reality that requires immediate global engagement. Given this reality, what role does a museum play in encouraging public awareness and activism? The Museum of Natural History of Neuchâtel, in presenting an exhibition (2 June 18 - 30 June 2019) on the polar regions and climate change, is hoping to stimulate a discussion about one of the most pressing issues of our time. By presenting our natural history collections in the context of the Poles and global warming, and by presenting pertinent research carried out in polar and alpine regions, the Museum encourages the visitor to enter an exhibition characterized by paradox. This polarized world is one both up and down, both water and ice, hostile yet teeming with life, plunged in crisis but with solutions in sight. In the context of the exhibition, participants have been invited to send us their personal reactions to a brief text written by Claude Lorius, the French glaciologist who first discovered that gases trapped in polar ice held the key to unraveling the history of earth’s climate. These reactions, whether in the form of text, video..., will be incorporated into our exhibition, allowing the public to manifest their opinions in the museum. We thus hope to create a synergic space where scientific, cultural and personal information is transmitted in two directions, both from the museum to its visitors and from the visitors to the museum.
Climate change is expected to impact on marine polar fish leading to local extinctions, invasions and modifications in the structure of the ecosystems. In the last decade, polar bodies and polar scientists have spent great effort in establishing monitoring activities in order to gather baseline data on both Arctic and Antarctic fish, and to interpret future reassessments in the communities. Over time, the potential for accessing and exchanging scientific information has greatly improved, but the need of specimen and tissue repositories (not only focusing on DNA) remains of high priority for polar research, representing an invaluable basis for monitoring plans and a legacy for the future.

Aiming at contributing to this issue, a polar fish chromosomes archive has been established in the framework of the PNRA Project “Polar Fish Cytogenetic Diversity” (POLICY) carried out at Institute of Marine Sciences, Genoa. The archive is hosted and curated by the Italian National Antarctic Museum (MNA), Section of Genoa which will guarantee the link with other biological databases. The archive is organized as a repository of cytogenetic samples (frozen mitotic cells and slide chromosome preparations) with an associated database including karyotypic and cytogenomic data and DNA barcodes. Such an overall organization aims at providing the polar community with a useful biological resource for a wide range of applications, from species characterization and identification to genome adaptation.
Like many regions of our planet, the Antarctic is currently undergoing profound environmental changes. Sea ice is a prominent element of this environment: it controls the heat, gas, mass and momentum exchanges between the atmosphere and the ocean. Sea ice has been steadily expanding in the Southern Ocean since the late 1970s but has displayed significant negative anomalies in recent years. Understanding and predicting how the sea-ice cover develops over time scales as short as a season is important not only for scientists but also for stakeholders or teams organizing field campaigns. Despite all potential applications, there has been to date no overall assessment of the capabilities of current prediction systems to forecast sea ice conditions at time scales of a season. This is the goal of SIPN South. SIPN South is a 2-yr project endorsed by the Year of Polar Prediction (YOPP) project. SIPN South aims at evaluating the skill of various forecast systems (statistical, dynamical) in predicting the regional summer conditions around the Antarctic continent. In this poster, we are presenting the very first coordinated austral sea ice prediction that will take place in February 2018 (summer sea ice minimum).
Operational Polar Sea Ice Forecast and Service in China

Chunhua Li1 (lichunhua0214@hotmail.com), Qinghua Yang1, Lin Zhang1, Ming Li1, Jiechen Zhao1, Zhongxiang Tian1, Longjiang Mu1, Xiaoyu Sun1, Xingren Wu2, Xi Liang1, Guanghua Hao1, Shang Meng1

1National Marine Environmental Forecasting Center, Beijing, China, 2Environmental Modeling Center (EMC), NCEP, NOAA, Washington, United States

The polar sea ice forecast and service is needed urgently with the development of polar research expeditions and Chinese cargo ship navigations through polar regions in recent years. The operational polar sea ice forecast and service system is developing at National Marine Environmental Forecasting Center of China (NMEFC). The synoptic scale sea ice forecasting system is based on a coupled ice-ocean model with multiple parameter data assimilation and is operational running. The subseasonal and seasonal sea ice prediction are based on the NCEP Climate Forecast System version 2 (CFSv2) and statistic forecasting method. Moreover, due to the importance of in-situ sea ice observation data for the sea ice forecast, the sea ice and snow thickness, albedo observations have been sustained for more than 5 years based on the Zhongshan station in the Antarctic, and ice buoys were placed on the floe ice in the Arctic ocean to monitor ice drift and ice thickness in recent several years. Synthesizing the forecast, satellite and site observation data, sea ice service are provided to users such as Xuelong icebreaker and Chinese merchant ship.
We summarize the model development for sea ice and ocean component and the initial evaluation for the CMIP6. A nominal resolution of 0.5 degree is adopted for grid of the ocean and sea ice components, with much improvement of spatial resolution in the Arctic region. A diagnostic floe-size parameterization and lateral melt scheme is integrated in the sea ice model, with observational data specific to both Arctic and Antarctic. Through initial evaluation based on OMIP, pre-industrial and historical runs in CMIP6, we show that the ocean-ice coupled model and the fully coupled model reproduces reasonable Arctic climatology and changes, and the positive bias in the Antarctic sea ice extent is greatly reduced. The improvements in the sea ice model and ocean model serve as an integral part of the coupled model development for CMIP6 at Tsinghua University.
Arctic Ice Ocean Prediction System (ArcIOPS): An Evaluation of Sea Ice Forecasts

Qinghua Yang¹ (yqh@nmefc.gov.cn), Longjiang Mu¹, Xi Liang¹, Chunhua Li¹, Lin Zhang¹
¹National Marine Environmental Forecasting Center, Beijing, China

The Arctic sea ice decline in summer opens new shipping routes and increases the marine operations in the Arctic Ocean. To well manage the opportunities and possible risks, accurate sea ice predictions are strongly required. In an effort towards reliable Arctic sea ice numerical prediction, the Arctic Ice Ocean Prediction System (ArcIOPS) was developed at National Marine Environmental Forecasting Center of China (NMEFC). This system is based on a regional Arctic configuration of the Massachusetts Institute of Technology general circulation model (MITgcm) and a localized error subspace transform ensemble Kalman filter (LESTKF) to assimilate weekly CryoSat-2 sea ice thickness data together with daily SMOS sea ice thickness and daily AMSR2 sea ice concentration data. The NCEP GFS numerical weather prediction is used as the atmospheric forcing. The real-time ensemble based sea ice forecasting experiments were carried out to facilitate the Chinese National Arctic Research Expedition in summer 2018 (CHINARE2018). The forecasts were evaluated against SSMIS sea ice concentration data and the in situ sea ice concentration and thickness data. Both sea-ice concentration and thickness forecasts show reasonable agreement with the independent observations, which proves the forecasting system has a good potential for the Arctic sea ice predictions.
Assimilating Copernicus SST into a Arctic Ice-ocean Model with a LSEIK Filter

Xi Liang¹ (liangxi700@126.com), Qinghua Yang¹, Lars Nerger², Svetlana Losa²
¹National Marine Environmental Forecasting Center, Beijing, China, ²Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

Sea surface temperature (SST) data from the Copernicus Marine Service are assimilated into a pan-Arctic ice-ocean coupled model using the ensemble-based Local Singular Evolutive Interpolated Kalman (LSEIK) filter. It is found that the SST deviation between model hindcasts and independent SST observations is reduced by the assimilation. Compared with model results without data assimilation, the deviation between the model hindcasts and independent SST observations has decreased by up to 0.2 °C at the end of summer. The strongest SST improvements are located in the Greenland Sea, the Beaufort Sea and the Canadian Arctic Archipelago. The SST assimilation also changes the sea ice concentration (SIC). Improvements of the ice concentrations are found in the Canadian Arctic Archipelago, the Beaufort Sea and the central Arctic basin, while negative effects occur in the west area of the Eastern Siberian Sea and the Laptev Sea. Also sea ice thickness (SIT) benefits from ensemble SST assimilation. A comparison with upward-looking sonar observations reveals that hindcasts of SIT are improved in the Beaufort Sea by assimilating reliable SST observations into light ice areas. The study illustrates the advantages of assimilating SST observations into an ice-ocean coupled model system and suggests that SST assimilation can improve SIT hindcasts regionally during the melting season.
Daily Arctic Sea Ice Thickness Estimates in Cold Seasons

Longjiang Mu¹ (mulj@nmefc.gov.cn), Martin Losch², Qinghua Yang³, Svetlana N. Losa²,³, Robert Ricker², Lars Nerger²
¹National Marine Environmental Forecasting Center, Beijing, China, ²Alfred Wegener Institute, Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, ³P.P. Shirshov Institute of Oceanology, St. Petersburg, Russian Federation

The Arctic multi-year sea ice thickness has undertaken substantial thinning in recent decades. However, direct observations are inadequate because of the limited in situ expeditions and immature satellite retrievals. The complementary of CryoSat-2 launched in 2010 and SMOS sea ice thickness allows it possible to combine these two datasets to get a purely statistical dataset CS2SMOS in cold seasons.

A new daily sea ice thickness dataset in cold seasons from 2010 to 2016 is generated by the Massachusetts Institute of Technology general circulation model (MITgcm) with the assimilation performed by a localized error subspace transform ensemble Kalman filter (LESTKF) filter coded in the Parallel Data Assimilation Framework (PDAF). The atmospheric ensemble forecasts of the UK Met Office Unified Model (UKMO) available in the TIGGE archive are used to force the model. The available weekly CryoSat-2 sea ice thickness data together with daily SMOS sea ice thickness and daily SSMIS sea ice concentration data are then assimilated into the model during analysis process. In situ sea ice thickness observations from Beaufort Gyre Exploration Project and Ice Mass Balances data are used to evaluate the sea ice thickness estimates. Statistic results show that the sea ice thickness data have comparable performance to CS2SMOS data in cold seasons, and further provide daily evolution for future studies.
The Southern Hemisphere sea ice extent has followed an overall positive trend over the last 30 years. In this context, the last two years appear unusual with a lower than normal sea ice extent for almost all the months. This drop in sea ice extent after a record high in 2014 highlights the importance of the Antarctic sea ice variability at the seasonal and interannual timescales. Multiple mechanisms have been proposed to explain this variability. Although there is evidence that recent changes in the Antarctic sea ice are triggered by atmospheric conditions, the persistence or re-emergence of the sea ice anomalies has been partly attributed to sea ice-ocean interactions. In this study, we explore the critical influence of the state of the Southern Ocean on the seasonal predictability of the sea ice. A simulation covering the period 1979-2016 using the ocean-sea ice model NEMO3.6-LIM3 driven by atmospheric fields derived from atmospheric reanalyses is first performed and compared to observations. In a second step, the state of the ocean is perturbed to evaluate the implications of a warmer or colder than usual ocean on the evolution of the sea ice. In practice, this is achieved by replacing the ocean conditions at specific times by those simulated at the same season but for a different year, while keeping the same atmospheric forcing. The impact of such changes on sea ice conditions over the following months is then assessed.
Ensemble sea ice forecasts of the Arctic Ocean is conducted with the KMA's GloSea5 seasonal prediction system. We assess the temporal and spatial characteristics of the monthly projection of Arctic sea ice extent and thickness in terms of forecasts accuracy and variability. The forecast skills are significant for all lead months, but anomalous around Siberian shelf, Chukchi Sea and Beaufort Sea during summer months. This study shows the summer sea ice prediction depends strongly on the previous winter sea ice thickness interacting with the accuracy of the snow depth. In spite of the uncertainties in atmospheric conditions, this system provides skillful Arctic seasonal sea ice cover predictions up to six months.
A data assimilation method capable of constraining the sea ice of an Earth system model in a dynamically consistent manner has the potential to enhance the accuracy of climate reconstructions and predictions. The difficulty in finding such a method lies in the strong nonlinearity of sea ice as well as in the sea ice variables, that are strongly non-Gaussian distributed and tightly coupled to the rest of the Earth system - particularly thermodynamically with the ocean.

We assess key practical implementations for assimilating sea ice concentration - the predominant source of observations in polar regions - with the Norwegian Climate Prediction Model that combines the Norwegian Earth system Model with the Ensemble Kalman Filter. For our study we conducted ten-year reanalyses in a perfect model framework. We discuss the benefits of weakly coupled (sea ice only) assimilation, as well as the impact of strongly coupled ocean-sea ice assimilation. Focusing on the ice variables, we investigate the performance of solving the analysis for the aggregated and for the multicategory ice states. The case of updating the ice volumes during the assimilation, thus necessitating the post-processing of unphysical thicknesses, will also be discussed. The robustness and reliability of the optimal setting is demonstrated for a 20-year reanalysis.

Finally, leaving the perfect model framework, we demonstrate the added value of sea ice assimilation in a realistic framework.
Re-interpreting Thermodynamic Arctic Sea Ice Feedbacks

Francois Massonnet¹ (francois.massonnet@uclouvain.be), Martin Vancoppenolle², Hugues Goosse¹, David Docquier³, Thierry Fichefet¹, Edward Blanchard-Wrigglesworth³

¹Université catholique de Louvain (UCL), Louvain-la-Neuve, Belgium, ²LOCEAN Laboratory, Paris, France, ³University of Washington, Seattle, United States

One of the clearest manifestations of ongoing global climate change is the dramatic retreat and thinning of the Arctic sea-ice cover. All state-of-the-art climate models reproduce consistently the sign of these changes but largely disagree on their magnitude. The very deep causes remain contentious and consensual methods to reduce uncertainty in projections are lacking. Here we propose a process-oriented approach to revisit this question. We show that inter-model differences in sea-ice loss and, more generally in simulated sea-ice variability at all time scales, can be traced back to differences in the simulation of two competing thermodynamic sea-ice feedbacks. In turn, we show that both feedbacks are closely tied to the average ice thickness simulated by each model, regardless of the complexity of its sea-ice component. The results prompt modelling groups to focus their priorities on the reduction of sea-ice thickness biases, as we provide physical evidence that Arctic sea-ice projections from models with unrealistic current thickness can robustly be distrusted. We finally show that because of the enhancement of the feedbacks as sea ice thins, the recent and future changes in sea-ice thickness induce a transition of the Arctic towards a state with increased seasonal-to-interannual variability and less persistence, in other words less predictability.
A TEOS-10-based Sea Ice Thermodynamic Formulation

Sea ice thermodynamics in Earth System Models have a well established physical basis, yet formulations are generally not fully consistent with the thermodynamics of the other components of the Earth System, in particular the ocean and continental ice sheets. The ocean components have recently adopted the International Thermodynamic Equation of Seawater 2010 (TEOS-10), which includes formulations for both seawater and pure ice.

Since sea ice is at typical temperatures composed of pure ice and concentrated seawater in brine inclusions, it seems natural to base sea ice thermodynamics on a combination of TEOS-10 standards for sea water and pure ice. Feistel and Hagen (1998) have proposed such an approach that can readily be used but should be updated following the recent TEOS-10 developments.

With derive a TEOS-10 thermodynamic formulation for sea ice and question: (i) how consistent the TEOS-10 based sea ice thermal properties are consistent with observations; (ii) how different a TEOS-10 sea ice formulation is from standard sea ice formulations in current Earth System Models; (iii) how this can be implemented in climate models.
Impacts on Sea Ice of Increased Ice Shelf Meltwater over Centennial Timescales

Inga J. Smith¹ (inga.smith@otago.ac.nz), Cecilia M. Bitz², Andrew G. Pauling¹,², Katherine Lilly¹, Patricia J. Langhorne³, Christina L. Hulbe³

¹University of Otago / Te Whare Wananga o Otago, Department of Physics, Dunedin, New Zealand, ²University of Washington, Atmospheric Sciences, Seattle, United States, ³University of Otago / Te Whare Wananga o Otago, National School of Surveying, Dunedin, New Zealand

The West Antarctic Ice Sheet may already be undergoing an irreversible mass loss that would result in near complete melt within the next millennium. The sea ice and climate response to increased Antarctic meltwater over centennial timescales is investigated with simulations in the Community Earth System Model version 1, with the Community Atmosphere Model version 4 (CESM1-CAM4). To investigate the response to meltwater released at the base of ice shelves in a higher CO₂ warming world, meltwater was injected at the depth of the front of the ice shelves, while simultaneously cooling the ocean by an amount required to melt the ice. The amount of freshwater added increased linearly over time, to represent gradually increased basal melting of ice shelves. To isolate the effects of ice shelf meltwater from greenhouse gas forcings, a pre-industrial (1850s) run was subjected to the increased freshwater for 150 years, consistent with published literature on the timescales of future ice shelf melting. This was then compared with the trends in the response to 20th and 21st century climate change.
The New Zealand Earth System Model (NZESM) is being developed and used through the Deep South National Science Challenge. NZESM is based on the UKESM1 physical model HadGEM3-GC3.1, which is a fully coupled atmosphere, land, ocean and sea ice model. In our research, we will use the NZESM to investigate the coupled response of the sea ice module (CICE) and the ocean module (NEMO) to freshwater forcings, including accounting for the meltwater latent heat. Freshwater flux runs have not been run for the NZESM and its predecessors in coupled (atmosphere-ice-ocean) mode. Runs with the NZESM will therefore fill a critical knowledge gap in terms of coupled model behaviour. We will initially run icebergs only (surface freshwater) runs, using state-of-the-art parameterisations for 1 degree models with and without their associated latent heat fluxes, to allow direct comparison with standardised control runs and the results from other models. Next, we will perform simulations with freshwater injection at depth to see if this makes any difference to the results.
Robustness of Arctic Sea-ice Predictability in GCMs

Ed Blanchard-Wrigglesworth¹, Mitch Bushuk² (mitchell.bushuk@noaa.gov)
¹University of Washington, Seattle, United States, ²Geophysical Fluid Dynamics Laboratory, Princeton, United States

General circulation models have been amply used to quantify Arctic sea-ice predictability. While models show commonalities in the general tendency of predictability loss, there is significant disagreement in its magnitude and timing. Here we show that inter-model differences in predictability are linked to inter-model differences in the persistence timescales of sea-ice anomalies that are unique to each model. Given this result, and previous work showing that within a single model simulation the magnitude of persistence fluctuates between periods of high and low persistence that may last several years, we assess whether initial-value predictability is dependent on the persistence state of the initial conditions. We find that forecast spread predictability is not significantly different across high/low persistence periods, suggesting that predictability may be robust within an unchanging climate mean state. Our results also imply that annual periods of high/low persistence are not predictable and are mainly forced by the atmosphere rather than the ice-ocean system.
Combining Information from Models and Automatic Classifications for Ice Charting

Jürgen Holfort¹ (juergen.holfort@bsh.de), Sandra Schwegmann¹
¹Bundesamt für Seeschifffahrt und Hydrographie, M12 Eisdienst, Rostock, Germany

Sea ice concentration and thickness from numerical models as well as from automatic sea ice classification algorithms using satellite data are still not suitable for direct use in the production of operational sea ice charts. However, the usability depends strongly on time and location. For areas with high concentrations both products are very usable in winter but at low concentrations and/or if the ice is rotten the quality deteriorates. In addition numerical models have also problems with the fast ice edge. Nevertheless, models and satellite data can deliver parameters which are not yet, or only in rare cases, depicted in operational ice charts. These range from directly usable parameters like floe size and ridges to more generalized parameters like roughness and orientation of linear features. In order to explore the possibilities and challenges a method was incorporated into the ice analyst routine, which gives the analyst the ice parameter values from models and automated classifications within the drawn ice polygon to help him setting the appropriate parameters in the ice chart. This method will be used in the Baltic winter season of 2017/18 and we will give some first insights gained.
Beyond sea ice concentration and thickness, ice drift and deformation are the most important parameters for ships passing through sea ice covered regions. However, knowledge on drift and deformation is sparse due to the lag of suitable and sufficient satellite data. Therefore, the only regular information is based on models. Models do not only show the actual state of ice drift and deformation but also provide the opportunity to display near real time ice development, which is essential for ship route planning. By the optimization of models with respect of sea ice drift both a better representation of the ice situation in total and a decision support for ship route planning considering ice deformation processes and near future ice development can be realized in future. As a first step towards this future, we analyze the accuracy of the BSH ice model by comparing the model ice drift with an operational ice drift product based on satellite data in the sea ice covered regions of the Baltic Sea. This small region is covered frequently by diverse satellites so that the ice drift can be calculated generally with a high temporal resolution. Meteorological and oceanographic conditions are investigated in order to detect drivers for differences between both products and to eliminate weaknesses in the model. Once the development of the models and S411 has moved on sufficiently, ice drift may become worldwide additional information transferred to the ships in sea ice covered regions.
The Sea Ice Drift Forecast Experiment (SIDFEx) was launched in summer 2017. SIDFEx is a community effort to solicit, collect, and analyze sea ice drift forecasts, based on arbitrary methods, for a number of IABP sea-ice buoys on a regular basis. The YOPP initiative is inspired by increasing research and operational needs to forecast future positions of assets drifting in Arctic sea ice. An example is the need to determine an optimal start position for the MOSAiC drift. Specifically, it is unclear whether forecast systems that account for initial conditions can provide additional skill over drift forecasts made using historical sea ice velocity fields. The MOSAiC drift provides a template for assessing the capabilities to forecast sea-ice drift for a range of applications, ranging from logistics support for future field experiments to potential search and rescue operations. The examination of sea ice drift forecasts provides an integrated assessment of many aspects of the coupled atmosphere-ice-ocean system and will motivate in depth investigations into how key variables are measured, modeled, and forecast. We expect that a systematic assessment of real drift forecasting capabilities will improve our physical understanding of sea ice and enable us to identify and resolve model shortcomings. We will present the current design of SIDFEx, discuss results obtained from one year of SIDFEx submissions, and present future plans in association with the MOSAiC drift.
The Arctic Marine Forecasting Centre (ARC MFC) provides 10-days forecasts of the ocean currents, sea ice, marine biogeochemistry and waves on a daily basis and a 25-year reanalysis of the Arctic Ocean updated every year. The ARC MFC is powered by the Topaz configuration of the HYCOM model, coupled to the sea ice model CICE, the ecosystem model ECOSMO, and assimilates the following data with the Ensemble Kalman Filter: along-track sea level anomalies, sea surface temperatures, sea ice concentrations, sea ice drift, sea ice thickness, in situ temperature and salinity profiles and (only in reanalysis mode) ocean colour data. Waves are forecasted using an Arctic configuration of the WAM model. We review the main achievements of the ARC MFC during the first 3 years of the services, the participation to model intercomparison exercises and the plans for its future developments.
Iceberg Meltwater Estimates for the Southern Ocean Including Giant Icebergs

Thomas Rackow¹ (thomas.rackow@awi.de), Christine Wesche², Ralph Timmermann³, Hartmut H. Hellmer³, Stephan Juricke⁴, Thomas Jung¹,⁵
¹Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research (AWI), Climate Dynamics, Bremerhaven, Germany, ²Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research (AWI), Operations and Research Platforms, Bremerhaven, Germany, ³Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research (AWI), Physical Oceanography of the Polar Seas, Bremerhaven, Germany, ⁴Jacobs University Bremen gGmbH, Mathematics & Logistics, Bremen, Germany, ⁵University of Bremen, Department of Physics and Electrical Engineering, Bremen, Germany

Iceberg calving is an important component of the mass balance of the Antarctic Ice Sheet, with recent estimates of ~1300 Gt/year being on the same level as ice shelf basal melting. The iceberg mass is usually assumed to be evenly divided between giant icebergs (length >10km) and smaller ones, with some estimates even preferring giant icebergs (as high as 89%). However, it is still unclear what the best way is to include giant icebergs into model estimates of the Southern Ocean freshwater cycle.

Here, we estimate the iceberg meltwater input from a simulation of present-day Antarctic icebergs and compare it to the balance between precipitation and evaporation (P-E) and sea-ice production rates. For the first time, an iceberg model is initialized with a set of nearly 7000 satellite-observed iceberg positions and sizes. It reproduces typical drift patterns for a large spectrum of size classes, including typical routes taken by giant icebergs.

The associated meltwater input is generally on the order of 5-20% of the P-E balance in large areas of the Southern Ocean, especially around the coast, with local maxima even exceeding P-E. Furthermore, the freshwater flux from melting icebergs is on the order of 5-20% of coastal sea ice production rates and, thus, partly compensates the effect of brine rejection in the annual mean. Iceberg melting is also the largest vector of freshwater input from frozen ice along (and northward of) the sea-ice edge.
We have recently developed a Lagrangian Ice Tracking System (LITS) for the Arctic Ocean. The LITS tracks motion of sea ice in a Lagrangian framework using sea ice drifts. It has been used to develop a seasonal forecasting model of the minimum sea ice extent (Williams et al. 2016) based on observational drifts. In continuity, we are working on the seasonal predictability of the sea ice system on a regional scale. The current version of the LITS uses the Polar Pathfinder sea ice motion vectors (V3, Tschudi et al. 2016). However, the raw drift vectors used to construct Polar Pathfinder contain biases. The satellite-derived velocities (from SMMR, SSM/I, AMSRE, AVHRR) and free drift estimates present a low bias when compared to the buoy drift observations, taken to be essentially true. Biases are larger in the summer, when fewer satellite-derived drifts are available and the composite sea ice drift relies more heavily on the free drift estimates. While being useful for climatic studies and model validation (Sumata et al. 2015), the issues found in Polar Pathfinder become more apparent when building a regional forecasting model. To this end, we recompile a new optimally interpolated sea ice drift dataset, using bias-corrected and error-weighted raw drift vectors from Polar Pathfinder, buoy data, free drift estimates derived from reanalyses, and other available satellite-derived drifts.
Forecasts of 2017 Arctic Sea Ice States Using the Regional Arctic System Model

The rate of Arctic climate warming has been at least twice as fast as the global mean. Increasing surface air temperatures and declining sea ice have been some of the main attributes of that change. Wide-ranging sub-seasonal to seasonal (S2S) year-around forecasts of sea ice and climate states are becoming increasingly vital to surging human operations in the area, however the advancement of their skill remains challenging. This presentation summarizes our approach and results on 2017 Arctic sea ice thickness and concentration S2S forecasts using the Regional Arctic System Model (RASM).

RASM is a fully coupled regional climate system model, including atmospheric, ocean, sea ice, and land-hydrology components and a flux coupler to connect them. RASM is used to dynamically downscale the Climate Forecasting System Reanalysis (CFSR) for 1979-2017 and to create consistent initial conditions for all model components for S2S ensemble forecasts for each month of 2017. After the initialization, forecasts are forced at the model boundaries with output from 9-month CFSv2 global forecasts. Their skill is assessed against available observations. In particular, the effects of lead time, initial conditions, and sea ice rheology on the skill of forecasts are investigated. Based on these findings, an approach for future forecasts, including increased resolution of the RASM atmospheric model, marine biogeochemistry predictions and larger ensemble will be also outlined.
The rapid changes in the Arctic sea ice raises increasing demands for seasonal sea ice prediction. However, there were large biases in the predicted sea ice extent and thickness due partly to the poorly-known initial sea ice conditions. In this study, a coupled regional ocean-sea ice model ROMS-CICE is applied to investigate the effect of assimilating sea surface temperature (SST), sea ice concentration (SIC) and sea ice thickness (SIT) on the seasonal prediction of September Arctic sea ice from April. The years 2011-2016 are chosen as the study period when all the observations of SST, SIC and SIT are available (although SIT is only available during winter period). The model is initialized with monthly mean ocean and sea ice state from the UK Met Office’s Forecasting Ocean Assimilation Model (FOAM). A nudging scheme is employed to assimilate the SST, SIC and SIT, respectively. Both ERA-Interim and ERA5 atmospheric reanalysis are used to assess the effect of atmospheric impact.
Superimposed Ice Contribution to Arctic Sea-ice Mass in an Excessive Snow Region

Caixin Wang¹ (wang_caixin@126.com), Anja Rösel², Keguang Wang¹, Robert Graham², Mats Granskog², Sebastian Gerland²
¹Norwegian Meteorological Institute, Tromso, Norway, ²Norwegian Polar Institute, Fram Centre, Tromso, Norway

Snow on sea ice may delay or slow down the growth and melt of sea ice due to its strong insulative properties and high albedo. It also can directly contribute to sea-ice mass balance through superimposed ice. Superimposed ice is a layer of ice formed at the snow-ice interface from freezing water (e.g. melted snow, liquid precipitation) on contact with underlying cold sea ice. Its contribution to sea-ice mass is substantial in the Antarctic and sub-Antarctic seas. It also forms in the Arctic, but has not attracted much attention. With the thinning of the Arctic sea ice, the warming of Arctic and possible increase in precipitation, superimposed ice may become more important. During the Norwegian young ICE expedition N-ICE2015, excessive amount of snow were found on sea ice north of Svalbard and the contribution of snow to sea-ice mass was up to 15%. Studies indicate that this might be typical for this region where frequent storms bring precipitation into the ice pack. During the N-ICE2015, an Ice Mass Balance buoy (IMB) was deployed at 82.2° N in late May 2015 and then drifted towards Fram Strait. The IMB recorded the evolution of snow and ice thickness until 6 July 2015 when it reached 78.9° N. Ice cores from Fram Strait in summer 2015 indicated that superimposed ice had been formed. Using 1-D sea ice models, we examine how snow depth, date of melt onset and other factors affects the formation and role of superimposed ice in Arctic sea-ice mass balance.
A Probabilistic Verification Score for Contours Applied to the Arctic Ice Edge

Helge Goessling\(^1\) (helge.goessling@awi.de), Thomas Jung\(^1\)

\(^1\)Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany

We introduce a verification score for probabilistic forecasts of contours—the Spatial Probability Score (SPS). Defined as the spatial integral of local (Half) Brier Scores, the SPS can be considered the spatial analog of the Continuous Ranked Probability Score (CRPS). Applying the SPS to idealised ensemble forecasts of the Arctic sea-ice edge in a global coupled climate model, we demonstrate that the metric responds properly to ensemble size, spread, and bias. When applied to individual forecasts or ensemble means (or quantiles), the SPS is reduced to the ‘volume’ of mismatch, in case of the ice edge corresponding to the Integrated Ice Edge Error (IIEE). By comparing initialised forecasts with climatological and persistence forecasts, we confirm earlier findings on the potential predictability of the Arctic sea-ice edge from a probabilistic viewpoint. We conclude that the SPS is a promising probabilistic verification metric, for contour forecasts in general and for ice-edge forecasts in particular.
The Arctic sea ice deforms continuously due to stresses imposed by winds, ocean currents and interaction with coastlines. The most dominant features produced by this deformation in the ice cover are leads and pressure ridges that are often referred to as Linear Kinematic Features (LKFs). With increasing resolution of classical (viscous-plastic) sea ice models, or using new rheological frameworks (e.g. Maxwell elasto-brittle), sea-ice models start to resolve this small-scale deformation. Typical measures for evaluating the modelled LKFs include scaling properties of sea-ice deformation or lead area density. These metrics avoid the problem of detecting individual LKFs by applying statistics over continuous fields such as sea ice deformation or concentration. In this way, these statistical metrics can provide specific information, but lack a comprehensive description of LKFs. We detect individual LKFs in sea ice deformation fields from satellite observations with an object detection algorithm. Combining this information with the sea ice drift fields used to derive the deformation fields, the LKFs are tracked in time. In doing so, the spatial characteristics (density, length, orientation, intersection angle, curvature) and the temporal evolution can be extracted from the same data-set. Our algorithm can be applied to both observed and modelled sea-ice deformation and drift making possible a consistent comparison and thorough evaluation.
Improved Sea Ice Edge Prediction Based on Ice Chart Uncertainty Metrics

Penelope Wagner\textsuperscript{1} (penelopew@met.no), Sean Helfrich\textsuperscript{2}, Nick Hughes\textsuperscript{1}, Antti Kangas\textsuperscript{3}

\textsuperscript{1}Norwegian Meteorological Institute, Norwegian Ice Service, Tromsø, Norway, \textsuperscript{2}NOAA, Center for Satellite Applications and Research (STAR), Washington D.C., United States, \textsuperscript{3}Finnish Meteorological Institute, Finnish Ice Service, Helsinki, Finland

Ice charts include a composite of near-real time sea ice information to provide consistent, reliable, and timely information for ship operators. With the onset of satellite sea ice record from 1979, data from ice charts have shown potential to improve the climatology record. There is the assumption that the methodology and data sources, and the resulting bias in the charts, has remained consistent. However, there have been significant improvements to sources going into ice charts. Information integrated into manual and automated operational ice products is often misunderstood because it is dependent on operational needs and these vary from those of the science community. The scientific community requires operational ice information that includes uncertainties. Uncertainties with human bias in ice charts are difficult to quantify, but can be accounted for by the data sources, “smearing” of the imagery into polygons, interpreter bias, and time difference between charting and data sources. A test algorithm has been developed to account for these uncertainty metrics. Imagery interpretation bias was prioritized due the potentially large contribution and little knowledge of this error source. A study was developed and tested with a training manual given to ice analysts to gauge their competency in evaluating ice information from various sources. The training results demonstrate the capability of the ice chart uncertainty metric to quantify the human bias and other uncertainties.
The World Meteorological Organization (WMO) is establishing a multi-node Arctic Polar Regional Climate Centre (PRCC) whose functions include long-range forecasting of Arctic sea ice. Through the YOPP-endorsed project “Forecasting Regional Arctic Sea Ice from a Month to Seasons” (FRAMS), capacity is being developed to produce multi-model, user-relevant sea ice forecast products. This presentation will describe developments that have occurred thus far under FRAMS and the anticipated next steps. Included in these initial developments is the extension of a procedure for producing probabilistic seasonal forecasts of local sea ice coverage to a multi-model forecasting framework. Such probabilistic forecasts that represent uncertainty can be essential for end-users who want to quantify risk and make decisions taking forecast uncertainty into account. This methodology consists of fitting single-model ensemble forecasts of local sea ice concentration to a well-suited probability distribution, and then calibrating these distributions using trend-adjusted quantile mapping. Here we report on the utility of this approach in the context of multi-model probabilistic forecasting by combining calibrated outputs from different models and comparing these forecasts against reference probabilistic forecasts based on simpler techniques.
The Statistical Seasonal Forecast Model of the Norwegian Ice Service

Nicholas Hughes¹ (nick.hughes@met.no)
¹Norwegian Meteorological Institute, Norwegian Ice Service, Tromsø, Norway

The Norwegian Ice Service has developed and run since 2013 a statistical seasonal forecast model to predict the future sea ice area in waters around the Svalbard archipelago. The objective is to provide an indication to the ice service, and its users, of the likely severity of the next ice season in the area. This take as inputs sea ice data from the operational ice charts, and uses a combination of environmental input data including sea level pressure (SLP) data from the NCEP/NCAR Reanalysis 1 and sea surface temperature (SST) from the NOAA Extended Reconstructed Sea Surface Temperature V3b. This data has been run through the data mining software Weka to assess the utility of a number of machine learning techniques to seasonal prediction. Recently, the forecasts have also been forced up to 6 months in advance using SLP and SST ensemble predictions from the ECMWF Seasonal Forecast System to provide a spread of possible outcomes. We report here on the techniques used, and evaluate the effectiveness of the model forecasts.
The permeability of sea ice is a fundamental characteristic with implications in atmospheric chemistry, polar biology and oceanography. Permeability is controlled by a complex network of brine channels that develops as the ice forms and whose nature depends upon ice type, depth, and temperature. Recent advances in three-dimensional imaging using x-ray micro-computed tomography have enabled the quantification of the brine network morphology and variability. Using imaging of first-year sea ice samples collected near Utqiagvik, Alaska, we have collected statistics on brine channel geometry that have allowed us to parameterize the pore networks based on the variables mentioned above. This enables us to create a mathematical network model to characterize the topology and connectivity of brine channels. An initial set of nodes at the top of the sea ice column is selected, where the nodes have throat sizes consistent with the probability distribution found in natural sea ice. Branches can grow or shrink, split into multiple branches, join with other branches, remain constant, or stop, all with probabilities dependent upon the given node throat size, depth/temperature, and proximity to other nodes. The model produced can help address questions such as how fluid flow varies with depth and temperature and to what extent it is microstructure and path dependent.
The response of Arctic region to an increase in atmospheric GHG concentrations simulated by climate models is investigated here using the Brazilian Earth System Model (BESM) and compared with CMIP5 models dataset. We evaluated the ability of climate models to represent the Arctic sea ice changes and climate sensitivity to the atmospheric Carbon dioxide (CO₂) forcing. To do this, we used decadal simulations (1980-2012), Future scenarios with Representative Concentration Pathway RCP 4.5 and RCP 8.5 (2006-2100) and quadrupling of the atmospheric CO₂ concentration (2006-2300). We validated our results with satellite observations. BESM results for the Arctic sea ice seasonal cycle are consistent with CMIP5 models and observations. However, almost all models tend to overestimate Sea Ice Extent (SIE) in March compared to observations. Future scenarios show dramatic decrease in SIE as response to an increase in radiative forcing. The projected future sea ice loss is explained by the combined effects of both: the amplified warming in northern hemisphere and climate feedbacks. The quadrupling of CO2 concentration numerical experiment shows the amplified warming as response to CO2 forcing with strongest warming in winter and Autumn season. The interdisciplinar effects of Anthropogenic forcing in Arctic region still are considering a hot topic and lack conclusive answers.
Impact of Snow Salinity on CryoSat-2 Arctic Sea Ice Freeboard Measurements

Vishnu Nandan\textsuperscript{1} (vishnunandan.nandaku@ucalgary.ca), John Yackel\textsuperscript{1}, Torsten Geldsetzer\textsuperscript{1}, Mallik Mahmud\textsuperscript{1}
\textsuperscript{1}University of Calgary, Geography, Calgary, Canada

The European Space Agency's CryoSat-2 satellite radar altimeter mission provides sea ice freeboard data that are used to derive estimates of sea ice thickness and volume. These data are crucial to understanding recent variability and changes in Arctic sea ice. Sea ice thickness retrievals at the CryoSat-2 frequency require accurate measurements of sea ice freeboard, assumed to be attainable when the main radar scattering horizon originates at the snow/seas ice interface. Using an extensive snow thermophysical property dataset from late winter conditions in the Canadian Arctic, we examine the role of saline snow on first-year sea ice (FYI), with respect to its impact on the location of the main radar scattering horizon, its potential ability to decrease radar penetration depth, and its subsequent impact on FYI thickness estimates. Based on the dielectric properties of saline snow commonly found on FYI, we quantify the vertical shift in the CryoSat-2 main scattering horizon. This is found to be approximately 0.07 m. We propose a thickness-dependent snow salinity correction factor for FYI freeboard estimates. This significantly reduces CryoSat-2 FYI thickness retrieval error. Relative error reductions of ~ 11% are found for an ice thickness of 0.95 m and ~ 25% for 0.7 m. Our method also helps to close the uncertainty gap between SMOS and CryoSat-2 thin ice thickness retrievals. Our results demonstrate that snow salinity should be considered for FYI freeboard estimates.
Retrieving Sea Ice Surface Elevation and Total Freeboard from MABEL Data

Xiaoyan Wang¹ (wangxiaoy@lzu.edu.cn), Hongjie Xie², Alberto M. Mestas-Nuñez², Stephen F. Ackley²
¹Lanzhou University, Lanzhou, China, ²University of Texas at San Antonio, San Antonio, United States

Multiple Altimeter Beam Experimental Lidar (MABEL), the simulator of NASA’s Ice, Cloud and land Elevation Satellite-2 (ICESat-2) to be launched in 2018, is the first of its kind to use a photon-counting technique for mapping ice surface elevation. In this paper, we will present the MABEL dataset collected over sea ice off Greenland (northwest, north, and northeast), describe its data processing, and discuss an application to the retrieval of sea ice elevation and sea ice total freeboard. The signal photons are first separated from noise photons using a histogram-based surface-finding algorithm provided by NASA. The resulting signal photons are then low-pass filtered with three different methods (Gaussian, Wavelet, and LOESS) to estimate the ice surface elevation. The Wavelet method seems to give better results than the other two. The open water/lead along the track are discriminated solely on the different photon numbers of signal and background, with open water/lead usually having much smaller number of signal and background photons than other surfaces. The total freeboard values of ice floe are then retrieved as the difference of surface elevation and water/lead elevation, after the correction of mean sea surface height is applied. It is expected that the data analysis procedures developed for MABEL data will serve as a guide for data processing and applications of ICESat-2 data.
Snowmelt processes on sea ice are the key drivers determining the seasonal sea-ice energy and mass budgets. While there is strong surface melt on Arctic sea ice, snowmelt on Antarctic sea ice is weak with most snow surviving the summer. Here, we compile time series of snowmelt onset dates on perennial Antarctic sea ice from 1992 to 2014 using active microwave observations from European Remote Sensing Satellite (ERS-1/2), Quick Scatterometer (QSCAT) and Advanced Scatterometer (ASCAT) radar scatterometers. Describing snowmelt processes, we define two transition stages: A weak backscatter rise indicating the initial warming and metamorphosis of the snowpack (pre-melt), followed by a rapid rise indicating the onset of thaw-freeze cycles (snowmelt). Results show large interannual variability with average pre-melt and snowmelt onset dates of 29 November and 10 December, respectively, without any significant trends over the study period. Related to different signal frequencies, we show that QSCAT Ku-band (13.4 GHz signal frequency) derived pre-melt and snowmelt onset dates are earlier by 25 and 11 days, respectively, than ERS and ASCAT C-band (5.6 GHz) derived dates. This offset has been considered when constructing the time series. As different signal frequencies result in different penetration depths, we hypothesize that the different sensors respond to typical snowmelt processes in different depths within the snow cover.
The austral autumn sea ice cruise to the Ross Sea and Terra Nova Bay under the research project PIPERS (Polynyas, Ice Production and Seasonal Evolution in the Ross Sea) presented extraordinary opportunities to acquire co-located SARS imagery and terrestrial laser (LiDAR) scans of the sea ice surface during autumn freeze-up conditions. Numerous sites, representing mixed first-year ice types (nilas, consolidated pancakes, and ridged first year) were laser scanned at sub-centimeter scale using a Riegl VZ-1000 LiDAR scanner in both on-the-ice surveys from multiple scan positions and single-position scans from the high vantage point of the ship’s (N.B. Palmer) bridge wing. Scans generally encompassed areas of at least 100m x 100m with sufficient point cloud returns to generate surface topography rasters at better than 5 cm resolution. SAR data from two high-resolution polar orbiting satellites (TerraSAR-X and Sentinel 1) were co-spatial and co-temporally acquired of the LiDAR survey sites. We present comparisons of raw backscatter, entropy, and roughness parameters from the polarimetric SAR data for direct comparison to sea ice topography and elevation-derived surface roughness parameters. Very thin or non-existent snow cover during the cruise period will negate some of the problematic volume scattering seen in other SAR imagery, and allow better interpretation of the backscatter signal from this imagery in terms of ice type.
Snow Cover Observations on Antarctic Sea Ice from in-situ and Model Studies

Leonard Rossmann\textsuperscript{1} (leonard.rossmann@awi.de), Marcel Nicolaus\textsuperscript{1}, Michael Lehning\textsuperscript{2,3}, Stefani Arndt\textsuperscript{1}, Nina Maaß\textsuperscript{4}, Lars Kaleschke\textsuperscript{4}, Nander Wever\textsuperscript{2}, Christian Haas\textsuperscript{1}

\textsuperscript{1}Alfred Wegener Institute, Bremerhaven, Germany, \textsuperscript{2}WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland, \textsuperscript{3}École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland, \textsuperscript{4}Universität Hamburg, ZMAW, Hamburg, Germany

The snow cover on Antarctic sea ice impacts the energy, mass, and momentum balance of the sea ice cover. This strongly influences fluxes between ocean, sea ice, and atmosphere. The snow depth is qualified as an Essential Climate Variable, whereas the knowledge of the snow cover distribution and properties is still mostly vague and no large-scale snow depth data product is available. The Snow cover is characterized through a high spatial and temporal variability, and shows a highly heterogeneous internal stratification. This poses a challenge to air or space borne snow depth retrieval algorithms. Similarly, sea ice models are not yet able to resolve snow processes with enough accuracy.

Here we present measurements of snow depth and physical snow properties along drift trajectories of autonomous Snow Buoys, which were deployed in the Weddell Sea since 2014. Resulting time series of snow depth show an event driven snow accumulation even during austral summer, whereas melting and a significant decrease of snow depth is only observed along the marginal sea ice zone. Additional analysis with the 1D multi-layer thermodynamic snow model SNOWPACK provides insights into internal processes such as snow to ice development. For these studies the previous land-based snow model SNOWPACK has been extended with a sea ice module and is forced with re-analysis data. Comparisons between model and in-situ measurements show the capability of the model to reproduce the prevalent snow stratigraphy.
Snow Depth Efficacy on the Retrieval of Arctic Sea Ice Thickness and Volume

Lu Zhou¹ (zhou-l15@mails.tsinghua.edu.cn), Shiming Xu¹, Jiping Liu²
¹Tsinghua University, Beijing, China, ²State University of New York at Albany, Albany, United States

Accurate understanding of snow loading and snow depth is crucial to sea ice thickness and volume retrieval from satellite altimetry. This study accesses the efficacy of snow depth data in both radar and laser altimetry using high resolution airborne OIB observation for 2010-2016. In addition, three reanalysis datasets (ERA-Interim, JRA-55 and MERRA-2) are adopted to investigate long term changes in the snow loading and accumulation speed. We also review inter-annual variability of snow loading both from climatology and observations in the recent decade. Although there is potential for the retrieval of sea ice thickness distribution (ITD) with current satellite data due to their high spatial resolution, the retrieval in state of the art methods are compromised due to the lack of fine-scale snow depth and the covariability between snow depth and freeboard, which has profound influence on the thickest part of basin-scale ITD. The effects are more prominent in laser altimetry (ICESat). These results show that there exists lack of efficacy of existing snow loading and snow depth data for satellite altimetry, and small-scale variability plays an important role in retrieval for both types of altimetry.
Snow Metamorphism at the Interface between Ice and Snow

Mareike Wiese¹ (mareike.wiese@slf.ch), Martin Schneebeli¹
¹WSL Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland

Temperature gradient snow metamorphism at the interface between ice and overlying snow shows a strongly different evolution compared to the structural evolution in the bulk snowpack under the same mean temperature gradient. We demonstrate that a positive temperature gradient leads to the formation of a new interfacial snow layer caused by the sublimation of the ice. We measured these processes by time-lapse micro-tomography. Numerical simulations show a strong horizontal variability of the temperature gradient at the sub-millimeter scale. This explains the macroscopically observed “enhanced” temperature gradient at such interfaces. We conclude that this process is relevant for the evolution of the energy balance of a snowpack on ice, but also for the chemical properties of the snowpack.
Retrieval of Snow Depth on Sea Ice from FY3B MWRI in the Arctic

Lele Li1 (lilele@ouc.edu.cn), Haihua Chen1, Lei Guan1
1Ocean University of China, Qingdao, China

Given the high albedo and low thermal conductivity, snow on sea ice is regarded as one of the key reasons for the amplification of the warming in polar regions. This study focused on the retrieval of snow depth on sea ice from brightness temperatures of the Microwave Radiation Imager (MWRI) on board the FengYun (FY)-3B satellite during the period from December 1, 2010 to April 30, 2011. After cross calibrated to the Advanced Microwave Scanning Radiometer-EOS (AMSR-E) Level 2A data, the MWRI brightness temperatures were applied to calculate the sea ice concentrations based on the Arctic Radiation and Turbulence Interaction Study Sea Ice (ASI) algorithm. The snow depths were derived according to the proportional relationship between the snow depth and the surface scattering in 18.7 and 36.5 GHz. In order to eliminate the influence of uncertainties in grain sizes of snow as well as sporadic weather effects, the seven-day averaged snow depths were calculated. Then the results were compared with the snow depths from two data sets: IceBridge ICDS4 data set and the AMSR-E Level 3 Sea Ice products. The bias and standard deviation of differences between the MWRI snow depth and the IceBridge data are 3.34 cm and 2.79 cm for a total of 52 matchups, respectively. And the biases between the MWRI and the AMSR-E Level 3 products are ranged between -1.09 and -0.32 cm. It is proved that the method taken in this study is feasible and the results are reasonable.
Snow depth on Arctic sea ice is one of the key parameters to describe and understand changes in the Arctic climate. Due to its low thermal conductivity, snow strongly influences the growth and melt of Arctic sea ice. Snow has a high albedo and is therefore important for the Arctic energy budget. Sea ice thickness retrievals from altimetry rely on accurate snow depth and density estimations.

Observations from satellite radiometers provide a great tool to monitor the Arctic region on a daily and Arctic-wide scale. The first retrieval for snow depth on sea ice was developed by Marcus and Cavalieri and is based on passive microwave satellite observations at 19 and 37 GHz. However, in the Arctic, the retrieval is limited to seasonal ice and snow depths below 50 cm. In addition, rough ice and snow metamorphism can strongly influence the retrieval.

In this study, a new retrieval for snow on Arctic sea ice is derived using multiple AMSR-E/2 frequency combinations. The retrieval is trained with airborne snow depth measurements obtained from the NASA Operation IceBridge campaigns. First results indicate a good performance of the retrieval over seasonal ice and a reasonable performance over multiyear ice. In a study with the Microwave Emission Model MEMLS, the theoretical influences of different snow and ice properties on the retrieval are investigated using in situ measurements from the N-ICE2015 campaign. Additionally, the effects of salty snow and snow metamorphism are analyzed.
The snow layer on top of the sea ice plays an important role in the retrieval of ice freeboard and thickness from satellite altimeter data. In situ observations of the snow layer are needed as input to the retrieval algorithms and for validation of the resulting thickness estimates. In this study, snow data from the Soviet airborne expeditions Sever have been analyzed for the period 1959-1986, combined with data from the North Pole Drifting stations, in order to estimate the snow depth climatology for March, April, and May. The data covers the essential parts of the Arctic sea ice areas, with most data in the Eurasian seas. The following snow parameters have been analyzed: average snow depth on the level ice, height, and area of sastrugi, depth of snow dunes attached to ice ridges, and depth of snow on hummocks. The research resulted in a new snow depth climatology for the winter months, showing lower values compared to the Warren climatology in the central Arctic and more detailed estimates for the Eurasian seas. The analysis of the Sever data showed that the average depth of undisturbed snow on the level ice varied from 9.8 cm in the Laptev Sea to 15.3 cm in the East Siberian Sea. The highest values in the East Siberian Sea are explained by the larger proportion of multiyear ice which generally has thicker snow layer than first-year ice. The new climatology of snow depth will be a useful reference data against which new observations can be compared.
Deformed ice and Level Ice Distinction from Dual-polarized Sentinel-1

Tingting Zhu¹, Fei Li¹,² (fli@whu.edu.cn), Yu Zhang³, Shengkai Zhang³, Gunnar Spreen⁴, Georg Heygster⁴, Wolfgang Dierking⁵
¹Wuhan University, Collaborative Innovation Center for Territorial Sovereignty and Maritime Rights, Wuhan, China, ²Wuhan University, The State Key Laboratory for Information Engineering in Surveying, Mapping and Remote Sensing, Wuhan, China, ³Wuhan University, Chinese Antarctic Center of Surveying and Mapping, Wuhan, China, ⁴University of Bremen, Institute of Environmental Physics, Bremen, Germany, ⁵AWI, Bremerhaven, Germany

SAR is the most promising technique for observing sea ice conditions in polar regions due to its all-weather and all-day availability. Sea ice consists of level and deformed ice floes covering the polar sea zone. It is significant to understand the relationships between deformed ice and thickness redistribution when Arctic sea ice thinning since deformed ice including ridges and brash ice over first year and multiyear ice dominates Arctic surface topography, which alludes to importance of ice deformation distribution in the total ice volume. Although different scattering mechanisms of deformed ice and level ice provide the proxy for sea ice type distinction, level ice and deformed ice distinction can only rely on SAR backscatter intensity from Sentinel-1. An operational algorithm is developed in combination with rich features to capture texture pattern of deformed ice and level ice. The rich features to depict the deformation ice pattern including ridges, brash ice and rubble surface field include ridging density, deformation pattern geometry characteristic, GLCM texture and surface roughness. We focus on Fram Strait, where is a faster export of sea ice allowing larger drifting speed and deformation using Sentinel-1 dual polarization data from October, 2014 to October, 2017 for ice deformation identification based on the SVM by feeding rich features. The deformation distribution will be used to retrieve snow depth over sea ice with different roughness surface.
Brightness temperatures (TB) observed by satellite microwave radiometers allow us to retrieve the sea-ice area fraction (sea-ice concentration or SIC) with an accuracy of ~ 2% during winter. The accuracy during the melting season is unknown. Once melting of the snow cover on sea ice commences, TBs change - first due to the snow wetness and/or an elevated snow grain size due to melt-refreeze cycles, later due to the formation of melt ponds, i.e. puddles of melt water on the snow or ice surface. Because the penetration depth of microwave radiation into liquid water is about a few millimeters, melt ponds have the same radiometric signature as open water in leads and openings between ice floes. Consequently, SIC retrieved over sea ice covered with melt ponds should represent the net ice surface fraction (ISF). Here we show results of our analysis of the joint EUMETSAT OSISAF - ESA CCI SIC data products. Time-series of SIC suggest an increase in fractions of SIC near 100% during early melt (May/June) indicative of the impact of wet snow. Inter-comparison with melt-pond fraction (MPF), 1 minus open-water fraction from leads and openings (SIC_M), and ISF derived from MODIS optical data reveals an overall negative bias between SIC and SIC_M of only ~1%. However, from a more detailed analysis we find regional biases between SIC and SIC_M ranging from -20% to +10%. We also find that SIC exceeds ISF by up to 35%; this over-estimation often but not always equals the MPF.
Studying a Full Year of Snow on Arctic Sea Ice - Plans for MOSAiC 2019/20

Marcel Nicolaus¹ (marcel.nicolaus@awi.de), Sebastian Gerland², Donald K. Perovich³
¹Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, ²Norwegian Polar Institute, Fram Centre, Tromso, Norway, ³Dartmouth College, Hanover, United States

The snow cover on sea ice dominates many exchange processes and properties of the ice covered polar oceans. While it is known for its extraordinarily large spatial and temporal variability, snow properties and even snow depth distributions are among the least known and most difficult to observe climate variables. Starting in autumn 2019 and ending in autumn 2020, the international MOSAiC drift experiment will allow to observe the evolution of a snow pack on Arctic sea ice over a full annual cycle. During the drift with one ice floe along the transpolar drift, we will be able to perform most comprehensive studies on seasonal sea ice and relate them to previous expeditions and parallel observations at different locations. Here we present the current status of our planning of the MOSAiC snow program. The field program will include regular manual observations and sampling on the main floe of the central observatory, autonomous recordings in a distributed network, airborne observations in the surrounding, and retrievals of satellite remote sensing products. Along with the field program, numerical simulations of the MOSAiC snow cover will be performed on different scales, including large-scale interaction with the atmosphere and the sea ice. The snow studies will also bridge between the different disciplines, including physical, chemical, biological, and biogeochemical measurements, samples, and fluxes.
Impact of Sea Ice Thickness and Freeboard Products on Forecast Performance

Thomas Kaminski¹ (thomas.kaminski@inversion-lab.com), Frank Kauker²,³, Leif Toudal Pedersen⁴,⁵, Michael Vossbeck⁶, Helmuth Haak⁷, Laura Niederdrenk⁷, Stefan Hendricks³, Robert Ricker³, Michael Karcher²,³, Haijo Eicken⁸, Ola Grabak⁹

The A+5 project of ESA’s Arctic+ initiative has constructed a flexible system for Arctic Mission Benefit Analysis (ArcMBA) that evaluates in a mathematically rigorous fashion the observational constraints imposed by individual and groups of EO data products in using the quantitative network design (QND) approach. The assessment of the observation impact (added value) is performed in terms of the uncertainty reduction in a four-week forecast of sea ice and snow volumes for three regions along the Northern Sea Route. The assessments covered seven EO products, three real products and four hypothetical products. The real products are monthly sea ice thickness (SIT), sea ice freeboard (SIFB), and radar freeboard (RFB), all derived from CryoSat-2 by AWI. These are complemented by two hypothetical laser freeboard products and two hypothetical snow depth products.

On the basis of the per-pixel uncertainty ranges that are provided with the CryoSat-2 products, the SIT achieves the best performance for SIV forecasts. For SNV, the performance of RFB is better. A hypothetical laser freeboard (LFB) product with low accuracy has a similar impact as RFB on both SIV and SNV. A reduction in the uncertainty of the LFB product yields a significant increase in performance.

Combining with a hypothetical snow depth product achieves a significant performance.
Variability in thickness, density and emissivity of snow on sea ice is a major limiting factor for the accuracy of sea ice thickness retrievals from laser and radar altimetry as well as for ice concentration retrievals from microwave radiometer measurements. In addition, snow plays a significant role in sea ice thermodynamics by limiting sea ice growth rates due to its strong insulating effect.

In this study, we have compared a number of datasets for snow on sea ice obtained from operational ice/ocean models, climate models and remote sensing observations. We have compared the snow thicknesses obtained by the different methods to radar snow depth measurements from NASAs Operation Ice Bridge (OIB) and we find significant differences between models as well as between observation datasets.
Sea Ice Concentration Observed Low Microwave Frequency Radiometers

Carolina Gabarro, Mukesh Gupta, Justino Martinez, Antonio Turiel

Institute of Marine Research ICM-CSIC, BEC, Barcelona, Spain

The launch of the Soil Moisture and Ocean Salinity (SMOS) mission, in 2009, marked the dawn of a new type of space-based microwave observations. Although the mission was originally conceived for hydrological and oceanographic studies, SMOS is also making inroads in the cryospheric sciences by measuring the thin ice thickness. SMOS carries an L-band (1.4 GHz), passive interferometric radiometer (the so-called MIRAS) that measures the electromagnetic radiation emitted by the Earth's surface, at about 50 km spatial resolution, continuous multi-angle viewing, large wide swath (1200-km), and with a 3-day revisit time at the equator, but more frequently at the poles. AMSR-2 instrument is on JAXA’s GCOM-W1 spacecraft, and was launched on 2012. AMSR-2 have radiometers working at several bands: 6.9, 7.3, 10.65, 18.7, 23.8, 36.5, and 89.0 GHz. An assessment on the differences on the sea ice concentration (SIC) maps obtained from low microwave frequencies radiometers, 6.9GHz (from AMSR-2) and SMOS, versus higher frequency (19Ghz and 37GHz) radiometers are presented. Despite its lower spatial resolution relative higher frequencies, SMOS-derived SIC products are little affected by the atmosphere and the snow (almost transparent at L-band). Moreover L-band measurements are more robust in front of the accelerated metamorphosis and melt processes during summer affecting the ice surface fraction measurements.
As a consequence of a general thinning of Arctic sea ice the snow depth to sea-ice thickness ratio is increasing. At some point, this will result in more widespread negative freeboard in parts of the Arctic, where the snow depth at a given time in a season stays constant or increases. These areas could potentially be flooded in case of mechanical breaking of ice due to deformation or when sea ice becomes permeable. Flooding of sea ice can create new habitats for snow infiltrating phytoplankton communities. Flooding also effects remote sensing applications, like radar based sea-ice thickness retrievals from CryoSat-2, by biasing the retrieved sea ice thickness towards higher values. In colder months this flooded layer will freeze, creating snow-ice. Snow-ice formation will release additional heat from the ocean to the atmosphere and contribute to the sea-ice mass balance. These processes are widespread on seasonal sea ice in Antarctica. However, recent studies show a significant occurrence of snow-ice in the Arctic Ocean north of Svalbard in 2015, due to the high precipitation in this region compared with other parts of the Arctic. In this study we examine the potential of flooding and subsequent snow-ice formation in different regions of the Arctic Ocean with respect to inter-annual variability of snow precipitation and sea-ice thickness, by using a 1D-snow/ice thermodynamic model forced with sea ice drift and reanalysis data.
Snow cover on Arctic sea ice is crucial to the global climate system through snow-ice albedo feedback mechanism. In order to solve the issue of lacking of snow depth information on Arctic sea ice at a large spatial scale, we constructed the snow depth model using the Ice Mass Balance buoys measurements in the Arctic, compared with previous snow depth model, and analyzed the variation of monthly average snow depth on the Arctic sea ice. The results show that the snow depth model built up in this paper efficiently reflects the distribution of snow depth on Arctic sea ice, with the bias varies from -0.3 to 1.0cm, and -5% to 12% for mean relative error. Monthly average snow depth calculated from the model indicates that the snow depth on the Arctic sea ice rose gently from January to March, and stabilized in April and May, continued to decrease from June to July and fell to the minimum in August. In September and October, the snow depth increased rapidly in the Canadian Arctic Archipelago and Northern Greenland. The snow depth model constructed in this paper can provide basic information and reference for the study of sea ice and global climate change.
In this contribution, the authors consider snow not as a (suite of) parameter(s) to be measured, but as an impediment to the accurate retrieval of Sea Ice Concentration (SIC) and Type (SIType) from space-borne Passive Microwave Radiometers (PMR). In the Arctic winter the accuracy of SIC and SIType retrieval algorithms is at present limited by the lack of knowledge of snow characteristics such as depth, grain size, wetness, density, layering and emissivity. State-of-the-art SIC algorithms allow retrieval uncertainties in the order of 3-5% (1-sigma), but should aim to 0.5-1% to really be useful for constraining the heat fluxes through cracks and leads.

We investigate the patterns of the noise observed in the recent EUMETSAT OSI SAF and ESA CCI SIC data records, and link these to snow and upper sea ice properties. We also use emission models to illustrate how snow contributes to the inaccuracies of SIC algorithms, and how the impact differs between the algorithms. Inaccurate first-year/multi-year sea ice classification due to snow is also investigated in the Copernicus Climate Change (C3S) sea ice type data record. We show how lack of knowledge of the snow parameters propagates as non-white noise for the retrieval of SIC and SIType.

Finally, we show results from early attempts to either mitigate the influence of snow in the SIC algorithms, or to jointly retrieve concentration, type, and snow parameters from multi-channels PMR such as the JAXA’s AMSR2.
About a Way to Improve Snow-depth Retrieval for Antarctic Sea Ice

Burcu Ozsoy¹ (ozsoybu@gmail.com), Stefan Kern²
¹Istanbul Technical University, Polar Research Center, Istanbul, Turkey, ²University of Hamburg, Integrated Climate Data Center - ICDC, Hamburg, Germany

Snow on Antarctic sea ice is known for its large spatiotemporal variability. High cyclone activity causes a deeper snow cover in the Antarctica. Physical properties like density, grain size, liquid water content, and salinity are more diverse comparing to Arctic. This provides big challenges for the retrieval of sea ice concentration and sea ice thickness from satellite observations. Particularly there is still an accurate data set of snow depth on sea ice needed.

Satellite microwave radiometry (MWR) permits to retrieve snow depth on sea ice on hemispheric scale. Several studies demonstrated, however, that these snow depth estimates are biased depending on various snow and sea-ice properties. One of these is surface roughness. Combination of satellite MWR with surface roughness information from altimetry was shown to mitigate this bias. We elaborated on this approach and combine the along-track variability of total (sea ice and snow) freeboard estimates from ICESat laser altimeter observations with the classic approach to compute snow depth because such surface roughness data is not available for the entire satellite MWR. Therefore, we analyze a unique data set of ICESat roughness, satellite scatterometer data, satellite microwave brightness temperatures (other than those used in the classic retrieval), meteorological data from reanalysis, and ship-based observations of sea ice and snow properties to find a proxy for the surface roughness.
Snow cover is a common and important feature in polar regions. It strongly affects the radiative transfer of Arctic sea ice by increasing its reflectance and drastically reducing the amount of light reaching the water column. As a consequence, the snow layer plays a crucial role with ocean primary production which is mainly light limited before the onset of melt. Observing snow properties and sea ice optics is thus a fundamental key to a better understanding of the links between snow and ocean biology.

Intensive snow samplings, covering the entire melt season, were conducted during GreenEdge campaigns in 2015 and 2016 over landfast sea ice near Qikiqtarjuaq community in Baffin Island. Optical properties such as albedo, vertical profile of irradiance in snow and transmittance through the ice were measured as well as physical properties including stratigraphy observations and vertical profiles of snow density and snow specific surface area.

Based on these observations, the melt season can be divided in four main phases with very different signatures in albedo spectra as a consequence of snow metamorphism. Among all parameters, snow height was the main factor controlling transmittance. An ice algae bloom was observed in 2015, and its intensity depended on the snow history which was derived from the vertical profile of snow physical properties. The onset of melting marked the end of this bloom.

Improving Observations and Understanding of Snow on Arctic Sea Ice: ESA Arctic+

Michel Tsamados1 (m.tsamados@ucl.ac.uk)
1University College London, London, United Kingdom

Only satellite remote sensing can provide the pan-Arctic view required to fully understand changes to the Earth’s sea ice fields but important observational gaps remain which limit both our interpretation of remote-sensing data and our understanding of the Arctic climate system. In that regard, snow on sea ice represents both a major source of uncertainty in sea ice concentration and thickness retrievals from satellite data, and a poorly resolved quantity of climatic importance. The overarching objective of this proposal is to address these issues and to produce a state of the art now on sea ice thickness and density product. To achieve this goal we will use data from the most advanced and recent EO missions.

We will utilize a comprehensive array of airborne and in-situ snow measurements to develop and validate two independent approaches to snow thickness retrieval on Arctic sea ice. In the Dual-altimeter Snow Thickness (DuST) product, we will utilize data from multiple contemporary satellite altimeters to derive information about the snow layer. In the Snow on Drifting Sea Ice (SnoDSI) product we will utilize satellite-derived sea ice drift and precipitation from atmospheric reanalysis to build a package that accumulates, redistributes and melts snow on individually tracked ice parcels at daily resolution. Because of the impact of the snow thickness and density estimates for sea ice thickness retrievals this proposal will feed in the Arctic+ Theme 2: Sea Ice Mass project.
The high albedo and low heat conductivity of snow on sea ice strongly influence polar radiative processes and heat transfer, needed for climate and numerical weather prediction models. Furthermore, accurate snow depth data are required to retrieve sea ice thickness from altimeter freeboard measurements. Only passive microwave sensors on satellites offer the possibility to continuously retrieve snow depth on Antarctic scale independent of daylight and cloud cover. However, in the Antarctic specific processes (flooding, melting and refreezing) together with sea ice ridges and leads cause highly variable snow properties so that often the accuracy of the retrieved snow depth is not known.

Here the empirical snow-depth retrieval algorithm by Markus and Cavalieri (1998), later adapted to AMSR-E (Advanced Microwave Scanning Radiometer for EOS) data by conversion of AMSR-E brightness temperatures to SSM/I equivalent brightness temperatures (Comiso et al., 2003, Brucker and Markus, 2013) is re-calibrated using visual ship-based observations from an extended ASPeCt data set (Worby and Allison, 1999, Worby et al., 2008) on a monthly basis and by Antarctic sectors so that the resulting algorithm is directly applicable. A data set for the years 2002-2017 will be presented together with a physical analysis of monthly average snow depths sea ice concentration and air temperature, as well as their trends and correlations.
Several processes have been hypothesized to explain the slight overall expansion of Antarctic sea ice over the satellite observation era, including externally forced changes in local winds or in the Southern Ocean’s hydrological cycle, as well as internal climate variability. Here, we show the critical influence of an ocean-sea-ice feedback. Once initiated by an external perturbation, it may be sufficient to sustain the observed sea-ice expansion in the Ross Sea, the region with the largest and most significant expansion. We quantify the heat trapped at the base of the ocean mixed layer and demonstrate that it is of the same order of magnitude as the latent heat storage due to the long-term changes in sea-ice volume. The evidence thus suggests that the recent ice coverage increase in the Ross Sea could have been achieved through a reorganization of energy within the near-surface ice-ocean system.
Holocene Sea Ice Variability Driven by Wind and Polynya Efficency in Ross Sea

Karin Mezgec¹, Barbara Stenni¹, Xavier Crosta³, Valerie Masson-Delmotte⁴, Carlo Baroni⁵, Martina Braida⁶, Virginia Ciardini⁷, Ester Colizza⁶, Romana Melis⁶, Maria Cristina Salvatore⁵, Mirko Severi⁶, Claudio Scarchilli⁷, Rita Traversi⁶, Roberto Udisti⁸, Massimo Frezzotti⁷ (massimo.frezzotti@enea.it)
¹University of Siena, Department of Physical Sciences, Earth and Environment, Siena, Italy, ²Ca' Foscari University of Venice, Department of Environmental Sciences, Informatics e Statistics, Venice, Italy, ³Université de Bordeaux, UMR-CNRS 5805 EP, Pessac cédex, France, ⁴Université Paris Saclay, LSCE (CEA-CNRS-UVSQ/IPSL), Paris, France, ⁵University of Pisa, Department of Earth Sciences, Pisa, Italy, ⁶University of Trieste, Department of Mathematics and Geosciences, Trieste, Italy, ⁷ENEA, Roma, Italy, ⁸University of Florence, Department of Chemistry “Ugo Schiff”, Florence, Italy

The causes of the recent increase in Antarctic sea ice extent, characterised by large regional contrasts and decadal variations, remain unclear. In the Ross Sea, where such a sea ice increase is reported, 50% of the sea ice is produced within wind-sustained latent-heat polynyas. Combining information from marine diatom records and sea-salt sodium and water isotope ice core records, we here document contrasting patterns in sea ice variations between coastal and open sea areas in Western Ross Sea over the current interglacial period. Since about 3600 years Before Present, an increase in the efficiency of regional latent-heat polynyas resulted in more coastal sea ice, while sea ice extent decreased overall. These past changes coincide with remarkable optima or minima in the abundances of penguins, silverfish and seal remains, confirming the high sensitivity of marine ecosystems to environmental and especially coastal sea ice conditions.
Sea-ice Production in Arctic Polynyas between 2002 and 2017

Andreas Preußer1 (preusser@uni-trier.de), Sascha Willmes1, Kay I. Ohshima2, Günther Heinemann1
1University of Trier, Environmental Meteorology, Trier, Germany, 2Institute of Low Temperature Science, Hokkaido University, Ocean and Sea Ice Dynamics, Sapporo, Japan

In this study, a high-resolution (2 km) MODIS thermal infrared satellite data set featuring spatial and temporal characteristics of 17 Arctic polynya regions is presented for winter seasons 2002/2003 to 2016/2017. The data set features the most recent updates of the employed MOD/MYD29 sea ice product (Col. 6) which includes improvements to the cloud masking and land/ocean separation. Thin-ice thickness distributions are calculated from MODIS ice-surface temperatures, combined with ECMWF ERA-Interim atmospheric reanalysis data in an energy balance model. Daily thin-ice thickness composites are subsequently computed. A gap-filling approach is applied to account for clouds and missing data in the thermal infrared imagery. The most recent winter season in the data set (2016/17) features the so far highest annual sea-ice production with a volume of 2258 km³, presumably originating from highly active polynyas throughout the eastern Arctic and/or a particularly thin and less extensive wintertime sea-ice coverage that season. Thin-ice thicknesses from an AMSR-E passive microwave data set are used to evaluate and quantify sensor-specific capabilities and error sources for a large-scale pan-Arctic polynya monitoring. Despite obvious differences, such as the acquired signal at the sensor, varying spatial resolutions or the individual sensitivity for cloud cover, both data sets are coherent in terms of capturing the general properties of Arctic polynyas for an overlapping 9-yr period.
The Impact of Snowmelt on the Arctic Ocean Heat Budget

George Duffy¹ (george.a.duffy@vanderbilt.edu), Ralf Bennartz¹
¹Vanderbilt University, Earth and Environmental Sciences, Nashville, United States

The ocean surface heat flux is typically calculated from the sum of longwave radiation, shortwave radiation, sensible heat flux, and evaporative heat flux. In polar oceans, an additional heat sink may also arise through the melting of snowfall. In this study, we use Cloudsat measurements and ECMWF-ERA interim reanalysis to quantify the impacts of snowmelt in the Arctic Ocean. Focusing on the freeze-up season, we find that the cooling from snowmelt can provide a cooling in the order of 1-10% of the net ocean heat flux on month-long time scales. During heavy snowstorms, the cooling from snowmelt may represent the dominating factor in oceanic heat flux.
The aim of the COMBINISO project is to disentangle the different influences on the water isotope composition on the East Antarctic plateau to provide more faithful reconstruction of climate and water source origin from the snow cores over the last decades. A wealth of isotopic measurements have been acquired at the continuum between surface snow, subsurface snow and atmosphere mainly at the Dome C station showing how precipitation, temperature and metamorphism influences the snow surface isotopic composition. In parallel, a huge modeling effort have been deployed both at the global scale and at the local scale by (1) implementing tritium in the atmospheric model equipped with stable water isotopes LMDZ-iso and (2) implementing water vapor transport and water stable isotopes in the snowpack model CROCUS. Finally, an array of snow cores analyzed at different Antarctic stations are interpreted together with modeling outputs to provide insight on the recent evolution of climate and moisture source, including stratospheric input in very dry regions of the East Antarctic plateau.
Strengthened Circumpolar Deep Water (CDW) intrusion into shelf region around Antarctic can increase oceanic heat supply on the shelf, enhancing ice shelf basal melt and suppressing sea ice production synchronously. In Prydz Bay, highly modified CDW (mCDW) upwells to subsurface in the southeastern embayment, where relative warm mCDW inflow encounters with extremely cold denser shelf water. Strengthened convection during ice freezing season extends to as deep as 300 m, bringing the upwelled warm water to surface. Accumulated upward heat supply through convection from intermediate mCDW to surface during March-August is estimated at $3.9 \times 10^{15}$ kJ, which can reduce sea ice production by 12.7 km$^3$, approximate half of the ice production volume in Davis Polynya. This study highlights the potential reversal of sea ice increasing trend in the southern ocean and further hindering of dense shelf water formation around Antarctic due to strengthened intrusion of CDW.
Submarine melt of the Greenland Ice sheet (GrIS) is significantly contributing to the accelerating mass loss of GrIS. When this additional freshwater flows into the central Labrador Sea, the vertical density stratification could increase and weaken deep convection, and thus the meridional overturning circulation. How much submarine melt water (SMW) reaches the convection region and where it leaves the Greenland Boundary Current is up to now uncertain. Helium and Neon isotopes are unique tools to identify and quantify the fraction of SMW in the ocean down to fractions of 0.05%. Here we present SMW distributions from hydrographic and noble gas measurements in the Greenland Boundary Current and the Labrador Sea form historical data and samples taken in summer 2015.
In polar regions, open water areas (e.g., polynyas) are regions of high production rates of new sea ice. If the wind is sufficiently strong, streaks of frazil ice tend to form on the sea surface. Observations show that the streaks have several remarkable features: their spacing is irregular; there are sharp boundaries between regions with high and low frazil concentration; neighboring streaks tend to merge into larger ones, but they never split. These features make the Langmuir circulation an unlikely explanation for the formation of frazil streaks. In this paper, we propose a model reproducing the overall behavior and evolution of frazil streaks, and we make an attempt to answer a question whether their formation is solely a result of upper-ocean turbulence, with ice crystals behaving as a passive tracer that accumulates in convergence zones, or, alternatively, whether the presence of ice itself affects the turbulence patterns in a way that further reinforces streak formation. Our results suggest that the second scenario is consistent with observations, and that growth rates of frazil clusters on the sea surface are enhanced by turbulence suppression within those clusters - which in turn is a consequence of enhanced viscosity in areas of high frazil concentration and lowered effective restitution coefficient between colliding crystals. This last property speeds up transition of frazil/grease ice into pancake ice, thus substantially influencing the evolution of the ice cover.
Deuterium excess is an important second order isotope parameter that has been widely used for paleoclimate reconstructions mainly of sea surface temperature but also of relative humidity. Deuterium excess is a particularly powerful tracer for moisture source properties, because it is intrinsically sensitive to non-equilibrium conditions occurring in unsaturated (i.e. strongly evaporative) environments and thus allows to quantify the deviation from thermodynamic equilibrium during phase changes. To first order, the deuterium excess of water vapour is conserved during transport and moderate rain out along an air parcel’s trajectory. On this poster, a robust process-based link is established between cold advection induced by the occurrence of cyclones and the interannual variability of precipitation deuterium excess at four stations of the Global Network of Isotopes in Precipitation (GNIP) in the North Atlantic. Positive anomalies of annual precipitation deuterium excess are found to be linked with positive anomalies of strong ocean evaporation in the moisture source region of the respective station’s precipitation. Furthermore, a strong signal is also detected in the occurrence frequencies of cyclones located to the northwest of the moisture source region. The possible implications of these results for the use of precipitation deuterium excess as a proxy for the location of the storm track are discussed.
Changes in Sea Ice Deformation and Impact of the Wind Forcing

Alexandra Kazlova\textsuperscript{1} (kazlova@uni-bremen.de), Gunnar Spreen\textsuperscript{1}
\textsuperscript{1University of Bremen, Bremen, Germany}

An increase in Arctic sea ice speed during recent decades by 10-15\% per decade has been observed from buoy and satellite observations. Higher resolution Synthetic Aperture Radar (SAR) observations are best suited for sea ice deformation retrieval, but they were not yet fully analysed for long-term ice deformation changes. How much the different components in the sea ice force balance have contributed to the observed changes in sea ice dynamics is not fully understood.

Sea ice motion fields from SAR observations can be used to obtain sea ice strain rates i.e. sea ice deformation fields. Currently, there is no SAR satellite sea ice deformation datasets covering the complete Arctic Basin available. The RGPS data mainly covers the Canadian Arctic region (1996-2008) and the ENVISAT dataset covers the European Arctic region (2007-2012). Since 2015 Sentinel-1 offers a better coverage of the Arctic basin. Available SAR datasets are analysed for the changes in space and time. Findings will contribute to better quantify the changes in Arctic sea ice dynamics and evaluate sea-ice models.

Observed sea ice deformation changes are compared to Atmospheric reanalysis to gain understanding of causes. On short time scale wind is the main driver of sea ice drift. Studies show that for most of the Arctic Basin changes in wind speed cannot explain the increase in sea ice drift speed. In this study we compare sea ice deformation fields from satellites to wind forcing from reanalysis to quantify their relation.
The Platelet-affected under-Ice Boundary Layer

Natalie Robinson1 (natalie.robinson@niwa.co.nz), Brett Grant1, Craig Stevens1,2, Ben Galton-Fenzi3
1National Institute for Water and Atmospheric Research, Marine Physics, Wellington, New Zealand, 2University of Auckland, Physics, Auckland, New Zealand, 3Antarctic Climate & Ecosystems CRC, Hobart, Australia

The influence of the ice shelf cavities on sea ice processes has not been quantified at any scale. Here we focus on processes in the upper ocean boundary layer in a region of Ice Shelf Water (ISW) outflow. Accumulations of platelet ice, up to several metres thick, form the physical boundary structure through most of the year in Western McMurdo Sound in the Ross Sea. Recent observations have revealed an amplified ocean response to the modified boundary in excess of 30 m deep. We interpret these observations as multiple modes contributing to effective drag of up to two orders of magnitude greater than is presently used in regional ocean models. Here we suggest quantifiable relationships between the upstream and ambient conditions; the thickness of the platelet layer; and the longevity of supercooled ISW front the calving front; which are intended to inform under-ice boundary layer parameterisations.
Albedo and Energy Balance of Melt Pond During Late Summer in the Central Arctic

Tao Li¹ (litaoocean@163.com), Jialiang Zhu¹
¹Ocean University of China, College of Oceanic and Atmospheric Sciences, Qingdao, China

In order to understand the thermodynamical process on the melt pond surface in the Arctic, in situ observations of the melt pond radiation have been carried out in the Central Arctic during the Chinese Arctic Surveys in 2012, 2014 and 2016. Based on the surface state of melt pond, we categorize the melt pond into five types: original melt pond (ORMP), water-ice covered melt pond (WIMP), thin snow covered melt pond (TSMP, snow depth is less than 1cm), moderate snow covered melt pond (MSMP, snow depth is between 1 to 2cm) and deep snow covered melt pond (DSMP, snow depth is more than 2cm). The albedos of the five types of melt pond are 0.1-0.2 for the ORMP, 0.2-0.35 for the WIMP, 0.35-0.55 for the TSMP, 0.55-0.8 for the MSMP and 0.8-0.95 for the DSMP. Moreover, the albedos of ORMP and WIMP decrease gradually with the increased depth of melt pond. On the contrary, the albedos of TSMP, MSMP and DSMP are not affected by the depth of melt pond but the covered ice thickness that increase the albedo with ice growing. During the late summer, solar shortwave radiation is still the main energy resource for the melt pond developing. The partitioning of solar radiation into the melt pond system has been calculated based on previous theory and in situ measurements. The covered ice cap has absorbed less than 5% of the solar radiation, while about 60% of them has been absorbed by the melt water and 35% by the underlying ice and ocean.
Sea ice change in the Southern Ocean and the Arctic Ocean influences the pollutant, gases and particles across the air/sea/ice interface and ultimately interactions and feedbacks with the climate and ecological system. One of the discoveries response to dynamic of sea ice in these regions is the mercury cycling. Atmospheric chemistry occurring on and above sea ice is found to destroy mercury in the marine boundary layer in the austral summertime, and increase or retreat of sea ice influences the air-sea exchange of mercury. A lot of saturated mercury in the seawater below the ice, and will be released with the ice melts. Such kinds of chemical and physical processes are important to understand and evaluate the risk of ecosystem exposed to this toxic element. Sea ice will also influence on the biological activities, which will contribute a substantial organic fraction of the atmospheric aerosol. The concentration of bacterium over the floating sea ice region was higher than found over the open sea areas. Temporal and spatial change in biological particles including primary organic aerosol, secondary organic aerosol and associated biogenic volatile compounds (e.g. isoprene, halocarbon, and DMS) for atmospheric processes and air/sea/ice interfaces are thus urgent to fully investigate. These results will provide constraint for model simulation of climate change in the regional scale.
Stable water isotopes (SWI) have been used as climate proxies for several decades. At the synoptic time-scale, SWI serve as tracers to investigate moist processes associated with weather systems. In this presentation, we link hourly signals of boundary layer vapour SWI with air-sea fluxes induced by the synoptic-scale flow. For this the measurements performed in the framework of the Antarctic Circumnavigation Expedition (ACE) are used. During this international campaign in the austral summer 2016/2017, SWI in atmospheric water vapour, precipitation and ocean surface waters were measured on board the Russian research vessel Akademik Tryoshnikov. Together with radio sonde profiles, radar observations and high-resolution humidity measurements a comprehensive data set is available to study the Southern Ocean fresh water cycle. In order to put the measurements in a spatial context, the SWI measurements are combined with operational analysis data of the European Centre for Medium-Range Weather Forecasts and simulations from the isotope-enabled regional numerical model COSMOiso.

Here we present two cases studies of one cold and one warm advection event, in which we highlight the relevant processes that influence the strongly contrasting SWI signatures associated with these events. A composite analysis of ~20 temperature advection events shows that cold, respectively warm advection, is associated with distinct SWI signatures of the near-surface water vapour.
Fri_264_OS-7_989
Surface Drag over Arctic Sea Ice: Direct Observations from an Icebreaker

John Prytherch¹ (john.prytherch@misu.su.se), Ian Brooks², Margaret Yelland³, Dom Salisbury⁴, Ben Moat³, Michael Tjernström¹
¹Stockholm University, Department of Meteorology, Stockholm, Sweden, ²University of Leeds, ICAS, Leeds, United Kingdom, ³National Oceanography Centre Southampton, Southampton, United Kingdom, ⁴ECMWF, Reading, United Kingdom

The surface drag, or roughness, over sea ice is prescribed in numerical weather prediction, climate and Earth system models in order to determine atmosphere-ice/ocean momentum exchange. There are few direct observations of surface drag available to develop drag parameterisations from. This is particularly the case for both the Marginal Ice Zone (MIZ), and for modern Arctic conditions.

Here we present direct eddy covariance and inertial dissipation estimates of surface momentum exchange obtained in the Arctic Ocean from the icebreaker Oden during two expeditions; the Arctic Clouds in Summer Experiment (ACSE) in 2014 and Arctic Ocean 2016. The extensive data set spans a range of surface conditions during the Arctic summer and autumn, with both melting and freezing periods, ice-free to ice-covered ocean with a large fraction of measurements within the MIZ, and 10-minute average winds up to 22 m/s.

The wind measurements are corrected for platform motion and for flow distortion using computational fluid dynamic modelling of the airflow over Oden. Surface conditions are characterised using ship-based digital imagery and infrared temperature sensors, as well as satellite-based estimates of sea ice concentration. The dependence of the measured drag on surface conditions is analysed and compared to published parameterisations.
The East Siberian Arctic Shelf (ESAS) seas have been proposed as a substantial source of methane (CH₄) to the atmosphere, and are an important sink for atmospheric CO₂. We report extensive direct eddy covariance observations of CO₂ and CH₄ fluxes between the sea and the atmosphere, from a ship in the ESAS seas during July-August 2014.

Our results show that that sea emissions of CH₄ leading to atmospheric enhancements of CH₄ above the ESAS are regionally explainable by wind-driven diffusive fluxes. Based on our measurements, we estimate an annual sea-air flux of 1.49 Tg yr⁻¹ for the entire ESAS. Areas of enhanced flux from seafloor-released bubbles transferring CH₄ directly into the atmosphere were observed but had limited spatial extent. For example in one location in the East Siberian Sea, we observed sea-air CH₄ fluxes exceeding 600 mg m⁻² d⁻¹, over an area of ~100 m². Although locally impressively large, such fluxes make a negligible contribution to total ESAS CH₄ emissions.

We also present direct determination of the CO₂ and CH₄ air-sea gas transfer velocity in a wide range of Arctic sea ice conditions. We show that the gas transfer velocity increases near linearly with decreasing sea ice concentration and that previous modeling approaches may overestimate gas transfer rates in sea ice regions.
Multi-annual Observations of Tropospheric BrO at Two Antarctic Stations

Udo Frieß¹ (udo.friess@iup.uni-heidelberg.de), Richard Quere³, Karin Kreher³, Jan-Marcus Nasse³, Ulrich Platt¹
¹University of Heidelberg, Im Neunheimer Feld 229, Heidelberg, Germany, ²National Institute for Water and Atmospheric Research, Lauder, New Zealand, ³BK Scientific GmbH, Mainz, Germany

The presence of high amounts of bromine monoxide (BrO) each spring in Polar Regions has a substantial impact on the oxidative capacity of the polar boundary layer. Released by autocatalytic processes on saline surfaces, such as sea ice, snow and aerosols, BrO frequently leads to a virtually complete destruction of near-surface ozone. Furthermore, the oxidation of DMS by BrO can have a potential impact on climate. The oxidation of elemental mercury by BrO leads to an enhanced influx of this toxic compound into the polar biosphere.

Here we present multi-decadal observations of the vertical distribution of tropospheric BrO and aerosols using Multi-Axis Differential Optical Absorption Spectroscopy (MAX-DOAS) measurements performed at the New Zealand Antarctic Observatory Arrival Heights (78°S) since 1998 and at the German Antarctic Station Neumayer (70°S) since 2003. By detection of absorption structures of atmospheric constituents in scattered sunlight from different directions, this technique allows for the reconstruction of vertical profiles of trace gases and aerosols in the atmospheric boundary layer. We present a detailed statistical analysis of the amount, frequency, and vertical distribution of BrO in the Antarctic boundary layer, enabling the identification of possible source regions and the impact of blowing snow and aerosols on the release of BrO, as well as transport processes, such as an influx of reactive bromine from the boundary layer into the free troposphere.
The mass loss from the Greenland Ice Sheet (GrIS) is one of the main sources for the global sea level rise and almost quadrupled from 1992-2000 to 2000-2011. The additional freshwater could influence the formation of components of the North Atlantic Deep Water and thereby might alter the strength of the climate relevant Atlantic Meridional Overturning Circulation. The accelerated run-off is influenced by an intrusion of warm water onto the shelf near the outlet glaciers and an increased atmospheric warming impacting surface melt. The drainage basin of the Northeast Greenland Ice Stream covers 16% of the GrIS. Main outlets of this ice stream are the Nioghalvfjerdsfjorden Glacier with a calving front of around 30 km and the Zachariae Isstrøm, both are located near the Fram Strait and the Greenland Sea. We identify and quantify the submarine and surface melt water distribution in the near- and far-field of these glaciers by analyzing the low soluble noble gases helium and neon. They are used in an Optimum Multiparameter analysis in combination with hydrographic data to calculate the submarine and surface melt water fractions. Early results show strong glacial melt water outflow from the cavity below the marine-terminated Nioghalvfjerdsfjorden Glacier into the upper 200 m, indicated by high noble gas concentrations in front of the glacier.
Importance of Deformed Ice in the Polar Regions for the Climate Models

Jean Sterlin\textsuperscript{1} (jean.sterlin@uclouvain.be), François Massonnet\textsuperscript{1}, Thierry Fichefet\textsuperscript{1}
\textsuperscript{1}Université catholique de Louvain / Earth and Life Institute, ELIC, Louvain-la-Neuve, Belgium

Sea ice comes in a variety of sizes and shapes depending on the mechanical and thermodynamical events it has undergone. New ice offers little resistance to the winds and currents, while deformed ice contains hummocks and ridges that influence how heat and momentum are transferred at the atmosphere-ice-ocean interfaces. In most climate models, the surface fluxes are determined from "bulk formulas" with constant drag coefficients based on roughness length estimates. Therefore, these formulations do not account for the space-time variability of transfer coefficients due to variations in ice roughness. However, the ice roughness can be estimated from the models by quantifying the amount of deformed ice (Tsamados et al, 2013). To study the effect of ice deformation on the surface fluxes and the associated impact on the sea ice, we implement a tracer of deformed ice into the ocean-ice model NEMO-LIM3 v3.6 and modify the drag coefficients accordingly. From a run of NEMO-LIM3 between 1958 and 2015 at 1 degree resolution, we examine the spatial and temporal evolution of the drag coefficients in the Arctic and Antarctic regions. We investigate the effects on the surface fluxes and impacts on the sea ice state. This study allows us to formulate an initial assessment on the importance of deformed ice variability for the current climate models.
Hydrodynamics between Prydz Bay and India Bay (Antarctica) during 2012 - 2017

Alvarinho J. Luis¹ (alvluis1@gmail.com), Vinit Ravindra Lotliker¹, Shridhar D. Jawak¹
¹National Centre for Antarctic and Ocean Research (ESSO-NCAOR), Polar Remote Sensing Division, Polar Sciences Group, Vasco da Gama, India

Under India’s project “Monitoring of hydrodynamics of coastal Antarctica between Prydz Bay (69S, 76°E) and India Bay (66oS, 9°E),” vertical profiles of density were recorded at every 1° longitude apart using Expendable CTD probes during austral summer of 2012-2017 onboard cargo ships chartered for Indian Antarctic Expedition. The thermohaline structure showed mixed layer thickness of about 50 m on average which deepened to 80 m due to anomalous environmental forcing such as storms in 2017. High salinity winter water (>34.5 psu) dominantly occupied the water column all along the Prydz Bay - India Bay. It is inferred that bottom topographic features and coastal geometry influenced the thermohaline structure. The depth integrated heat content revealed high values (>840 x 10⁹ Jm²) at 42°E, while low value were encountered at India Bay and Prydz Bay due to large influx of melt water. T-S diagrams revealed freshening signatures of water masses at most hydrographic stations. The distribution of different water masses is as follows: Antarctic Surface Water was confined to the upper 25 m, Ice Shelf Water was detected between 350 and 500 m, Continental Shelf Water was identified between 350 and 700 m, while Circumpolar Deep Water was confined to below 900 m. We address the role of air-sea heat fluxes and winds on the evolution of thermohaline structure and its inter-annual changes. The observational program will continue to generate a long time series for unraveling climate signals.
Polar sea ice plays a major role in Earth’s climate system. Sea ice growth and decay is governed by complex 
feedbacks between sea ice, the atmosphere, and the ocean. Sea ice is, however, more responsive to
atmospheric forcing, seasonal changes in air temperature being the main driver. Moreover, a high correlation
exists between anomalies in sea ice extent and mean sea level pressure as shown by previous studies.
Polar lows are intense maritime mesocyclones forming at high latitudes, extending over hundreds of
kilometers, and are associated with high surface wind speeds and large heat fluxes out of the ocean. As a result
of strong air-sea fluxes, sea ice conditions are impacted. The extent to which polar storms impact sea ice
conditions has been, however, hardly investigated previously.
This study proposes a long term (1996-2017), monthly analysis of major polar lows as derived from ERA-Interim
reanalysis data. The reanalysis will be evaluated against the monthly sea ice extent obtained from spaceborne
observations. The overall aim is to assess the impact of storms on regional sea ice extent and identify regions
that are prone to a greater change as a result of atmospheric forcing. During the 2016 spring, the Antarctic sea
ice extent was at its lowest since the late 1970s, with pronounced regional sea ice extent anomalies.
Investigations will be carried out to determine the possibility of anomalous sea ice extent during different
seasons being impacted by polar storms.
Seasonal Impact of the Southern Annular Mode on Antarctic Sea Ice Extent

Edward Doddridge¹ (ewd@mit.edu), John Marshall¹
¹Massachusetts Institute of Technology, Earth, Atmospheric, and Planetary Sciences, Cambridge, United States

Through analysis of remotely-sensed sea surface temperature (SST) and sea ice concentration data we investigate the impact of winds related to the Southern Annular Mode (SAM) on sea ice extent around Antarctica. We show that positive SAM anomalies in the austral summer are associated with anomalously cold SSTs that persist and lead to anomalous ice growth in the following autumn, while negative SAM anomalies precede warm SSTs and a reduction in sea ice extent during autumn. The largest effect occurs in April, when a unit change in the detrended summertime SAM is followed by a 1.8±0.6 ×10⁵ km² change in detrended sea ice extent. We find no evidence that sea ice extent anomalies related to the summertime SAM affect the wintertime sea ice extent maximum. Our analysis shows that the wind anomalies related to the negative SAM during the 2016/17 austral summer contributed to the record minimum Antarctic sea ice extent observed in March 2017.
When ocean waves interact with the solid Earth, they generate seismic signals called microseisms that peak in two different period bands between 1 and 20 seconds. These peaks are visible on most station noise spectra worldwide; they tend to amplify during winter due to stronger storm activity in the oceans. Using data recorded between 2001 and 2009, Grob et al. (2011) showed that Antarctic noise spectra behave differently: they tend to attenuate during winter due to the presence of sea ice. They also proved that Antarctic microseisms exhibit seasonal behavior that correlates directly with the local sea-ice conditions near the recording station. We aim to monitor sea-ice formation and its variability at key locations along the Antarctic coast, such as the Dumont d’Urville station, by extending the Grob et al. (2011) study to data recorded between 2010 and 2017.
Carbon Dynamics during the Formation of Sea Ice at Different Growth Rates

Daniela König¹ (daniela_koenigd@bluewin.ch), Lisa Miller², Svein Vagle², Kyle Simpson²
¹ETH Zurich, Zürich, Switzerland, ²Institute of Ocean Sciences, Sidney, Canada

Given the potentially important contribution of sea ice to sequestration of inorganic carbon (TIC) in deep waters, relatively little is known about the distribution of TIC during the formation of sea ice or how different ice growth rates might affect the allocation of carbon to ice, water, or air. To illuminate these carbon dynamics, we grew ice in an experimental seawater tank (1 m³) under abiotic conditions up to a thickness of 20 cm at three different air temperatures (-40 °C, -25 °C, -15°C). Carbonate system parameters were determined by discrete sampling of ice cores and water, as well as continuous measurements by multiple sensors deployed mainly in the water phase. A budgetary approach revealed that of the initial TIC content of the water, only 5 % was located in the ice phase by the end of the experiment at the slowest growth rate (1 cm/d), while for the fastest growth rate (12 cm/d), this value increased to over 10 %. Exchange with air appeared to be negligible, with the majority of the TIC remaining in the under-ice water (90-95 %). Along with a good correlation between salinity and TIC in the ice and water samples, these observations highlight the importance of brine drainage to TIC redistribution during ice formation. For experiments without mixing of the under-ice water, the sensor data further suggested a stronger stratification, and thus potentially larger carbon sequestration for ice grown at a colder temperature and faster growth rate.
Unexpected Halogen Activation during Fall at Neumayer III/Antarctica

Jan-Marcus Nasse\textsuperscript{1} (jan.nasse@iup.uni-heidelberg.de), Udo Frieß\textsuperscript{1}, Denis Pöhler\textsuperscript{1}, Stefan Schmitt\textsuperscript{1}, Holger Sihler\textsuperscript{1,2}, Rolf Weller\textsuperscript{3}, Thomas Schaefer\textsuperscript{3,4}, Zsófia Jurányi\textsuperscript{3}, Ulrich Platt\textsuperscript{1}

\textsuperscript{1}Institute of Environmental Physics, University of Heidelberg, Heidelberg, Germany,  \textsuperscript{2}Max-Planck Institute for Chemistry, Mainz, Germany,  \textsuperscript{3}Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany,  \textsuperscript{4}Leibniz Institute for Tropospheric Research, Leipzig, Germany

The influence of Reactive Halogen Species (IO, BrO, ClO, etc.) on the lower polar troposphere has been subject of intense research for over three decades. Ozone Depletion Events or the oxidation of gaseous elemental mercury are well observed phenomena that occur during the respective springtime in both Arctic and Antarctic. While an autocatalytic release mechanism from salty surfaces (sea ice or aerosols), the so-called bromine explosion, has been identified as the likely cause of the rapid increase of inorganic bromine mixing ratios, many other aspects of the atmospheric halogen chemistry, like chlorine release, remain unclear.

Since January 2016, we are operating a fully automated Long-Path DOAS instrument at Neumayer III in coastal Antarctica. It can detect a wide range of trace gases including ClO, BrO, OCIO, IO, and NO\textsubscript{2} at a temporal resolution of 5-30 minutes.

The analysis of two years of observations shows several surprising findings which give new insights into polar halogen chemistry. For instance, we detect unexpectedly strong bromine activity in late summer and autumn (in addition to springtime events) with BrO mixing ratios frequently exceeding 20 ppt and peaks up to unprecedented 110 ppt. Furthermore, ClO mixing ratios up to 90 ppt and OCIO up to 10 ppt could be detected - the source mechanism for reactive chlorine, however, remains unclear. We will give an overview of the time series and discuss interesting case studies with regard to chemistry and meteorology.
A Scaling Law for the Floe Size Distribution of Pancake Ice

Alberto Alberello\(^1\) (alberto.alberello@outlook.com), Luke Bennetts\(^2\), Miguel Onorato\(^3\), Marcello Vichi\(^4\), Alessandro Toffoli\(^1\)

\(^1\)The University of Melbourne, Parkville, Australia, \(^2\)University of Adelaide, Adelaide, Australia, \(^3\)Università degli Studi di Torino, Torino, Italy, \(^4\)University of Cape Town, Cape Town, South Africa

In the pancake ice region of the marginal ice zone (MIZ), the sea ice cover begins to affect the momentum exchange between atmosphere and ocean. Moreover, the ice cover begins dissipating energy of surface waves travelling through it. However, remote sensing techniques often fail to provide accurate informations on the geometrical properties of the small floes (i.e. diameter less than 10 meters). In this context, bridge based observations are necessary to improve and calibrate all other techniques. The Antarctic Sea Ice Processes and Climate (ASPeCt) protocol provides a streamlined methodology to classify sea ice, however, there is a certain degree of subjectivity on the data quality that relies on the ability of the trained observer. The S.A. Agulhas II sailed the Southern Ocean in the austral winter of 2017. During the cruise, the icebreaker encountered a large patch of pancake ice that extended for more than 150 km from the edge of the MIZ. The sea-ice was digitally recorded with a camera installed on the monkey bridge. A MATLAB algorithm has been developed to analyse the digital images and extract the ice concentration and the floe size distribution. It was found that the pancake size exceedance probability follows two distinct power laws, with the exponent changing for pancake diameters roughly equal to 3 meters.
Modeling Modified Circumpolar Deep Water Intrusions onto Prydz Bay

Chengyan Liu¹ (chengyan-liu@qq.com), Zhaomin Wang², Chen Cheng¹, Ruibin Xia¹, Bingrui Li³
¹Nanjing University of Information Science & Technology, School of Marine Sciences, Nanjing, China, ²Hohai University, College of Oceanography, Nanjing, China, ³Polar Research Institute of China, Nanjing, China

An eddy-resolving coupled regional ocean-sea ice-ice shelf model is employed to locate the hot spots where modified Circumpolar Deep Water (mCDW) intrudes onto the continental shelf within Prydz Bay, and locate the paths through which mCDW is transported to the Amery Ice Shelf (AIS) calving front. Evaluation of the model output is with satellite, hydrographic and borehole data. Two critical windows responsible for mCDW intrusions are identified. The first is the eastern branch of the cyclonic Prydz Bay gyre (PBG) that carries mCDW to the ice front line, accounting for an annual mean heat transport of ~8.7 ×10¹¹ J s⁻¹. The second is located to the east of the Four Ladies Bank (FLB) where mCDW is channeled through submarine troughs, accounting for an annual mean heat transport of ~16.2 ×10¹¹ J s⁻¹. The eddy-induced heat transport accounts for ~23% in the path of the PBG and ~52% in the path of the eastern coastal current, with respect to their total onshore heat transport. The seasonal pulsing of mCDW intrusions is greatly dependent on the seasonal cycle of the Antarctic Slope Current (ASC) that peaks with a maximum of ~29.3 Sv at 75°E in June. In austral winter, mCDW is allowed to access the eastern flank of the AIS calving front with potential consequences for the basal mass balance of the AIS. The dynamic effects of small-scale troughs on the longshore ASC play an important role in the onshore mCDW transport.
Studying seasonally varying snow and sea-ice properties in the ice-covered oceans is a key element for investigations of processes between atmosphere, sea ice, and ocean. A dominant characteristic of Antarctic sea ice is the year-round snow cover, which substantially impacts the sea-ice energy and mass budgets by, e.g., preventing surface melt in summer, and amplifying sea-ice growth through extensive snow-ice formation. However, substantial observational gaps in the description of year-round Antarctic pack ice and its snow cover lead to a limited understanding of important processes between atmosphere, sea ice and ocean.

Here, we introduce a unique observational dataset comprised of a number of critical parameters relevant to the snow/ice and ice/ocean interface, recorded by a suite of snow and ice-mass balance buoys (IMBs) deployed in the Weddell Sea between 2013 and 2018.

From these data we infer seasonal snow accumulation rates, which allow to describe the spatial distribution and temporal evolution of the Antarctic snowpack. Vertical temperature profiles from co-deployed IMBs are used to validate these findings, and to calculate energy budgets across the atmosphere-ocean boundary.

Our results highlight that data from autonomous, ice-based platforms are a key element in better understanding sea-ice and snow properties, processes and their seasonal evolution.
Antarctic sea ice production is thought to be fundamental to determining the strength of the southern hemisphere meridional overturning circulation and the solubility pump, through its control of air-sea exchange, and through brine rejection. The unbuffered gases (He, Ne, N₂, O₂, N₂, Ar, Kr, and Xe), dissolved in seawater, contain a fingerprint of sea ice and other bio-physical processes that ultimately determine gas content in the deep ocean. We collected discrete noble gas samples and in-situ gas measurements using an Underwater Mass Spectrometer (UMS) attached to the CTD rosette, during the PIPERS cruise between April 11 to June 14 2017 in the Ross Sea. The UMS is an early prototype of instrumentation that has the potential to expand the spatial and temporal coverage of in-situ dissolved gases such as N₂ and Ar. These measurements reveal glacial meltwater effluents that are incorporated into subsurface waters before those waters exit the continental shelf along the abyssal troughs in the Ross Sea. Within the mixed layer, persistent under-saturation in all the dissolved gases reflects heat loss that fast exceeds the rate of air-sea and air-ice gas exchange, leading to shelf waters that do not convey their entire gas burden into the deep sea during their transformation into deep water. We use the gases and hydrography to reflect on the competing effects between secular freshening in the Ross Sea and the salination process of shelf water during polynya ice production.
Mapping Antarctic Peninsula Iceberg Melt Variability with Satellite Imagery

Mariama C Dryak¹ (mariama.dryak@maine.edu), Ellyn M Enderlin¹
¹University of Maine, Earth and Climate Sciences, Climate Change Institute, Orono, United States

Warming air and ocean temperatures have led to a global increase in glacier and ice sheet melt, impacting the amount of freshwater being added to the oceans. Along the Antarctic Peninsula climate warming is responsible for the break-up of ice shelves that formerly buttressed the flow of ice from marine-terminating glaciers to the ocean. Both ice shelf collapse and subsequent acceleration of glaciers that previously fed the shelves has resulted in increased iceberg discharge to neighboring ocean basins. In order to fully understand the impacts of increased iceberg discharge on local-to-global ocean properties, iceberg freshwater fluxes must be quantified. Patterns in Antarctic iceberg melt can be mapped through the differencing of repeat high-resolution digital elevation models (DEMs), as has been recently demonstrated around Greenland. Specifically, here we use repeat very high-resolution WorldView satellite images to create iceberg DEMs, then difference the iceberg elevations in time to construct estimates of iceberg melting from 2011 to 2018. Spatial and temporal variations in iceberg melting are analyzed in order to determine whether iceberg meltwater fluxes have varied considerably in the past decade.
Evidence of Polynya Frazil Ice Growth over Tens of Vertical Meters during PIPERS

Lisa De Pace1 (lisamdepace@gmail.com), Brice Loose¹, Madison Smith², Samuel Gartzman¹, Sharon Stammerjohn³

¹University of Rhode Island, Narragansett, United States, ²University of Washington, Seattle, United States, ³University of Colorado Boulder, Boulder, United States

Strong katabatic winds and subzero air temperatures drive extreme oceanic heat loss in coastal polynyas, during the polar night. We observed repeated katabatic wind events in the Terra Nova Bay polynya of the Ross Sea, during the PIPERS cruise, which occurred between April 11 and June 14, 2017. During these conditions, mixed layer depth extended to 600 m and mixed layer temperatures were driven to or below the freezing point. Yet, temperature and salinity profiles were not perfectly homogenous throughout the mixed layer. Instead, we observed an apparent source of heat and salt in the top tens of meters, evident as a warmer saltier bulge in the CTD profiles. Considering both the colder air above and water below, we surmise that the increase in temperature and salinity reflects latent heat and salt release during unconsolidated ice production throughout the upper water column. We use the thermodynamic state equations and models of frazil ice production to test whether frazil ice production could lead to the observed thermohaline anomalies. Conversely, we use simple heat and salt budgets to put bounds on the amount of frazil ice production that is implied by these observations. These and related measurements provide insight to the boundary conditions for the dense water that is produced in coastal polynyas, and eventually incorporated into Antarctic Bottom Water.
Mesocyclones (MC) in high latitudes are important maritime atmospheric phenomena, characterized by strong wind speeds and surface heat fluxes. The lack of assimilated observational data in Southern Hemisphere (SH) in the global ocean and atmospheric models and also the rough resolution of the latter does not allow realistic representation of MC in these datasets. Most of modern studies of the MC activity in SH are using tracking algorithms based on reanalyses data, significantly underestimating number of MC and their intensity (Irving et al., 2010; Pezza et al., 2015). Thus, dynamical characterization of MC, developed in these studies covers only a fraction of mesocyclone population.

In this study, we present thermodynamical and lifecycle characteristics of polar MC in SH, basing on the high-resolution (10 km) Weather Research and Forecasting model regional hindcast for winter 2004. The hindcast is validated involving different observational data: satellite-derived integral water vapor content (AMSR-E), surface winds (QuikSCAT), AMRC AAWSP weather stations data. The WRF reproduced 95% of polar MC of satellite-based dataset of the Southern Ocean MC tracks (Verezemskaya et al., 2017). Dynamical characteristics of polar MCs from satellite database such as surface fluxes, CAPE/CIN, existence of cold/warm core, Eady rate, potential vorticity anomalies are calculated for different types of MCs according to their cloudiness pattern type and large-scale background conditions.
Primary production on the Ross Sea continental shelf is thought to be limited by the supply of dissolved iron (DFe), which is derived from melting of sea ice and glacial ice, intrusion and upwelling of Circumpolar Deep Water, and vertical resupply from the benthos. The latter will be most important during winter, when katabatic winds drive sea ice formation and convective overturn in coastal polynyas, although the impact of these processes on the water-column distribution of DFe has not been previously documented. As part of the project Polynyas and Ice Production Evolution in the Ross Sea (PIPERS), we collected hydrographic data and water-column samples for DFe analysis in the Terra Nova Bay (TNB) and Ross Ice Shelf (RIS) polynyas during April-June 2017 (fall-early winter). We observed several intense katabatic wind events in the TNB polynya, where the surface mixed layer varied from ~250 m to ~600 m depth over lateral distances of ~10 km. Stations occupied in the RIS polynya, where weather conditions were less extreme, revealed surface mixed layer depths < 300 m. These observations and our preliminary DFe data suggest that convective overturn progresses slowly and episodically over winter, perhaps earlier in the TNB polynya, where there is also evidence of substantial DFe inputs associated with Ice Shelf Water.
High Heat Flux Events and the Role of Sea Ice in the Iceland Greenland Seas

James Pope¹ (japope@bas.ac.uk), Tom Bracegirdle¹, Ian Renfrew², Andy Elvidge²
¹British Antarctic Survey, Cambridge, United Kingdom, ²University of East Anglia, Norwich, United Kingdom

The Iceland Greenland seas Project (IGP) represents a coordinated meteorological and oceanographic study of the Iceland and southern Greenland Seas. The aim being to characterise the atmospheric forcing and the ocean response of coupled atmosphere-ocean processes; in particular cold-air outbreaks in the vicinity of the marginal-ice-zone and their triggering of oceanic heat loss and the generation of dense water masses. Within the project a climatological assessment using regional climate modelling tools of changes in the distribution late winter/early spring (January-February-March-April) sea ice concentration will be undertaken. The modelling will focus on how changes in the location of the sea ice front over the duration of the satellite record have impacted on location, magnitude and frequency of cold air outbreaks and high heat flux events. Here we present the initial analysis of these modelling studies, using three fixed sea ice conditions representative of the maximum (1986), minimum (2016) and median (2004) sea ice concentrations. Our results will focus on the changes in the distribution and frequency of high heat flux events and an initial assessment of how these will change into the future.
Contrasting Carbon Monoxide Cycles in the North Pacific and the Amundsen Sea

Young Shin Kwon1,2 (kwonys@kopri.re.kr), Tae Siek Rhee3, Doshik Hahm3, Hyun-Chul Kim3, Hyoun-Woo Kang4
1Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of, 2University of Science and Technology-Korea, Daejeon, Korea, Republic of, 3Pusan National University, Pusan, Korea, Republic of, 4Korea Institute of Ocean Science and Technology, Pusan, Korea, Republic of

To investigate how the CO budget in the mixed layer governs the CO emission from sea to air, we measured air-sea gas exchange, microbial consumption rate, and CDOM on-board during two expeditions in the Amundsen Sea and the North Pacific in summer season of 2012. Dark incubation experiments revealed that microbial consumption rate in the North Pacific was 4.5 nM d⁻¹ whilst 0.8 nM d⁻¹ in the Amundsen Sea. Also CO production rate was about 3.5-times higher in the North Pacific (2.4 nM d⁻¹) due mainly to inefficient dilution by shallow mixed layer in the region. It seems that this different CO budget between the two regions causes different amplitude of diurnal variation of dissolved CO. That is, compared to the Amundsen Sea, CO is produced faster in daytime and removed faster throughout the day in the North Pacific where the amplitude of CO cycle is larger. In both regions, sea-to-air flux density was insignificant (about 0.1 nM d⁻¹ for the both regions) compared to microbial consumption which covers above over 95% of CO. Our observations indicate that the source strength of the ocean was evenly weak regardless of the scale of CO budget in the ocean. That is, marine biota can be thought as a main control of CO in the atmosphere, the important trace gas for the global climate change.
The integrative effects of increased winter storm activity in the Arctic's Atlantic sector were studied using a collection of field observations and analyses. In early 2015, during the six-month N-ICE2015 expedition in the pack ice north of Svalbard, we observed a chain of events in the atmosphere-ice-ocean system that was triggered by several powerful winter storms. Our unique, interdisciplinary observations show that these winter storms entail significant effects that last much longer than the short-lived storm events themselves. The rapid warm and moist air advection associated with the storms contributed to a deep snow-pack and ice surface warming that inhibited thermodynamic sea-ice growth. Instead, the heavy snow-load promoted flooding and formation of snow-ice. The strong winds deformed the sea ice, opening up leads, increased air-to-sea CO$_2$ fluxes by a factor of 20 and increased the concentration of sea-salt aerosols. The storms also enhanced ocean mixing, with ocean-to-ice heat fluxes that were 17 times larger than background values when warm Atlantic Water was near the surface. This resulted in mid-winter bottom-ice melt rates of 5-25 cm/day. In spring, the aggregate effect of winter storms promoted algal growth at the flooded snow-ice interface, produced ice algal hotspots in pressure ridges, and the light transmission through leads set off an extensive under-ice phytoplankton bloom. Frequent winter storms have profound impacts in a thinner Arctic sea-ice regime.
The cold regions on Earth are undergoing significant climate change. Yet many underlying chemical, biological, and physical processes and feedbacks are still poorly understood strongly motivating continued research in cold regions. Such research inherently requires cooperation among researchers and programs across national boundaries to achieve science objectives. CATCH is an emerging activity of the IGAC (International Global Atmospheric Chemistry) project and is endorsed by SOLAS (Surface Ocean-Lower Atmosphere Study). CATCH facilitates interdisciplinary and international research with a focus on interactions between snow, ice, ocean, aerosols, and clouds in cold regions. CATCH science addresses cold region research challenges to help reduce model uncertainties and improve climate predictions. Here we give an overview of scientific aims and strategy to develop collaborative research teams and projects. Particular areas of interest include: sea ice changes, atmosphere-ice-ocean interactions and their impacts on atmospheric chemistry; feedbacks between climate change and atmospheric chemistry mediated by changes in the cryosphere; the production, processing and climate impacts of aerosols and cloud precursors; ice cores as archives of past environmental change, and the influence of background atmospheric chemistry on the fate of pollution. CATCH seeks to link research on a fundamental, molecular level with larger scales targeted by field and satellite observations.

On behalf of the CATCH Implementation Team, IGAC, http://www.igacproject.org/activities/CATCH, Boulder, United States
Evaporation at 2 Poles: Moisture & Sensible Heat Flux in the Arctic & Antarctic

Linette Boisvert¹ (linette.n.boisvert@nasa.gov), Chung-Lin Shie¹
¹NASA Goddard Space Flight Center, Greenbelt, United States

The process of evaporation provides water vapor from the surface to the atmosphere, where it becomes the most radiatively important and abundant greenhouse gas altering the Earth's energy balance and water cycle. However, it is often poorly captured because surface in-situ measurements of evaporation are scarce, especially over the Polar Regions.

The sea ice at both poles acts as a barrier between the ocean and atmosphere inhibiting the exchange of heat, momentum, and moisture. However, variations in the sea ice cover could lead to changes in the amount of heat and moisture supplied to the atmosphere. Since the Arctic and Antarctic sea ice have been behaving very differently over the satellite record, it is crucial to study these changes on the moisture and sensible heat fluxes. These variations could affect surface energy budgets, larger occurrences of low-level clouds, and higher near-surface humidity and temperatures.

Little research has been done looking at the moisture and sensible heat flux from the Arctic and Antarctic sea ice pack. This work will use data from NASA's AIRS and the scheme from Boisvert et al., 2013, which utilizes the Monin-Obukhov Similarity Theory. Changes have been made to the boundary layer parameterizations specifically for sea ice in order to produce a 2003-2016 moisture and sensible heat flux product. Regional and seasonal differences will be addressed along with any trends and interannual variability.
Surface Heat Budgets in the Ross and Weddell Seas and Global Climate Variability

Giannetta Fusco¹ (giannetta.fusco@uniparthenope.it), Yuri Cotroneo¹, Giuseppe Aulicino², Dario Cerrone¹
¹Parthenope University, Napoli, Italy, ²Università Politecnica delle Marche, Ancona, Italy

The monthly mean surface heat budgets, over last fifty years, in the Ross and Weddell Seas have been estimated using meteorological parameters provided by the ECMWF and sea ice information from SSM/I data and SIT (sea ice thickness) algorithm.

The areas show opposite variations before 1998 and synchronous behaviour after 1999. This may be explained by the global climate variability expressed by ENSO, SAM and wavenumber-3 pattern or by combination among them. Also ACW could be involved. The interaction among these signals can imply a different behaviour of surface heat budgets in the two areas.

Our results show that circumpolar SLP and SST signals exhibit coherent components on interannual whereas covarying significant energy between SAM and ENSO variability is observed. This implies that SAM and ENSO modes play a superimposed role interfering constructively or destructively on interannual scale. Furthermore, the hovmoller diagrams for interannual SLP anomalies exhibits two stronger ACW cycles around 1982-1991. Before 1982 and after 1991 the absence of ACW seems to be related to the dominant signature of SAM in modulating circumpolar variability.

Also CEOF analysis show that the SAM has assumed a leading role between 1972-81 and 1991-2000 determining no ACW events. Starting from 2003 until present a wavenumber-3 pattern could have played a role in continuing the phase relationship between heat fluxes in the two Antarctic sectors.
Remote sensing is essential for monitoring polynyas dynamics. On regional scales, passive microwave (PM) radiometers provide useful information about their extent. Their coarse resolution often limits an accurate separation of open water from ice cover. Despite their sensitivity to the presence of clouds, thermal infrared (TIR) Moderate Resolution Imaging Spectroradiometers (MODIS) provide high resolution information (typically 1 Km) at large swath widths, several times per day.

In this study we apply a new methodology that combines a sequence of MODIS swath-based scenes to examine the TNB evolution in the winter season during the last 14 years (2003-2016). Results have been validated through the comparison with a huge set of SAR images acquired by ENVISAT, SENTINEL and COSMO-SkyMed satellites. The good agreement with most of the analyzed SAR images demonstrated the potential of this tool for the continuous monitoring of the polynya extent and the consequent estimation of ice production rates. A comparison with TNB polynya extent estimations retrieved by other MODIS and PM based tools has also been carried out and differences discussed. Furthermore, the polynya events identified through our technique have been compared to the katabatic events captured by the automatic weather stations located along the TNB coast, and their interannual variability analyzed.
Biogenic Aerosol in Central Antarctica: The Ocean-atmosphere Interaction

Silvia Becagli1 (silvia.becagli@unifi.it), Rita Traversi1, Mirko Severi1, Laura Caiazzo1, Luigi Lazzara2, Giovanna Mori2, Christian Marchese3, Claudio Scarchilli4, Virginia Ciardini4

1University of Florence, Department of Chemistry 'Ugo Schiff', Sesto Fiorentino, Italy, 2University of Florence, Department of Biology, Florence, Italy, 3Université du Quebec a Rimouski, Dep.de Biologie, Chimie et Geographie, Rimouski, Canada, 4ENEA, Laboratorio di Osservazione e Analisi della Terra e del Clima, Rome, Italy

Ten years data of atmospheric oxidised sulphur compounds (methanesulphonic acid (MSA) and non-sea salt sulphate, nssSO4) from the east Antarctic Plateau at Dome C (75° 06' S, 123° 20' E, 3220 m a.s.l. and 1100 km away from the nearest coast) are here presented. Biogenic sulphur aerosol is produced by the oxidation of the dimethylsulphide produced by phytoplankton. The two sulphur-derived species exhibit a seasonal cycle characterised by maxima in the summer from October to March. In particular MSA presents two summer maxima the first one in November and the second in February, the latter with MSA concentrations higher than the first-one. The two maxima are characterized by different size distribution and seem to be related to different source area of DMS characterized by different timing of primary production. The two maxima of MSA are analysed also as function of sea ice extent and area of ice free in the marginal ice zone in the two different source areas. Sea ice is an important parameter affecting polar primary production. It regulates primary production in the shelves by:

(i) providing a substrate for algal growth on the underside of the ice;
(ii) limiting the photosynthetic radiation available to primary producers;
(iii) limiting the development of thermal or fresh water stratification in the freezing season; and
(iv) enhancing water stratification during the melting season, therefore regulating the amount of available nutrients in the euphotic layer.
The Antarctic Bottom Water (AABW), the densest and coldest water that occupies the bottom layer of the world ocean, is formed in few areas around Antarctica. The production of the AABW plays a major role in determining the strength of the Meridional Overturning Circulation. Observations within the Southern Ocean’s Pacific sector indicate a decadal trend of reduced salinity of both the AABW and shelf waters. CTD data and moored time-series collected in the Ross Sea from 1995 to 2017 in the framework of the Italian National Antarctic Research Program (PNRA) show strong changes in the thermohaline characteristics of the dense shelf water (SW), a precursor of the AABW. We observe a freshening of about 0.05 per decade in the western Ross Sea both at the SW formation area (Terra Nova Bay polynya - TNBp) and at the Ross Sea shelf break near Cape Adare (CA) where the AABW is formed and exits the Ross Sea. Besides the negative salinity trend, we note a periodical variability of the salinity time series of about 6-7 years in the TNBp and of 4-5 years at CA. The physical processes driving the SW interannual variability in the Ross Sea are poorly understood, here we investigate the relationship of the complex interaction among the atmospheric forcing, sea ice production, and ocean thermohaline variability.
The large-scale circulation and dense water formation (DWF) in the Svalbard archipelago influence the thermohaline circulation in the whole Arctic. DWF depends on the rate of cooling and homogenisation of the Atlantic water along its northward pathway, brine rejection, boundary convection on shelves and slopes, and open-ocean convection. This study focuses on the shelf and slope dynamics and the entrainment processes, which occur along the west Spitsbergen margin. Two short (~140m) moorings (S1 and ID2), deployed at a depth of ~1040 m over the slope, collected multiannual (2014-2017) time-series in an area of interaction between the West Spitsbergen Current and the descending shelf plumes. Time-series revealed a large thermohaline and current variability between October and April. Data highlight the presence of Norwegian Sea Deep Water (θ = -0.90°C, S = 34.90, ωθ = 28.07 kg m⁻³) influenced by occasional intrusions of warmer (up to +2°C), saltier (up to ~35), less dense (down to 27.98 kg m⁻³), and more oxygenated water during fall-winter periods. The result is the injection of heat into the deep sea. Notably, such intrusions occur simultaneously at both sites 170km apart, suggesting that strong winds could trigger the formation of gravity plumes but is the particulate matter that renders them more energetic and heavier than pure TS plumes. Here we discuss the origin, timing, and role of such plumes in a period characterized by a general warming and ice reduction of the Arctic.
Observations and model results suggest existence of a negative feedback between the intensity of the oceanic and the atmospheric heat fluxes at scales of 30-year and longer time scale, the so called Bjerknes compensation. The link between the oceanic and atmospheric fluxes is maintained through ocean-atmosphere heat exchange, mostly over the north Greenland Sea and the Barents Sea. A local positive feedback in the ocean-ice-atmosphere system makes the latter to strongly amplify the intensity of the forced fluctuations.

In this work, variations of convergence of advective heat fluxes in the ocean \((dQ_{oc})\) and in the atmosphere \((dQ_{atm})\) in the regions were investigated for time scales of 1-10 years, using model results and observations. In both, \(dQ_{oc}\) and \(dQ_{atm}\) data, the 2-4-year and 5-8 year cycles were detected. Cross-wavelet analysis of \(dQ_{oc}\) and \(dQ_{atm}\) showed nearly out-of-phase variations of \(dQ_{oc}\) and \(dQ_{atm}\) in the Barents Sea region at 5-8 year scales. This was not the case for \(dQ_{oc}\) and \(dQ_{atm}\) for the north Greenland Sea region. The results suggest a significance of ocean-atmosphere exchange over the Barents Sea in maintenance of the Bjerknes compensation mechanism in the Arctic.

The research was supported by RSF project 17-17-01151
Climate warming affects the development and distribution of sea ice, but at present the evidence of polar ecosystem feedbacks on climate through changes in the atmosphere is sparse. By means of synergistic atmospheric and oceanic measurements in the Southern Ocean near Antarctica, we present evidence that the microbiota of sea ice and sea ice-influenced ocean are a previously unknown significant source of atmospheric organic nitrogen, including low molecular weight alkyl-amines. Given the keystone role of nitrogen compounds in aerosol formation, growth and neutralization, our findings call for greater chemical and source diversity in the modelling efforts linking the marine ecosystem to aerosol-mediated climate effects in the Southern Ocean.
Long-term Measurements of CO₂ Flux over Sea Ice in the Canadian Arctic

Brian Butterworth¹ (brian.butterworth@ucalgary.ca), Brent Else¹, Shawn Marriott¹

¹University of Calgary, Geography, Calgary, Canada

The Arctic marine environment plays an important role in the global carbon cycle. However, there remain large uncertainties in how sea ice, in particular spring melt and autumn freeze-up, affect air-sea fluxes of carbon dioxide (CO₂). To test the impact of these ice regimes, measurements of CO₂ flux (as well as momentum, sensible and latent heat) were collected from a 10 m eddy covariance tower installed on Qikirtaarjuk Island (a small rock outcrop in the Dease Strait located roughly 35 km southwest of Cambridge Bay, Nunavut in the Canadian Arctic). The study area exhibited open water in the summer and full sea ice cover in the winter months, making it possible to study the transitional ice periods in the spring and autumn. The system incorporated recent developments in the field of air-sea gas exchange by measuring CO₂ mixing ratio using a closed-path infrared gas analyzer system with a dried airstream, thus avoiding the known water vapor issues associated with using open-path gas analyzers in low flux environments. The results from one year of continuous flux measurements will be shown, highlighting the seasonal trends in gas exchange and comparing flux magnitudes during melt and freeze-up to those found in laboratory experiments and previous field studies.
Changes in Heat Content and Melt-water at Maxwell Bay, King George Island

Pedro J. Llanillo¹ (pedro.llanillo@usach.cl), Christopher M. Aiken², Raul R. Cordero¹, Alessandro Damiani³, Edgardo Sepulveda¹, Kyu-Cheul Yoo⁴, Hoil Yoon⁴

¹Universidad de Santiago de Chile, Santiago, Chile, ²Pontificia Universidad Católica, Santiago, Chile, ³Chiba University, Chiba, Japan, ⁴Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of

Ocean processes controlling the oceanic heat flux to the ice face of Antarctic tidewater glaciers are crucial to understand the reduction of the Antarctic ice-shelves. With the support of Instituto Antártico Chileno (INACH), we carried out a field campaign in Maxwell Bay, King George Island, in February 2016. These measurements provided a valuable dataset of current oceanographic conditions, which we compared with the oceanographic conditions measured in a previous campaign carried out by the Korea Polar Research Institute (KOPRI) in December 2000. From that comparison, we found warming and freshening of the upper part of the water column in Maxwell Bay. These hydrographic changes might be explained by the intra-seasonal cycle (February versus December) or might be due to interdecadal changes (i.e. an increased penetration of warmer subsurface waters into the Maxwell Bay area and an increased freshwater input from the surrounding tidewater glaciers). The origin of these changes will be discussed in the light of the new measurements to be obtained during our next field campaign in December 2017.
Processes affecting the surface state of the Labrador Sea are of wider interest due to its role as a site of water mass formation. Sea ice can modify the surface state; however, the processes by which its variability is forced are unclear in this region. Motivated by this, the mechanisms responsible for the interannual- to decadal-scale variability of the Labrador Sea ice in winter are analysed, drawing on observations, an ice-ocean model, and a fully-coupled simulation from the CMIP5 archive. A coherent series of mechanisms is found in all cases. The highest values of sea ice area occur when the northern Labrador Sea is ice covered. The sea ice in this region is found to be primarily thermodynamically forced, with growth occurring in response to anomalously fresh surface conditions. Positive freshwater anomalies propagate rapidly to the region from a source area off the southeast Greenland coast and originate from sea ice melt, associated with the enhanced offshore transport of sea ice here. The sea ice transport is in turn driven by local atmospheric wind conditions, which are strongly correlated with Greenland blocking. A further link is found both with the sea ice transport through the Denmark Strait in the preceding autumn, representing a dependence on the availability of sea ice to be melted, and also, at longer time scales, with the Atlantic Multidecadal Oscillation, suggesting a multidecadal-scale link to wider sea surface temperature conditions.

Heat Loss Variability and Subantarctic Mode Water at Southern Ocean OOI Mooring

Sarah Ogle¹, Veronica Tamsitt², Simon Josey³, Sarah Gille², Ivana Cerovecki², Lynne Talley² (ltalley@ucsd.edu)
¹Carleton College, Northfield, United States, ²University of California San Diego, Scripps Institution of Oceanography, La Jolla, United States, ³National Oceanography Centre, Southampton, United Kingdom

The Ocean Observatories (OOI) air-sea flux mooring, deployed in February 2015 at 54S, 90W, in the southeast Pacific sector of the Southern Ocean, is the furthest south open ocean mooring ever deployed. Observations analyzed here (Feb 2015-Aug 2017) provide the first accurate quantification of the annual cycle of net air-sea heat exchange and the wind stress from one of the prime Subantarctic Mode Water (SAMW) formation regions. We find that extreme turbulent heat loss events reaching a daily mean of -290 W m⁻² promote the formation of deep winter mixed layers up to 600 m deep. Extreme heat loss events are associated with winds from the southwest bringing relatively cold, dry air to the mooring location leading to large air-sea temperature and humidity differences. There is large interannual variability in the frequency of wintertime extreme heat loss events and associated mixed layer deepening, with strong heat loss in winter 2015 and weak heat loss in 2016. These results have important implications for the role of turbulent heat loss in Subantarctic Mode Water (SAMW) formation.
Observations of Significant CO₂ Uptake in Antarctic Polynyas

Tae Siek Rhee¹ (rhee@kopri.re.kr), Christopher J Zappa², Young Shin Kwon¹, Taejin Choi¹, Eun-Jin Yang¹, Ji Hee Kim¹

¹Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of, ²Lamont-Doherty Earth Observatory of Columbia University, Ocean and Climate Physics, Palisades, United States

We present the first direct observations of ocean and atmospheric pCO₂ measured at the Korean Antarctic base, Jang Bogo, locating near the Terra Nova Bay (TNB) polynya in the Ross Sea since February, 2015. The TNB polynya opens a small area (~1000 km²) in the winter. In contrast, the area exposed to the atmosphere in the summer is greater than 8 times the winter polynya, therefore, significantly enhancing air-sea gas exchange. The pCO₂ in seawater swung from ~120 matm in February to ~425 matm in early October. In November, the pCO₂ suddenly dropped as much as ~100 matm in a week. This decrease of pCO₂ continued until late February when the sea-ice concentration was minimal. With growing sea ice, the pCO₂ increased in parallel catching the atmospheric concentration in June/July, depending on the year, and continued to increase until October. Daily mean of air-sea CO₂ flux in the TNB polynya widely varied from ~70 mmol m⁻² d⁻¹ to ~20 mmol m⁻² d⁻¹. Based on these observations of pCO₂ in the TNB polynya, the annual uptake of CO₂ came up with ~9 g C m⁻², which takes into account the fraction of sea-ice concentrations estimated from AMSR2 microwave emission imagery. Extrapolating to all polynyas surrounding Antarctica, we expect the annual uptake of ~ 9.5 Tg C of CO₂ from the atmosphere. This is comparable to the amount of CO₂ degassed into the atmosphere south of the Antarctic Polar Front (62°S).
Petermann Glacier, one of the largest marine-terminating glaciers of Greenland, loses the majority of its mass through basal melt by the comparatively warm ocean. The fate of this meltwater is virtually unknown, for it circulates more than 100 m below the surface and cannot easily be monitored. Ocean surface currents and sea ice drift in contrast can be retrieved continuously through satellite remote sensing. We here investigate whether remote sensing monitoring of the meltwater layer could be possible.

Using an MITgcm simulation validated by a unique new dataset of surface drifters and hydrographic profiles from the I/B Oden Petermann2015 expedition, we quantify the relationship between the surface currents and the circulation of the meltwater in Petermann Fjord and surrounding Nares Strait. A series of sensitivity experiments determines whether this relationship is most pronounced in specific wind and/or sea ice conditions.

Year-round monitoring of glacial meltwater flows around Greenland, and ultimately into the North Atlantic, is a prerequisite to understand the particular role of meltwaters on the global ocean circulation.
We identify a spring atmospheric Pacific-Arctic mode (PAM) and investigate its connections to summer Beaufort Sea ice. PAM is the second EOF mode of seasonal sea level pressure poleward of 20°N with a variance of 12%. A positive PAM has a negative anomaly in the subpolar Pacific and positive anomalies in the Beaufort-Chukchi region of the Arctic and the midlatitude Pacific, exhibiting an intensified Aleutian Low and North Pacific High, and a northward displaced Beaufort Sea High. PAM is associated with the distribution of cyclone activity and tracks and warm (polar) air advection due to modulation of the tropospheric circulation anomalies associated with the East Asian trough and the Pacific side of the polar vortex. PAM accounts for 16% of the internal variability of the following September Beaufort sea ice coverage. A positive PAM leads to increased open water days in the Beaufort Sea during spring and summer. During positive PAM, strong easterly winds in the Beaufort Sea enhance ice advection and reduce ice thickness, due to the associated intensified and northward extended Aleutian Low. Moreover, the increased solar radiation further accelerates ice melt, due to reduced cloud cover and water content associated with fewer cyclones in the Beaufort Seas. Thinner ice and increased open water foster a stronger summer ice-albedo feedback resulting in accelerated early-summer ice melt. PAM is a potential predictor for Beaufort Sea ice melting.
Evaluation of Wind Products with Wave Glider Observations in the Southern Ocean

Sebastiaan Swart\textsuperscript{1} (sebastiaan.swart@marine.gu.se), Kevin Schmidt\textsuperscript{2}, Chris Reason\textsuperscript{2}, Sarah Nicholson\textsuperscript{3}

\textsuperscript{1}University of Gothenburg, Marine Sciences Department, Gothenburg, Sweden, \textsuperscript{2}University of Cape Town, Cape Town, South Africa, \textsuperscript{3}CSIR, Cape Town, South Africa

Surface ocean wind datasets are required to be of high spatial-temporal resolution and precision to accurately force or be assimilated into coupled numerical models and to understand ocean-atmospheric processes. In situ observed surface winds from the Southern Ocean are scarce and, consequently, the validity of models is often questioned. Multiple wind products were compared to the first high-resolution in situ measurements of wind speed from Wave Glider (WG) deployments in the Southern Ocean to determine which blended product best represents the magnitude and variability of the observed wind field. Results show that the ECMWF product is the most accurate in representing the temporal variability of winds, exhibiting consistently higher correlation coefficients with in situ data across all wind speed categories. However, NCEP-II Reanalysis matches in situ trends of deviation from the mean and performs best in depicting the mean wind state, especially at high winds. ECMWF also leads to smaller differences in wind speeds from the in situ data, while CFSv2 showed higher biases and a greater RMSE. The SeaWinds (SW) product performed poorly at representing the mean or wind stress variability compared to WG observations. Overall, the study shows autonomous surface vehicles provide valuable observations by which to validate, understand, and potentially assist in correcting satellite/reanalysis products, particularly in remote regions, where few in situ estimates exist.
Factors Controlling Water Mass Variations over the Chukchi Borderland, Arctic

Kyoung-Ho Cho¹ (kcho@kopri.re.kr), Young-Seok Choi¹, Eri Yoshizawa¹, Sung-Ho Kang¹
¹Korea Polar Research Institute, Incheon, Korea, Republic of

We have carried out hydrographic surveys since 2010 to monitor the Pacific-origin waters over the Chukchi Borderland (CBL) in the western Arctic Ocean. Based on CTD data analysis, the heat content from the Pacific Summer Water (PSW) is highly correlated with sea ice extent reduction over the region. Yearlong mooring and numerical simulation data are analyzed to verify what factors lead the PSW variation. We found two factors controlling the variation of PSW over the region: variation of summer waters incoming through the Bering Strait (BS) and variation of local winds over the East Siberian Sea (ESS) shelf. Temporal variation of PSW temperature over CBL is in-phase with that of the Alaskan Coastal Water (ACW) temperature even if there is a time lag. Relatively cold water over the ESS shelf is transported to the CBL by local winds and subducted into the PSW layer by the thermohaline intrusion.
Remote in situ Measurements of Sea Ice Evolution

Rachel Obbard¹ (rachel.w.obbard@dartmouth.edu), Alice Bradley¹, Ignatius Rigor², Jim Johnson²
¹Dartmouth College, Thayer School of Engineering, Hanover, United States, ²University of Washington, Applied Physics Laboratory, Seattle, United States

We present the results of field experiments in Elson Lagoon (Utqiaġvik, Alaska), designed to test our ability to remotely monitor the onset of freezing, freezing rate and ice type in natural sea ice in real time. Two Microstructure in situ Salinity and Temperature (MIST) buoys were launched in open water in October 2017 and allowed to freeze into the developing sea ice. Each buoy carried two vertical arrays of wire harps (Notz, Wettlaufer and Worster, 2005), developed to make in situ measurements of salinity and solid fraction profiles in growing sea ice. The technique measures temperature and impedance as sea ice grows downward across regularly spaced wire pairs, and is based on the principle that pure solid ice is a good insulator whereas interstitial saltwater brine is a good conductor. Impedance and temperature data, along with air temperature, GPS location, and buoy tilt was transmitted hourly via iridium. Salinity of the interstitial brine was inferred from the liquidus relationship (Cox and Weeks, 1986) and combined with the measured solid mass fraction to give the time resolved bulk salinity profile of the growing sea ice.

We examined the sea ice growth process and the effect of changes in surface temperature and salinity on growth rate and microstructure. To interpret the data, we also conducted laboratory experiments on heat transfer in sea ice using the ICE-MITT, a purpose built refrigeration system that holds ice cores at user-defined temperature gradients.
Modeling the Formation and Persistence of an Open Ocean Polynya

Gustavo Marques¹ (gmarques@ucar.edu)
¹National Center for Atmospheric Research (NCAR), Climate & Global Dynamics, Boulder, United States

The recent appearance of the Weddell Polynya has motivated the need for a better understanding of this phenomenon. Climate models must be able to represent this phenomenon correctly, since it has the potential to affect bottom water formation and, therefore, impact the large-scale ocean circulation. The initial development of the Weddell Polynya has been explained by interactions between the large-scale oceanic flow and a seamount (Maud Rise). However, the environmental conditions necessary for the persistence of the polynya remain elusive. Here, we use numerical simulations in idealized geometric configurations to investigate how changes in atmospheric forcing and model parameters (e.g., grid resolution, boundary layer scheme and vertical coordinate) impact the formation, propagation and persistence of an open ocean polynya. The experiments are conducted using an ocean model (MOM6) coupled with a sea ice model (SIS2). We show that the formation and persistence of the polynya is strongly influenced by surface buoyancy fluxes. The threshold in buoyancy gain above which the polynya does not form varies depending on model parameters. Our results provide insights into the model parameters necessary to correctly represent an open ocean polynya in climate models.
The Arctic Ocean is cold, stratified and sea ice covered due to the presence of a cold and relatively fresh upper layer, here called the Arctic layer, which suppresses direct influence from the subsurface layer of warm and saline Atlantic Water below (the Atlantic layer). It is largely unknown if, how and to what extent heat and salt is transferred up from the deep Atlantic layer.

Based on an extensive observational hydrographic data set covering the northern Barents Sea from 1970-2016, we find that there is considerable vertical mixing of heat and salt between the Arctic and Atlantic layers, causing year-to-year variations in the Atlantic layer temperature. We show that the Arctic layer salinity largely controls the stratification, vertical mixing and upward heat and salt fluxes from the Atlantic layer.

Our findings demonstrate that vertical mixing between the Arctic and Atlantic layers is key to the Arctic environment, as it controls the rate of heat transfer from the deep Atlantic layer towards the surface, where it can influence sea ice concentration and lower troposphere temperatures. The corresponding upward salt flux constitutes a positive feedback, as increased salinity in the Arctic layer will weaken the stratification and enhance the mixing. This positive feedback mechanism is likely operating in larger parts of the Arctic Ocean, emphasizing the need for monitoring the changes in the water column to understand and predict the rapid climate transition in the Arctic.
Climate warming affects the development and distribution of sea ice around Antarctica and its associated ecosystems, but at present the evidence of feedbacks on climate through ecosystem-derived changes in the atmosphere is sparse. The PEGASO cruise visited the Antarctic region of the South Orkney Islands at the northern edge of the Weddell Sea, and the Subantarctic region of the South Georgia Island, in summer 2015. Each region was studied intensively in lagrangian mode over a few days and diel cycles. Oceanic measurements of plankton abundance, diversity, activity and physiology, plus organic matter characteristics, aerosol-forming organic volatile compounds (dimethylsulfide, methylamines, isoprene, halomethanes) and nutrient concentrations, were compared with simultaneous atmospheric measurements of aerosol numbers, size and composition. Samples of surface seawater and melted sea ice were bubbled in an aerosol-generation tank and the characteristics of the sprayed aerosol were monitored. This integrated study allowed to link phytoplankton bloom stages and the emission of aerosol-forming particulate and gaseous substances. Our findings call for greater chemical and source diversity in the modeling efforts linking the marine ecosystem to aerosol-mediated climate effects in the Southern Ocean.
Lake Bonney, in Taylor Valley, has two distinct lobes separated by a relatively shallow sill in a narrow channel referred to as the Bonny Narrows. Robert Falcon Scott passed through the Bonney Narrows in 1903 on his first expedition in the area, and made a measurement of the channel’s width that has been used to estimate lake level at the time in order to extend our lake level record for Lake Bonney to well over 100 years now. Lake level has risen between December 1903 and January 2017 by ~16 m, on average 0.14 m/yr. The sill depth was at most a meter deep during Scott’s visit and the two lobes had only joined in the years prior to Scott’s visit. Photographs taken by Griffith Taylor’s party on Scott’s second expedition show that there was a dramatic lake level rise between 1903 and 1911 of almost 3 m. The sill is now an important physical control of the geochemistry and ecology of the two lobes. West Lake Bonney (WLB) has a hypersaline brine bottom water which is held back from East Lake Bonney (ELB) by the sill. The brine is displaced over the sill, by a mechanism referred to as “chemocline leakage”. The brine sinks on the ELB side following a former river channel until it finds its neutral buoyancy in ELB, about 4 to 5 m below the sill depth. In this presentation, I will review the history of the connectivity between the two lobes of Lake Bonney as indicated by geochemical proxies and physical evidence collected from the lake surface and through recent diving operations.
Air Temperature in Franz Josef Land Archipelago from 1899 to 1940

Przemysław Wyszyński¹ (przemyslaw.wyszynski@umk.pl), Rajmund Przybyłak¹

¹Nicolaus Copernicus University, Department of Meteorology and Climatology, Toruń, Poland

The results of an investigation into the air temperature conditions in Franz Josef Land Archipelago (FJL) from 1899 to 1940, on the basis of all available early instrumental data gathered during exploratory and scientific expeditions, are presented. Traditional analysis based on mean monthly data was supplemented by an approach less popular in the scientific literature, i.e. the additional use of daily data (MAX, MEAN, MIN, DTR). Such rich sets of data allowed for more comprehensive and precise recognition of air temperature conditions in the FJL. Based on these kinds of daily data, it was also possible to calculate the number of so-called 'characteristic days' (i.e. the number of days with temperatures exceeding specified thresholds) and day-to-day temperature variability and, for the first time, to determine different characteristics of thermal seasons (duration, onset and end dates). The results were compared with contemporary temperature conditions (climate normals 1961-1990 and 1981-2010) to estimate the range of their changes between historical and present times.

The research work was supported by a grant entitled 'Causes of the early 20th century Arctic warming', funded by the National Science Centre, Poland (Grant No. 2015/19/B/ST10/02933) and a grant entitled 'Variability of the Russian Arctic and Subarctic Climate in the Last Three Hundred Years', funded by the National Science Centre, Poland (Decision No.DEc-2012/07/B/ST10/04002).
Mapping the Dispersion of Airborne Microorganisms in Byers Peninsula, Antarctica

Ana Justel¹ (ana.justel@uam.es), Lucas Fernández Piana²,³, Julio Rodríguez⁴, Marcela Svarc²,³, Sergi González⁵, Francisco Vasallo⁶, Pablo Sanz⁷, Antonio Quesada⁸

¹Universidad Autonoma de Madrid, Department of Mathematics, Madrid, Spain, ²Universidad de San Andres, Department of Mathematics and Science, Buenos Aires, Argentina, ³CONICET, Buenos Aires, Argentina, ⁴Universidad Autonoma de Madrid, Department of Economical Analysis, Madrid, Spain, ⁵Spanish Meteorological Agency (AEMET), Barcelona, Spain, ⁶Spanish Meteorological Agency (AEMET), Cádiz, Spain, ⁷Universidad Autonoma de Madrid, Scientific Computing Center, Madrid, Spain, ⁸Universidad Autonoma de Madrid, Department of Biology, Madrid, Spain

A new unsupervised classification method is proposed for exploring dispersal and colonization capacity of microorganisms in Antarctica with a large multivariate functional data set, which includes more than 88M observations from a combination of geographic positioning and meteorological variables. Definitions of the appropriate distance and standardization are crucial and is done taking into account the nature of the data as functions. The method is applied to clustering back-trajectories arriving to Byers Peninsula (Livingston Is, Antarctica) to establish the dispersal capability of microorganisms susceptible of colonizing newly exposed locations in a climate change scenario. Twelve years of 5-day back trajectories every six hours, computed with the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model, are clustered in groups that circulate in nearby regions, regardless of the moment they pass, and with similar environmental conditions (temperature, humidity, etc.). Main air transport patterns capture seasonal differences and rare events that influence in the microorganism viability, but do not take into account the speed at which propagules move. Another set of trajectories passing over Byers Peninsula and with origin in some of the terrestrial regions near Antarctica, are considered. The two clusters combination provides a map of airborne microorganism dispersion to be associated to in-situ captured propagules.
Modern climate models have long standing problems with the representation of cloud that result in large radiative biases over many regions of the globe, such as the Southern Ocean. To investigate these issues, cloud regimes are derived from satellite data and then compared to model output. In particular, cloud top pressure - cloud optical thickness joint histograms from the Moderate Resolution Imaging Spectroradiometer (MODIS) satellite are clustered using the self organizing maps (SOMs) clustering methodology. This results in the identification of 12 distinct cloud regimes from the MODIS data. These regimes were then used to cluster output from the HadGem3 GA7 atmosphere only model. This allowed for comparisons between the behaviour of the regimes in observational data and in model output to be undertaken. These comparisons initially focused on the rate at which a given regime occurs and how that occurrence rate changes between different regions. Further analysis investigated the mean cloud properties associated with a given regime. One of these properties was the cloud radiative effect (CRE) derived from CERES satellite observations, these are then compared with model output for each of the identified regimes. The overall CRE bias within the model was then attributed to each of the regimes, clearly identifying which regimes caused the largest problems in the model. This approach was also extended to other variables such as cloud phase and aerosol optical depth.
According to the description, this session aims at bringing together different communities of data users and emphasizes the integration of data and information from various sources and disciplines. However, before these goals of data integration across disciplines can be achieved, the data should be made available. The data from polar research should be easily findable for all users, should be accessible without impeding barriers, should be interoperable to allow data to be used in different applications and should be reusable to enable new, interdisciplinary science. In short, the data should be FAIR.

Fortunately, since about two decades, international groups of data managers have been building global data access infrastructures, which implement these FAIR-principles and cover most data types and all disciplines in the polar regions. A few examples are the systems built by SCAR’s Standing Committee on Antarctic Data Management (SCADM), by the Sustainable Arctic Observing Network (SAON) and by the Southern Ocean Observing System (SOOS).

This presentation will provide a comprehensive overview of the existing data access infrastructures in all disciplines. It will also address the current, joint effort by SCADM, SOOS and the Arctic Data Committee (ADC) to develop a federated search mechanism across existing infrastructures, linking these infrastructures to one point of entry and allowing users to re-use data which are easily findable, accessible and interoperable.
A Comparison of ISCCP D and ISCCP H Clouds over the Southern Ocean using SOMs

Simon Parsons¹, Adrian Mcdonald¹ (adrian.mcdonald@canterbury.ac.nz), Alex Schuddeboom¹
¹University of Canterbury, School of Physical & Chemical Sciences, Christchurch, New Zealand

Clouds play an important role in the global energy budget, with strong regional variations in cloud cover evident. One region of concern is the Southern Ocean, due to a short wave (SW) bias in the cloud radiative effect (CRE) from climate models when compared to satellite observations. This long standing problem is compounded by a sparse observational record in that region, other than satellite observations, which makes identification of the specific drivers of these biases difficult to determine. We use satellite data to compare with model output and test new methodologies for classifying the data to gain quantitative metrics which can help to identify particular model issues.

The International Cloud Climatology Project (ISCCP) was established to improve the understanding of clouds and their role in the climate system. Cloud top pressure and optical depth joint histograms from the ISCCP D1 dataset have been used with the Self-Organising Map (SOM) data mining methodology to determine 15 cloud regimes. The ISCCP D1 data set ended in 2009 and has been recently superseded by ISCCP H. This study presents a comparison between the ISCCP D1 and ISCCP H datasets which is undertaken using SOMs. The relative frequency of Occurrence (RFO) and total cloud fraction (TCF) of these cloud regimes are determined, with regards to the Southern Ocean. We also compare these two satellite datasets against results from the COSP satellite simulator applied to output from the HadGem3 GA7 model.
Even after a number of targeted field expeditions and improved satellite coverage, the polar ocean observations remain sparse and time series short. Given these circumstances, one could argue that reanalysis descriptions of polar oceans are the most complete ones. Therefore global and regional ocean reanalysis products (ORAs) are increasingly used in polar research, but their quality remains to be systematically assessed. To address this, the Polar ORA Intercomparison Project (Polar ORA-IP) has been established following on from the ORA-IP project. Several aspects of ten selected ORAs in the Arctic and Antarctic were addressed by concentrating on comparing their mean states in terms of snow, sea ice, ocean transports and hydrography. Most polar diagnostics were carried out for the first time for an extensive set of ORAs. In this presentation we focus on liquid ocean diagnostics, while Lovino and co-authors present sea-ice diagnostics. For the multi-ORA mean state, we found that deviations from observations were typically smaller than individual ORA anomalies, often attributed to offsetting biases of individual ORAs. The ORA ensemble mean therefore appears to be a useful product and, while knowing its main anomalies and recognising its restrictions, it can be used to gain useful information on the physical state of the polar marine environment.
Inside archives of polar research institutions records are preserved with historical scientific data. Taking the example of the Archive for German Polar Research (AGPR) of the Alfred-Wegener-Institute this talk will show

- what kind of records from polar research contexts contains scientific data,
- how these holdings found their way into the AGPR,
- how they are there conserved, preserved and described for a future use by scientists,
- what kind of efforts are made to provide the accessibility of these data for the scientific community and
- how far the cooperation between archives and data repositories is developed.

All these questions are discussed in the context of the history of archiving German polar Research and the AGPR’s tasks, resources and contents. Even the legal frame, the tradition of archival work and the archival organization and networks in Germany are considered.
We compare the statistics of surface wind regimes in reanalyses, general circulation models and remotely sensed observations using cluster analysis. In particular, we use the Self Organizing Map and k-means clustering approaches to identify representative wind regimes over the Ross Sea. These regimes are derived from reanalysis output from the ERA-20CM ensemble and the 20th Century Reanalysis version 2 ensemble. We then compare these patterns with the Coggins types which are derived from ERA-Interim reanalyses using a k-means scheme. The frequency of occurrence of specific patterns for the different ensemble members and the two different reanalyses are used to identify uncertainties in these occurrence rates, also comparing to the Coggins types. Variations in the frequencies derived as a function of time are also examined to identify trends in the surface winds over the Ross Sea. We then validate the representativeness of the various regimes relative to observations of surface wind velocity from the WindSat dataset and surface weather stations over a subset of the reanalysis period. We also examine whether frequencies derived from CMIP5 model output over the historical period compares with the reanalyses derived frequencies. Finally, we decompose the differences observed between the reanalyses derived patterns and the model output derived patterns into pattern variations and frequency changes to gain a greater understanding of the reasons for the observed differences.
Digitization and Analysis of the SPRI-NSF-TUD Radar Data Archive

Emma J. MacKie¹ (mackie3@stanford.edu), Dustin M. Schroeder¹, Julian A. Dowdeswell³, Katherine I. Vega¹, Matthew R. Siegfried¹, Winnie Chu¹, Robert G. Bingham⁴

¹Stanford University, Department of Geophysics, Stanford, United States, ²Stanford University, Department of Electrical Engineering, Stanford, United States, ³University of Cambridge, Scott Polar Research Institute, Cambridge, United Kingdom, ⁴University of Edinburgh, School of Geosciences, Edinburgh, United Kingdom

Between 1967 and 1979, airborne RES surveys were taken of Antarctica in a collaboration between the Scott Polar Research Institute (SPRI), the National Science Foundation (NSF), and the Technical University of Denmark (TUD), known as the SPRI-NSF-TUD surveys. These 400,000 km of surveys are the oldest observations of internal and subglacial features in Antarctica and provide the opportunity for comparison with modern RES campaigns in order to study temporal changes in the ice sheet over the last 50 years. However, the SPRI-NSF-TUD survey was recorded on 35 mm film and the resolution of existing prints makes it difficult for such comparisons to be made. We used Hollywood film scanning equipment to digitize this collection and obtain over two million high resolution images. We elaborate on the methods used to digitize and position this data and present our observations of features including internal layers, volcanic ash layers, subglacial channels, accretion plumes, grounding lines, and subglacial lakes. These are interpreted in the context of glaciological and geological processes.
Training a Machine Learning Model to Find Polar Data on the Web

Siri Jodha Khalsa¹ (sjsk@nsidc.org), Ruth Duerr², Chris Mattmann³, Karanjeet Singh⁴, Simin Ahmadi Karvigh⁵, Omid Davtalab⁵

¹University of Colorado Boulder, CIRES/National Snow and Ice Data Center, Boulder, United States, ²Ronin Institute, Boulder, United States, ³NASA, JPL, Pasadena, United States, ⁴University of Southern California, IRDS, Los Angeles, United States, ⁵University of Southern California, Los Angeles, United States

Increasing amounts of data about the polar environment are being made available on the Web. This includes the huge volumes of data coming from Earth observing sensor systems but also smaller, unique data sets from individual investigations, modeling experiments and data rescue operations. While finding these data in well-curated major repositories is straightforward, finding data that is published in journal papers, posted to investigators' websites or appearing in blogs is much more challenging. The "Polar Deep Insights" project, funded by the United States (US) National Science Foundation (NSF), is developing polar-specific indexing and search paradigms for improved content discovery, information extraction and exploration, while extending search capabilities to the deep web and nontraditional (e.g. multimedia) content. These next-generation search technologies are making it possible to understand people, places, things and the connections between them through analysis of unstructured text as well as online images, videos, web pop-ups, online forms, web scripts and other ways information is presented on the web. Interactive tools make it possible for domain experts to construct machine-learning (ML) models used by the crawler to identify web content of potential interest. In this presentation we give an overview of the project and provide example applications whereby historical information about the polar regions is made findable.

Historic Antarctic Peninsula Maps and Diary Accounts Linked to GIS Data Bases

Wolfgang Rack¹ (wolfgang.rack@canterbury.ac.nz), Ursula Rack¹
²University of Canterbury, Gateway Antarctica, Christchurch, New Zealand

The north-eastern side of the Antarctic Peninsula was scientifically explored from 1901-03 by the Swedish Antarctic expedition under Otto Nordenskjoeld. From this expedition originate a number of maps which show and illustrate in combination with diary accounts the state of the environment at the turn form the 19th to the 20th century. We relate the maps and described locations to present day satellite data and observations. This is achieved by a semi-automatic process identifying features in the drawings, diaries, and images. We interpret the expedition accounts based on our comparison, and we try to better identify features based on diary entries. Our result gives new insight in the outstanding observational achievements of the time, and in environmental change in space and time since then. We focus on changes in the cryosphere by confining past snow and ice areas as a baseline for climate change studies.
Both polar regions in themselves and taken together are characterized by the existence of a set of closely intertwined epistemic communities with a strong natural science core interacting with political, economic, and legal actors and systems (and, to a lesser degree, the social sciences). These epistemic communities do not participate in one, but in a range of partly overlapping but distinct discourses, contributing to providing sometimes overlapping, sometimes diverging cognitive frames that allow different kinds of actors to address the Arctic and/or the Antarctic as relevant objects within their respective discursive settings. Recursively, these discourses frame research priorities, political agendas, as well as the evolution and density of research communities.

The proposed paper will at first elaborate on the relation between epistemic communities and the evolution of cognitive frames conceptually. In a second step it will provide some illustrations particularly pertaining to the Arctic, demonstrating how various cycles of cognitive framing are connected to shifting (geo-)political representations. A final section will sketch a research project that aims at studying natural science research communities as core contributors to epistemic communities.

Stable Isotopes Meet Shakespeare: Antarctic Science in Literature

Johanna Grabow\textsuperscript{1,2} (johanna.grabow@gmx.de)
\textsuperscript{1}Leipzig University, Institute of British Studies, Leipzig, Germany, \textsuperscript{2}Scott Polar Research Institute, University of Cambridge, Cambridge, United Kingdom

Antarctica has undergone a shift from Terra Australis Incognita to the continent for science and a global laboratory. Yet it has also encouraged authors to fill the icy wastes with their own ideas, stories, dreams and visions. Literature and the science dealing with Antarctica, however, do not have to exist in mutually exclusive worlds; they can co-operate and benefit from each other.

This paper aims to discern how Antarctic science has inspired and been depicted in the literary output from the seventh continent - and how literature can in turn inspire science. From underwater lakes to remote sensing and ice core drilling, scientific projects populate the written page. Dystopian scenarios of climate change and highly spectacular findings are just as well fictionally played out as well-researched and detailed descriptions of scientific processes. These texts can be produced by literary inclined scientists, but most often they stem from authors interested in the subject matter and consequently wanting to engage their readership in the discourse.

I will look at the forms and functions these excursions into the world of science have in literature. Antarctic literature can bring both the science and the continent it is conducted on closer to the rest of the world. In short, science and literature should work together to promote Antarctica, its values, fragility and importance to a wider audience.
The creation of objects and imagery is a fundamental aspect of human intellect and expression. Though the cultural diversity of artistic expression is vast, a common thread is the compulsion to create and communicate. In Antarctica where there is no indigenous population and no indigenous cultural production is there value in importing cultural expression and representation? And if so, what is the value of artists’ presence?

Since the earliest days of Antarctic exploration visual artists were essential members of expedition teams. They had a valuable role in documenting topography, flora, fauna, expedition activities and environmental conditions for purposes specific to science, navigation, sovereignty claims and fundraising. With the development of photography, visual arts have evolved and diversified to offer ways of viewing and understanding Antarctica beyond documentary representation.

Visual artists from many countries continue to secure passage to Antarctica. Several national Antarctic programmes support artist residencies. The diversity of Antarctic arts production is wide having evolved out of different socio-cultural and political histories over hundreds, even thousands, of years. This paper will discuss methods to assess the value of artists working in Antarctica. Preliminary findings show that diverse cultural and artistic responses to Antarctica advance human understanding of and relationships with the continent and the wider world.
Methodological Challenges of Participant-produced Video Diaries in Antarctica

Meredith Nash¹ (meredith.nash@utas.edu.au), Robyn Moore¹
¹University of Tasmania, Sociology, Hobart, Australia

Although participant-produced videos provide many methodological benefits, this critical reflection provides fellow researchers with insights into the challenges faced when using such methods in a remote polar environment. To do so, we draw on our study of a leadership program for women in STEMM conducted on a ship in Antarctica. The remote location of this study raised methodological beyond the routine issues associated with video diaries. For instance, we discuss methodological challenges that arose throughout the research period including managing the burden of research participation in Antarctica, underestimating participant technological skills, lack of privacy and time to make videos, and data loss. To conclude, we highlight implications for using participatory video methods in other remote settings.
Helplessness in Antarctica: A Psychanalytic Approach on the Social Bonding

Michele Moraes¹, Rosa Arantes¹ (rosa@icb.ufmg.br)
¹Universidade Federal de Minas Gerais, Neuro-Immunopathology Laboratory, Belo Horizonte, Brazil

Here we reflect on the feeling of solitude and helplessness that silently permeates the sense of union among people in the Antarctic expeditions, based on our own experiences in Antarctica field and in interviews with other participants of diverse nationalities. It is our interest to discuss the individual's experiences in Antarctica focusing in helplessness, under the view of psychanalysis. One aspect is related to the features of Antarctica living condition and the singular socialization processes to deal with the threatening environment, the confinement and precarious condition of life. Helplessness, according to its theoretical development in psychoanalytic theory emphasizes its origin in the human newborn immaturity and impotence to deal bodily and psychically with the life demands. This helplessness emerges in Antarctic context as a sense of profound solitude, impotence against the nature and dependence on the others. Our civilization was built as a strategy to diminish our impotency against nature forces, life enigmas and our own death. We propose that in isolated and threatening situation such as experienced in Antarctica, the reduction of narcissistic defenses exposes the subject to a profound feeling of solitude and helplessness, as well as to a prominent anguish by depending on the others. The helplessness inaugurates the need of the other, the ability to desire, and the construction of social bondage that affects so many antarcticians and their discourses.
Human and Social Capacity of the Arctic Region of Neo-industrial Development

Marina Belonozhko1 (mlb@inbox.ru), Svetlana Siteva1, Alexander Gyurjinyan1

1Industrial University of Tyumen, Department of Marketing and Public Administration, Tyumen, Russian Federation

The beginning of the new stage of industrial development of the Russian Arctic, the implementation of a large-scale investment projects (oil and gas development, the construction of plants for the production of liquefied natural gas) actualized the problem of the demand of human resources with the required qualification and absence of social infrastructure.

The authors, on the basis of many years studying of the social situation in the Tyumen North, conducted a complex study of the human capacity required for the successful implementation of the planned investment projects.

Human capacity was considered not only as a recruitment opportunity to develop the Arctic region, but also as the formed actual capabilities of the personnel, demanded and necessary for the practical solving of specific tasks. First of all, these are the following interrelated indicators: socio-demographic characteristics of the quantity and quality of people who intend to live and (or) work in the Arctic; their professional competences; their physical, mental and social health, which are taken in the scales of the sociological dimension.

The results of the mass surveys of northerners and in-depth interviews of experts on polar issues are presented differentially in the context of four social groups of neo-industrial development: old residents of the Northern region, with the exception of the indigenous peoples of the North; representatives of indigenous ethnic groups; new residents; shift workers.

Antarctic Legacy of South Africa (ALSA): Past Decade, Approaches and Challenges

Ria Olivier1 (riaolivier@sun.ac.za)
1Stellenbosch University, Botany and Zoology, Stellenbosch, South Africa

Is there a place for an entity as ALSA within a South Africa National Antarctic Programme (SANAP) as well as the global Antarctic environment? This presentation will look at the activities of ALSA for the past decade and how it evolved to be an essential part of SANAP. The project has faced many challenges on different levels to maintain sustainability. The role that the ALSA has played in the past decade within the research community will be outlined. The importance of keeping record of human activity in the Antarctic region will be emphasised and how the project is preserving these records of human contribution and engagement. The evolving of the project in itself is not merely as a research medium and digital archive, but is of utmost importance for the contributions by the human involvement and interaction in the Antarctic region and their valuable contribution towards this region. The insights gained from the human interactions led to a much more comprehensive project in the last few years. The project started out as a novel approach in the history, humanities and social sciences, but developed into a project that can span collaboration on an international level. The management, including approach and challenges of the digital archive especially regarding collection and storage of data will form an essential part of the presentation. South Africa can contribute the knowledge and experience of an open accessed platform with its challenges to the wider polar community.
The internalization of environmental protection policy into the core of economic development strategies and policies of a state will be best applied through the Policy Integration Theory. The Policy Integration Theory enhanced the role plays by Antarctica in stabilizing the planetary raising temperature due to global warming from the negative impact of urbanization activities through The Antarctic Treaty 1959 and the Environmental Protocol of 1991. Today, this theory becomes a compromise used to reinforcing State standard on environmental protection policy which previously governed by the economic actors. This Theory adopted the international environmental protection policy initiated through Antarctica Treaty and its Environmental Protocol to be practiced and activated voluntarily by State in their quest for better quality of life from the aspects of environmental concerns and its economy. It is often suggested, there is an inherent conflict of interest between protecting the environment and promoting economic growth. Thus, Theory on Policy Integration may be the possible suggestion in pursuing the compromise. The paper will discuss, the effectiveness of Antarctica science diplomacy in National Polar Policy, The Policy Integration Theory in enhancing states economic sectors. Lastly, the key factors restraining the full potential of Antarctica science and its diplomacy in igniting an economic burst of the state member.
There is increasing concern on how the change in the cryosphere in the Hindu Kush Himalaya (HKH) will impact downstream populations and society. The majority of studies refer to retreat in glaciated areas and reduction of glacial mass, although there are unique exceptions in the Karakoram region where glaciers are stagnant or increasing in mass. Most studies refer in very general terms to “downstream populations” without specific information on how and to which extent the population would be impacted. Neither is there a comprehensive analysis on the number of people affected, or the socio-economic impact at stake. This presentation synthesises the existing body of literature on the human impacts of changing meltwater regimes from transborder glacier-fed and snow-fed river systems in the HKH. The presentation relies mostly on a recently peer-reviewed publication of the same name and distinguishes five main strands of existing research of cryosphere change in the HKH: socioeconomic impacts; hydropower; agriculture, irrigation and food security, and; cultural impacts. The review also reviews acute glacier-related hazards considering research in the field of glacier lake outburst floods (GLOFs) has gained attention. Each research stream is discussed and key case studies described, highlighting important methodologies and results found. Finally, an outline of topics requiring further research is offered.
Innovative Methods for Unpacking Team Process Dynamics

Steven Kozlowski¹ (stevekoz@msu.edu), Chu-Hsiang Chang¹, Subir Biswas²
¹Michigan State University, Psychology, East Lansing, United States, ²Michigan State University, Electrical and Computer Engineering, East Lansing, United States

Psychologists have studied small group and team effectiveness for decades and, although there has been considerable progress, there remain significant challenges. Meta-analyses and systematic research provide solid evidence for team psycho-social processes (cognitive, motivational, affective, and behavioral) that contribute to team effectiveness and empirical support for interventions that enhance team processes (team design, composition, training, and leadership). Yet, there are also concerns that team processes, which are inherently dynamic, have primarily been assessed as static constructs. Team-level processes and outcomes are multilevel phenomena that emerge, bottom-up from the interactions among team members over time, under the shifting demands of a work context. Thus, research to understand the emergence and evolution of team processes must capture their dynamics over time and over long durations. Our research, funded by NASA, is using several innovative methods to study individual and team psycho-social functioning in the Antarctic and in NASA mission simulations. The methods employed include daily ratings (experience sampling methods [ESM]) to assess team psycho-social functioning, linguistic analyses of daily journals to augment ESM ratings, and electronic sensors to capture team interaction networks and reactions (physiological, psychological). The presentation will highlight the intersection of these innovative methods and challenges for unpacking team dynamics.
Fri_333_SH-9_1945

In from the Cold? Interdisciplinary Perspectives on the Case of Sidney Jeffryes

Kimberley Norris¹ (kimberley.norris@utas.edu.au), Gary Steel², Elizabeth Leane³,⁴
¹University of Tasmania, Psychology, Hobart, Australia, ²Lincoln University, Lincoln, New Zealand, ³University of Tasmania, English, Hobart, Australia, ⁴Institute of Marine and Antarctic Studies, University of Tasmania, Hobart, Australia

Bringing together the expertise of researchers from Psychology, English, and History, this paper takes an interdisciplinary approach to examining the account of Sidney Jeffryes - an Australian Antarctic expedition member who demonstrated significant mental decline during his tenure 'on the ice', and following his return to Australia. Based on historical documents, hypotheses are proposed for the psychological diagnosis of Jeffryes' condition and factors (both interpersonal and intrapersonal) that precipitated it. Analysis of texts written by Jeffryes and those associated with him are examined to provide more context in understanding Jeffryes' experience during and after the expedition, shedding light on why this has remained a largely 'untold' piece of Antarctic history.
Since its discovery, a large number of experiences took place in have been the theater of a diversity of experiences the Antarctic sector and sub Antarctic territory administered by France (Terres Australes et Antarctiques Françaises, TAAF). Their manifestations, past and contemporary, illustrate the determination of man to appropriate that area. Keeping a memory of its origin is a sociological mechanism that structures the relationship between human being and their history. In the Southern, such a mechanism takes on particular significance since the place is a priori suitable for nobody. In the TAAF, remoteness and isolation have always constrained human settlement. Nevertheless, the associated activity subsists and daily life unfolds. Material and immaterial production, past and present, illustrates the ability of human to always transcend the constraints imposed due to the environment. It is this legacy specific to the heritage that constitutes the scientific object of this study. We question this issue from the anthropological point of view and from the point of view of the management of material associated with Sub-Antarctic and Antarctic cultural heritage.
Climate Awareness in Popular Culture

Astrid Surmatz¹ (a.m.surmatz@uva.nl)
¹University of Amsterdam, Humanities, Amsterdam, Netherlands

Climate change and climate awareness have been rising during the last decades. Earlier popular culture representations of arctic or antarctic areas e.g. in the 1950ies were often still centered around Science fiction scenario’s that emphasized the foreignness and often hostility of those areas. From the 1990ies onward, there are several reflections of the climate change discourse both in film, comics, thrillers, even picturebooks or digital representations in the wider sense, which shape a more diversifed and open image of the polar areas. Some of them rely heavily on emotional appeals, e.g. the cuteness factor of penguins, or the tragic situation for polar bear cubs. Others translate climate change threats into various plots of human interference with what is perceived as unspoiled nature or pristine surroundings. The way in which popular culture and multimedral approaches represent scientific developments, and the way they reflect on for instance climate change awareness are at the core of this paper, which combines cultural studies, multimedia studies, gender and postcolonial theory. The paper will conclude with a look at the Disney film Frozen and its allusions to polar discovery, (sub)arctic milieu and the influence of humans on climate developments. The medial and popular culture images of the polar areas including climate change then again trigger a broader discourse on the anthropocene, and may reflect back on how scientific approaches to climate change are viewed.
Fri_336_SH-9_2439
Cryosalide - A New Generation of Human-environment Observatory

Emmanuelle Sultan¹ (emmanuelle.sultan@mnhn.fr), Daphné Buiron², Ann-Isabell Guyomard³, Elisa Dupuis⁴
¹MNHN, DGD REVE, Dinard, France, ²Collectif CryoSalide, Paris, France, ³Oijha - Art and Ethics from Antarctica, Paris, France, ⁴Sorbonne Universités (Université 4), Paris, France

This new generation Observatory has the mission to collect, archive and promote Antarctic related elements in the broader sense: the Antarctic Treaty area including the Southern ocean and the Southern islands. Extending this concept, the Observatory will also consider other oecumene areas which share a system of common values, transcending national and academic frontiers.

It is a new generation Observatory considering its missions in the fields of academy, education, knowledge and arts dedicated to question the notions of committment and empowerment. Because of the diversity of actors related to Antarctica, this Observatory will gather different perceptions which will sometimes confront each other, bring value or transcend each other, making a link with the paradox of this continent as pristine and void from Antarctic people. Exploring the idea of « Antarctic people » will question about the relation, the standing and the place of Humanity in the circle of life.

This observatory is based on numerous corpus:
1) existing but scattered
2) being collected
3) to be imagined ...that will be presented in the framework of POLAR 2018.
Global Navigation Satellite System (GNSS) Precise Point Positioning (PPP) services enable geoscientists to obtain high quality position information in regions where no local surveying infrastructure exists. The Canadian government provides one such service, known as the Canadian Spatial Reference System Precise Point Positioning (CSRS-PPP) Service which works at any location on Earth and is free to the user. For management purposes CSRS-PPP log files containing information about the location of surveys, and some technical parameters are retained. Utilizing these files we see very substantial usage in polar regions, where such services would appear to be an excellent tool for geoscience. Prior to October 2015, over 64,000 GNSS files had been processed in the North Atlantic region (including Greenland), and 144,000 files had been processed in Antarctica. In general these observations were conducted with high quality dual-frequency equipment, with long observation times for cm-level positioning. Gridded maps of these observations are presented, showing continental-scale experiments, coastal studies, etc.

The CSRS-PPP service currently process over 1400 files each day on average, with the majority of these files for geoscience purposes, and the majority of the data obtained in a location outside Canada. Intended for the surveying community in Canada, the CSRS-PPP now also serves a global, geoscientific, clientele.
We present the first detailed bathymetry compilation for the Cape Darnley region in East Antarctica. This region is of broad scientific interest as it is a key location for understanding the Cretaceous breakup of central Gondwana, basins on the continental shelf contain valuable paleoenvironmental records, the shelf is an important marine habitat, and the Cape Darnley polynya is one of only four sites of Antarctic Bottom Water production - a cold, dense, nutrient-rich water mass that forms on the continental shelf and sinks to abyssal depths, driving ocean currents around the world. However, oceanographic and ecosystem models in this region are poorly constrained by lack of detailed bathymetry.

Single beam and multibeam bathymetry datasets were compiled from multiple marine science voyages undertaken over several decades. The data were held by several institutes and were of varying resolution and quality. The new dataset improves previous regional bathymetric representations and enables visualization of shelf and slope morphology in unprecedented detail. The compilation provides important baseline information underpinning a range of scientific applications. In particular, the bathymetry provides the first detailed insights into potential bottom water transport pathways from the Cape Darnley polynya into the global deep ocean circulation system. Geomorphic interpretation of the bathymetry data provides insights into past glacial dynamics and contemporary seafloor processes.
Real-time Imaging Flow of High-resolution Ice-sounding Radar

Shinan Lang¹ (langshinan@bjut.edu.cn), Qiang Wu¹, Xiaojun Liu², Bo Zhao²
¹Beijing University of Technology, Faculty of Information Technology, School of Information and Communications Engineering, Beijing, China, ²Institute of Electronics, Chinese Academy of Sciences, the Key Laboratory of Electromagnetic Radiation and Sensing Technology, Beijing, China

Ice-sounding radar is an established technique for probing ice masses and remotely sensing the basal conditions with sufficient resolution over a large area in a comparatively short period. Regarding the signal processing of ice-sounding radar, focused synthetic aperture radar (SAR) imaging techniques have been applied to ice-sounding data to improve the gain and resolution for many years. However, direct implementation of the imaging algorithms are still computationally expensive. At the moment, we are developing a real-time processor by using a modern commercial DSP chip named TMS320C6678. Therefore, it is essential to develop an appropriate real-time imaging algorithm which is adapted to the real-time processor based on DSP. Based on the comparison of the previous imaging algorithms, a range-Doppler algorithm (RDA) integrated with shift-and-correlate (SAC) algorithm is proposed for the real-time implementation of high-resolution ice-sounding radar imaging on the designed real-time processor. To clarify the practical feasibility of the RDA integrated with SAC algorithm, theoretical analysis is carried out in detail. In addition, the hardware architecture of the designed real-time processor, and the implementation of the proposed algorithm on the processor are demonstrated. The real-time imaging is carried on the data collected during the 33th Chinese National Antarctic Research Expedition (CHINARE 33) over Princess Elizabeth Land (PEL) via ice-sounding radar called HiCARS.
Antarctica's heat budget defines how it will respond to climate change. Antarctica cools itself mainly by emitting longwave infrared radiation. Approximately 50% of the emission happens at wavelengths beyond 15 µm. Because measurements made at these long wavelengths are scarce, it is not possible to model with confidence the response of Antarctica to changes in climate. This presentation outlines a process for developing site atmospheric state best estimates of temperature and water vapour to constrain a state-of-the-art radiative transfer model. The sensitivity to changes in the surface emissivity can then be tested using the radiative transfer model. Such a robust analysis of the problem is an essential first step before attempting to mitigate the knowledge gap through a measurement campaign. The presentation will outline our collaboration with international partners to design a campaign to measure the far-infrared emissivity above Antarctica.
iCUPE - Integrative and Comprehensive Understanding on Polar Environments

Tuukka Petäjä¹, Ella-Maria Duplissy¹ (ella-maria.duplissy@helsinki.fi), Pauli Paasonen¹, Hanna K. Lappalainen¹
¹University of Helsinki, Helsinki, Finland

iCUPE (Integrative and Comprehensive Understanding on Polar Environments) is a 3-year project that answers to ERA-PLANET (European network for observing our changing planet) thematic strand 4 (Polar areas and natural resources).

The vision of iCUPE is to establish and maintain long-term, coherent and coordinated observations and research activities on environmental quality and natural resources in polar areas. The core idea of iCUPE is the development of novel, integrated, quality-controlled and harmonized in-situ observations and satellite data in the polar areas, as well as data products to the end users. iCUPE combines the integrated in-situ and satellite Earth Observation with a modelling platform. It

1) synthesizes data from comprehensive long-term measurements, intensive campaigns and satellites, collected during the project or provided by on-going international initiatives,
2) relates the observed parameters to impacts, and
3) delivers novel data products, metrics and indicators to the stakeholders concerning the environmental status, availability and extraction of natural resources in the polar areas.

The project will improve our understanding of the pollution sources and sinks, environmental and anthropogenic changes and elements of the cryosphere in polar areas by conducting high-level and high impact research by analyzing these integrated data together with the modelling frameworks.

On behalf of the iCUPE Consortium, Helsinki, Finland.
Pacific Central Arctic Ocean (CAO) Observing System (K-AOOS)

Sung-Ho Kang1 (shkang@kopri.re.kr)
1Korea Polar Research Institute (KOPRI), Division of Polar Ocean Sciences, Incheon, Korea, Republic of

Sea ice-covered area in Pacific Central Arctic Ocean (CAO) is a major study site of the Korean Arctic program, regularly visited by its flagship and an icebreaker, Araon. Annually conducted ocean-going expeditions occupy a number of oceanographic stations and place a few moorings, focusing on baseline oceanography, sea ice dynamics and lower trophic level. Mid trophic level and fish, however, are yet to be the principal targets of the project. But fisheries potential in the Central Arctic Ocean and the basis for its sound management are of interest to Korea, as a party to the recent negotiation of the proposed fisheries agreement in the CAO. Korea-Arctic Ocean Observing System (K-AOOS) program has developed as a platform of international cooperation, welcoming numerous foreign scientists on board and providing instrument deployment opportunities. Currently K-AOOS Araon’s field program is designed for ecosystem and climate change focused researches. Efforts to engage more scientists from the national and international research communities are being made and especially collaborations between Korea Polar Research Institute and others are going well at individual and institutional scientist levels. K-AOOS advocates a data policy that promotes a wide sharing of validated and calibrated data. K-AOOS takes a view that a dedicated scientific leadership in the CAO is warranted that can coordinate multi-national and multi-partner field expeditions and maximize the scientific output.
Persys-WebGIS-based Permafrost Data Visualisation System for ESA GlobPermafrost

Antonie Haas¹ (antonie.haas@awi.de), Guido Grosse², Birgit Heim³, Andreas Walter⁴, Antonia Immerz⁴, Christian Schäfer-Neth⁴, Annett Bartsch⁵, Frank Martin Seifert⁶

¹Alfred Wegener Institute, Helmholtz Center for Polar and Marine Research, Computing and Data Center, Bremerhaven, Germany, ²Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Periglacial Research, Potsdam, Germany, ³Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Periglacial, Potsdam, Germany, ⁴Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Computing and Data Center, Bremerhaven, Germany, ⁵Zentralanstalt für Meteorologie und Geodynamik ZAMG, Vienna, Austria, ⁶European Space Agency ESRIN, Frascati, Italy

ESA GlobPermafrost (www.globpermafrost.info) provides a remote sensing data service for permafrost research and applications. This service comprises data product generation for various regions and spatial scales as well as specific infrastructures for visualisation and access to datasets. PerSys is the open access geospatial information system for dissemination and visualisation of remote sensing data derived within the ESA GlobPermafrost project. The data products are visualised in the PerSys WebGIS and are described and searchable in the PerSys Data Catalogue. The PerSys Data Catalogue is a core component of the Arctic Permafrost Geospatial Centre (APGC), set up within ERC PETA-CARB at AWI¹.

The visualisation employs the AWI WebGIS infrastructure maps@awi (http://maps.awi.de), relying on OGC-standardized Web Mapping/Feature Services (WMS, WFS). The WebGIS supports the project specific visualisation of raster and vector data products such as land cover, Landsat multispectral index trends, InSAR-based land surface deformations, rock glacier velocities, and permafrost model outputs. The WebGIS projects are adapted to the products specific spatial scales, e.g. the Arctic WebGIS visualizes Circum-Artic products as well as other large-scale data products. Rock-glacier data products of higher spatial resolution are visualised on regional scale in the WebGIS projects Alps, Andes and Central Asia. PerSys is accessible via the GlobPermafrost project webpage.
Mapping Surface Facies of Midtre Lovénbreen, Svalbard using WorldView-3 Imagery

Shridhar Jawak1 (shridhar.jawak@gmail.com), Alvarinho Luis1, Manoj Patley2, Timothy Warjri3, Sagar Wankhede4
1National Centre for Antarctic and Ocean Research (ESSO-NCAOR), Ministry of Earth Sciences, Vasco da Gama, India, 2Bharathidasan University, Department of Geography, Chennai, India, 3Savitribai Phule Pune University, Department of Geography, Ganeshkhind, India, 4Mangalore University, Department of Geoinformatics, Mangalore, India

Monitoring the spatial variability in snow and ice surface facies on ice sheets can improve our understanding of surface albedo variations and mass balance feedback mechanisms. Using high-resolution multispectral (MS) and shortwave infrared (SWIR) imageries captured by WorldView-3 and stereo digital elevation model (DEM) data, we map glacier surfaces of Midtre Lovénbreen, Ny-Ålesund, Svalbard. The objective of this study is to implement MS image for characterization of the glacier surfaces in Arctic region. We used geographical object-based image analysis (GEOBIA) methods by designing four spectral band ratios for glacier facies mapping: (a) Near Infra-Red (NIR) Ratio (NIRR) using NIR-1 and NIR-2, (b) traditional Normalized Difference Snow Index (NDSI) using green band and SWIR, (c) Normalized Difference Snow/Ice Index (NDSII) using red band and SWIR, and (d) Normalized Difference Glacier Index (NDGI) using traditional green and red bands. Seven glacier facies were identified, viz., fresh snow, wet snow glacier ice, melting ice, dirty ice, debris and shadowed ice. Accuracies of derived glacier facies maps were assessed using ground truth data collected during the 9th Indian Arctic Expedition. Results indicate that the object-oriented classification scheme yields 93% accuracy for mapping surface facies of Midtre Lovénbreen. Our future research would focus on spatiotemporal glacier surface change detection studies in the Arctic.
Concordia (75°S 123°E) is a scientific base located at Dome C, on the East Antarctica ice sheet. It is run by the French polar institute and the Italian Antarctic Program, and hosts a seismological observatory that is jointly operated by EOST (Strasbourg) and INGV (Roma). Concordia's seismometers have provided ten years of observatory-quality data from this remote and strategic location. The station was integrated into the GEOSCOPE network in 2008; its data are streamed in real time to the GEOSCOPE and IRIS datacenters under the station code CCD.

Concordia's seismometers - a Trillium T240 and a Streckeisen STS2 - currently operate in an artificial vault at ~12 m depth. The vault was constructed from shipping containers buried in snow, it is thermally stable, but it deforms due to the hydrostatic pressure of the snow. Its proximity to the base causes strong diurnal noise (~40 dB) at frequencies above 1 Hz, especially during the summer season; the ~100 m thick firn (snow) layer forms a waveguide that traps anthropic noise from the base and transmits it to the seismometers.

We are planning to upgrade the station by placing a posthole sensor at a depth of approximately 130 meters, i.e. below the firm layer waveguide and the ice pinch-out depth. This installation should minimize noise from thermal effects, from tilting, and from anthropogenic activity. Drilling is scheduled to start in January 2018. We shall present updates from the drilling and from in-situ instrument tests.
The SCAR GeoMAP Project has produced a digital geological dataset of West Antarctica, a tectonically active region of thin crust that is undergoing rapid glaciological change. Suitable for reproduction at 1:250 000 scale or more detailed, the dataset covers the on-continent coastal area bordering the southern Pacific Ocean. Supraglacial features and glacial till, seasonal water and blue ice are mapped using DigitalGlobe high resolution satellite imagery. These provide a baseline for past and future icesheet fluctuation. Sparse bedrock exposures are classified using data from published geological maps and literature, ground-based geological data, and firsthand observations. The bedrock data aid in evaluation of potential geological influences upon the cryosphere, such as bedrock roughness, subglacial volcanism and/or geothermal flux which may affect icesheet stability and the position and velocity of outlet glaciers. The database features links to bibliographic source files for primary literature and published maps. International GeoSciML data protocols are used for feature classification, making the database attribute-rich, queriable, and compatible with national/international geoinformatics and BigData programmes. The development of the resource is timely in respect to several international scientific research programmes, including IODP 379 in the Amundsen Sea, the Thwaites Glacier Project, and ongoing oceanographic surveys along the southern Pacific margin.
The ice flow velocity is a critical variable in understanding the glacier dynamics. The Synthetic Aperture Radar Interferometry (InSAR) is a robust technique to monitor Earth’s surface mainly to measure its topography and deformation. The phase information from two or more interferogram further helps to extract information about height and displacement of the surface. We used this technique to derive glacier velocity for Polar Record Glacier (PRG), East Antarctica using Sentinel-1 Single Look Complex images captured in Interferometric Wide mode. The PRG is located in the Prydz Bay area on the eastern side of the Amery Ice Shelf. It is the largest outlet glacier along the Ingrid Christensen Coast, bounded by Meknattane Nunataks and Dodd Island. For velocity estimation, Persistent Scatterer interferometry (PS-InSAR) method has been applied. This method uses time coherent of permanent pixel of master images and correlates to same pixel of the slave image to get displacement by tracking the intensity of that pixels. C-band sensor of European Space Agency, Sentinel-1A and 1B data were used in this study. Estimated average velocity of the PRG is approximated to be ≈400 m/year which varies from ≈100 to ≈700 m/year. This study found that PRG moves with a velocity of ≈700 m/year in lower part whereas the upper inland area flowing with ≈200 m/year. The western part of the glacier is moving faster in comparison with the eastern part of the glacier.
The project aims at proposing new methods for monitoring glaciers by means of a network of sensors based on a situational awareness model. Glaciers have a very important role in the planet’s climate, and changes in their behavior can trigger extreme weather events, change the climate and affect the level of the oceans and their ecosystems. Therefore, efforts to monitor the planet’s ice behavior have been increasingly necessary in order to better understand how glaciers interact with the atmosphere and oceans.

The idea is to implement a set of sensors, with a good spatial distribution, to collect data remotely, verifying the changes that occur throughout the ice masses. This approach would allow assessment of the melting rate of glaciers and their relation to climatic events.

Based on these characteristics, this project created two prototype network sensors to monitor glacier parameters and meteorological data on glacier surfaces in an integrated way. The edge sensor set consists of an Automatic Weather Station (AWS) and two ablation electronics (eAS) stations, both using the Arduino prototyping platform.

AWS were built to withstand extreme weather conditions, combining materials such as carbon fiber and stainless steel, being extremely portable and maintaining a low assembly cost. The eAS are an evolution of traditional ice stakes and use RFID technology to improve space-temporal resolution of ablation measurements.
Lessons Learned from Interdisciplinary Snow Research in Svalbard

Catherine Larose¹ (catherine.larose@ec-lyon.fr), Elena Barbaro², Adrien Boniface³, Mats Bjorkman³, Jean-Charles Gallet⁴, Jack Kohler⁴, Krystyna Kozioł⁵, Bartek Luks⁶, Tonu Martma⁷, Andrea Spolaor⁷, Thomas Vikhamar Schuler⁴, Christian Zdanowicz⁸

¹University of Lyon, Ecully Cedex, France, ²University Ca’ Foscari of Venice, Venice, Italy, ³University of Gothenberg, Gothenberg, Sweden, ⁴Norwegian Polar Institute, Tromso, Norway, ⁵Pedagogical University of Cracow, Krakow, Poland, ⁶Instytut Geofizyki Polskiej Akademii Nauk, Warsaw, Poland, ⁷Tallinn University of Technology, Tallinn, Estonia, ⁸Uppsala University, Uppsala, Sweden

For decades, the Svalbard archipelago has been an area of interest for physical, chemical and biological investigations of snow and ice, due to its vulnerable location for climatic interactions and air-mass transport pathways. However, despite the many and demanding field campaigns carried out during the last decades, it has been difficult to link the findings from different projects to obtain the larger picture of snow research in Svalbard, and therefore its importance to the Arctic system is likely underestimated. This is in part related to the heterogeneity of sampling locations and sampling times, which does not promote direct comparisons between the different projects and also to the often mono-disciplinary nature of the research being carried out. Here, we present some of the lessons learned during SnowNet, a collaborative research initiative, developed to foster interdisciplinary Arctic field research. We will discuss key aspects to ensure that the collected data are consistent and comparable, ranging from protocol development, sample collection strategies and data processing and formatting, as well as some of the difficulties encountered. By coordinating our efforts in the field, we can optimize the use of logistics and financial resources, while minimizing our environmental footprint.
Understanding Variability of Arctic Methane Fluxes and Addressing Knowledge Gaps

Kassandra Reuss-Schmidt¹, Donatella Zona² (d.zona@sheffield.ac.uk)
¹University of Sheffield, Sheffield, United Kingdom

Methane emissions from Arctic permafrost soils could result in substantial global warming, as permafrost soils store 1300-1370 Pg of organic carbon, two times the current atmospheric stock. The Arctic is warming at twice the rate of the global mean, causing the southernmost border of permafrost to steadily recede northwards. The main difficulties hindering an accurate baseline estimate are the high spatiotemporal variability in methane emissions, and the poor data available from these systems. Arctic wetlands are in fact extremely heterogeneous and methane fluxes can differ significantly between sites only meters apart. Here we evaluate the effect of footprint variability on the methane fluxes from two eddy covariance sites located on the large wetland area in the North Slope of Alaska. The local domain of each of these sites contains well developed polygonal tundra, as well as, other thermokarst features such as drained lake basins and their drainage channels. We found that the footprint variability, has a significantly influence on the observed methane fluxes, contributing to about 10% of the unexplained variability in CH₄ fluxes. We present and discuss the sources of this spatial variability and the remote sensing data required to assess the influence of this spatial variability on the CH₄ fluxes across the Arctic. This study highlights the data gaps and needs to be able to refine our understanding of the controls on the greenhouse gas fluxes across the Arctic.
The weakest component of the overall Arctic observing system is the in situ ocean observing system. Advanced drifting ice-ocean observatories provide multi-disciplinary data in near real time, but they require stable ice conditions. Profiling floats and gliders, frequently used in open ocean, have to surface to transmit data, update their clocks, and geo-position via satellite. In ice covered regions floats may not be able to surface for many months. During this time the sensors will collect data, but the positions where the data are taken will be unknown and the clocks will not be accurate.

Multipurpose acoustic networks will be an important contribution to the development of a sustainable Arctic Ocean Observing System. A network of fixed mooring systems with acoustic transceivers in the Arctic Ocean will provide an underwater geo-positioning system for all users in direct analogy with GPS positioning. The same system will provide ocean observation through acoustic thermometry, passive acoustic monitoring, and oceanographic point measurements. Moored multipurpose acoustic networks have been implemented in a sequence of year-long research experiments in the Fram Strait and in the Beaufort Sea. New initiatives for establishing acoustic networks in the interior of the Arctic have begun. These initiatives are timely given the several Arctic projects recently funded by the EU’s research program HORIZON 2020 and a number of national programs.
Enhancement of in situ Observing systems in the Arctic under the INTAROS Project

Agnieszka Beszczynska-Moeller, Peter Voss, Stein Sandven, Hanne Sagen, Andreas Ahlstroem, Truls Johannessen, Thomas Soltwedel, Mathias Goeckede

1Institute of Oceanology PAS, Sopot, Poland, 2Geological Survey of Denmark and Greenland, Copenhagen, Denmark, 3Nansen Environmental and Remote Sensing Center, Bergen, Norway, 4University of Bergen, Geophysical Institute, Bergen, Norway, 5Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, 6Max Planck Institute for Biogeochemistry, Jena, Germany

The H2020 project Integrated Arctic Observation System (INTAROS) aspires to increase the temporal and geographic coverage of in situ observations and add new key geophysical and biogeochemical variables in selected regions of the Arctic. Using a combination of mature and new instruments and sensors to be integrated with existing observatories, INTAROS aims to fill selected gaps in the present-day system and build additional capacity of pan-Arctic monitoring networks.

Three reference sites have been selected as key locations for monitoring ongoing Arctic changes: Costal Greenland, paramount for freshwater output from the Greenland ice sheet; North of Svalbard (shelf to deep basin) - the hot-spot for ocean-air-sea ice interactions, and heat and biological energy input to the European Arctic; and Fram Strait - the critical gateway for exchanges between the Arctic and the World oceans. Two distributed observatories: for ocean and sea ice and for terrestrial and atmospheric measurements will be extended with multidisciplinary observations, still missing from the central Arctic and remote coastal areas.

New sensors, integrated platforms and experimental set-ups will be implemented during a two-year long deployment phase (2018-2020) with an aim for sustained use in a future iAOS. New observations will be used for integration of new data products, demonstration studies and stakeholder consultations and contribute to ongoing and future long-term initiatives (e.g. OSPAR, SAON, YOPP).
Best Practices for a New Network to Monitor the Cryosphere

Charles Fierz¹ (fierz@slf.ch), Thorsteinn Thorsteinsson², Aldís Elfarsdóttir³,⁴, Anna Haberkorn¹, Petra Heil⁵, Rodica Nitu⁶, Craig Smith⁷, Penelope M. Wagner⁸

¹WSL Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland, ²Icelandic Meteorological Office, Reykjavik, Iceland, ³Harvard University, Cambridge, United States, ⁴Icelandic Meteorological Office, Reykjavik, Iceland, ⁵Australian Antarctic Division and ACE CRC, University of Tasmania, Hobart, Australia, ⁶World Meteorological Organization, Geneva, Switzerland, ⁷Environment and Climate Change Canada, Saskatoon, Canada, ⁸Norwegian Meteorological Institute, Tromsø, Norway

Global Cryosphere Watch, a cross cutting WMO initiative, aims at bringing together operational and scientific networks to monitor all components of the cryosphere and make this data available to all interested communities in near real time. CryoNet stations forming the core of this network are required to comply with best practices developed in common by the operational and scientific community. These best practices are based on existing guidelines. They will help homogenise measurement procedures and reporting to ensure that high quality data is collected worldwide on selected variables of each cryospheric component. This is the basis for a global exchange of cryospheric data that will lead to a better understanding of cryospheric processes but also contribute to deliver improved services to society. In this contribution we will present the status of our compilation of best practices and describe how we have integrated input and feedback from various scientific and operational communities to develop these documents. The future vision is to have an ongoing open but controlled update mechanism for these best practices, reflecting continuously new developments in measurement techniques and technologies.
Common Metadata Scheme for Translating between Metadata Dialects

Alexander Smirnov¹ (alexander@arcticportal.org), Pip Bricher², Taco de Bruin³, Anton Van de Putte⁴, Halldór Jóhannsson¹, Peter Pulsifer⁵, Stein Tronstad⁶
¹Arctic Portal, Akureyri, Iceland, ²Southern Ocean Observing System, Hobart, Australia, ³Royal Netherlands Institute for Sea Research, Texel, Netherlands, ⁴Royal Belgian Institute of Natural Sciences, Brussels, Belgium, ⁵National Snow and Ice Data Center (NSIDC), Boulder, United States, ⁶Norwegian Polar Institute, Tromsø, Norway

There is a demand to share metadata across polar data centers. However, a variety of metadata catalogues and standards makes this task challengeable. Presently the ISO 19115 is a key standard for sharing metadata. Unfortunately, due to its complexity it is not widely used among the community.

A common set of metadata elements relevant across polar sciences has been developed to facilitate interoperability and sharing between polar data repositories and online portals. We analyzed the metadata schemas for a set of catalogues (GCMD, Polar Data Catalogue, IPY, NSIDC, etc.) and found existing metadata elements common to all or many of the schemas. This set is proposed as a preliminary community recommendation for catalogue publishers to improve interoperability across catalogues.
**Fri_357_SY-1_2623**

**The National Polar Metadata Infrastructure**

Simona Longo\(^1\) (simona.longo@cnr.it), Angelo Pietro Viola\(^2\), Cosimo Elefante\(^2\), Vito Vitale\(^2\), Mauro Mazzola\(^2\)

\(^1\)CNR, DTA, Rome, Italy; \(^2\)CNR - ISAC - National Research Council, DTA, Rome, Italy

In the Arctic complex interactions between atmosphere, ocean, cryosphere and biosphere on a broad spectrum of temporal and spatial scales, are largely responsible for "arctic amplification". Measurements are fundamental to answer relevant questions on climate system variability. The CNR is in charge to managing and disseminate scientific results of Italian activities carried out either in the Arctic and in the frame of PNRA. In this contest, CNR is establishing the **National Polar Metadata Infrastructure**, using technologies based on brokering approach, to provide to the polar scientific community, instruments through which easily manage historical and real-time data and metadata. The infrastructure will ensure data discovery through the interconnection of the system with the most common ones, integration with the global environmental observation network of GEOSS, and will contribute to increase the entire GEO community. In this approach, different servers (called “nodes”) are connected to “brokering nodes”, hosting metadata and data. Every node communicates with the brokering system that allows data integration and interoperability between different kinds of servers. The Italian research activity in the arctic region has increased in the recent years and the CNR developed the infrastructure IADC a system to easily manage real-time data and metadata.
Development of Antarctic Seismo-acoustic Station: Results from ICE-VOLC Project

Scientific instrumentations installed in Antarctic regions will face the most extreme climate on the planet, so they have to be tolerant of very low temperatures and robust enough to survive extreme wind speeds. Furthermore, one of the most challenging task is powering a remote system year round at polar latitudes because of following factors: i) solar radiation varies through time from 24 hours during the Antarctic summers to no light during winters; ii) the high winds are often unpredictable in duration and in strength; iii) cold temperatures of the polar nights reduce the capacity of batteries.

In the framework of the ICEVOLC project (www.icevolc-project.com), a permanent seismo-acoustic station was developed able to face the aforementioned issues. Sensors and digital acquisition system were chosen to be rugged and operative at very low temperature. Hybrid powering system, integrating solar panel and wind generator, to guarantee continuous batteries charging in every weather conditions and Antarctic seasons, was chosen. Energy produced is managed by two controllers operating in synergy. In particular FASEL controller specifically designed for the project and another commercial controller carry out the following tasks:

i) ensure correct charging batteries,
ii) maintain temperature inside the battery case making use of heaters powered by extra energy,
iii) switches off the instruments in case of measured low battery package voltage to preserve batteries to deep discharges.
Low-temperature Tests of Ice Friction

Jialin Hong¹, Pavel Talalay¹ (ptalalay@yahoo.com)
¹Jilin University, Changchun, China

Ice friction is one of the major technological issue in almost every application that involves moving parts one of which is ice, such as glacier movements, design of offshore structures, different ice sports, drilling in the ice, ice/snow vehicles, icebreakers, aircraft on icy runway, etc. High friction on ice is desired for vehicles in winter road conditions and shoes on ice, while low friction is desired in ice sports and some parts of the ice breaker or drills. The main parameters influenced on the ice friction are temperature, sliding velocity, applied normal force, contact area, humidity, thermal conductivity and surface roughness, structure and hydrophobicity of slider and ice. Even numerous ice friction studies were focused on effect of temperature, most of them were done at temperatures above -25 °C which is not low enough to apply for some extreme environment as cold as polar regions. Thus, we investigated promising materials that can be used to decrease or increase friction in the wide temperature range from -60 °C to 0 °C using a linear friction tester by varying several impact factors.
Multi-Functional Ice Drills Testing Facility

Rusheng Wang¹ (wangrs@jlu.edu.cn), Pavel Talalay¹, Youhong Sun², Xiaopeng Fan¹, An Liu¹
¹Jilin University, Polar Research Center, Changchun, China, ²Jilin University, College of Construction Engineering, Changchun, China

The first stages of drilling equipment development is most sensibly tested in a laboratory facility prior to using it out in the field. A multi-functional Ice Drill Testing Facility (IDTF) allows to test all kinds of mechanical and thermal ice drills throughout the year including electromechanical cable-suspended drills, hot-water drills, rapid air drills, thermal sondes for subglacial lake exploration, and others. The IDTF consists of several systems:

1. Ice well and freezing system;
2. Heat-insulated building and cooling system;
3. Rotary drilling platform.

The liner of ice well made of steel cylinder (Ø1 m) is sunk into the shaft (Ø2.6 m) to a depth of 12.5 m below the ground. According to different operating mode, the different sub-glacial conditions can be imitated in the ice well by freezing system. A two-room, heat-insulated building, containing a tall hall (6×6×15.2 m) with air-cooling system and an entrance hall (3×6×4.5 m), was constructed above the ice well. A rotary drilling platform on the second level of the tall hall allows for the drilling of at least nine holes with a diameter of 130-150 mm around the perimeter of the ice well. The refrigerators were chosen by freezing the ice well within 72 hours. The temperature of artificial ice can be adjusted from -5 to -30 °C and the lowest temperature of ambient air in the IDTF can be controlled to -20 °C. The first tests performed in the IDTF illustrated the facility’s convenient performance for ice drill testing.
Environment Monitoring Demonstration Networks on Prydz Bay

Wenfang Cheng\(^1\), Jiangang Zhu\(^1\), Lizong Wu\(^1\) (wulizong@pric.org.cn)
\(^1\)Polar Research Institute of China, Shanghai, China

China promoted and implemented environmental monitoring programs and arrayed multi-discipline monitoring sensors on Prydz Bay since early 1990s. Multi-discipline data was collected including hydrological, meteorological, geophysical and biological data. A rapid data transmission network was framed connecting R/V Xuelong, polar Stations and domestic berth. For forecasting and prediction based on long-term monitoring, China designed a long-term environmental monitoring network on Prydz Bay based on the existing work. All the conventional monitoring works in China were covered in the design objectives in this network. We also expanded the monitoring works according to new international developments and long-term plans. This design has been proved performable and exemplary especially in the ice-breaking navigation work on Prydz Bay.
Small-diameter Vibrocorer for Sediment Coring Beneath Antarctic Ice Shelves

Xiaopeng Fan¹, Bing Li¹ (bing@jlu.edu.cn), Da Gong¹, Yunchen Liu¹, Yazhou Li¹, Pavel Talalay¹
¹Jilin University, Changchun, China

Sediments beneath the Antarctic ice shelves contain important paleo-climatic and paleo-environmental records, which will offer a long-term perspective on Antarctic ice sheet retreat history and sub-ice shelf ocean circulation patterns. We designed a vibrocorer which could collect sediments from beneath Antarctic ice shelves through an access hole formed with the hot-water drill. This vibrocorer includes four units: water-proof pressure chamber, vibrator, core-barrel unit and spring buffer. For the vibrator, we utilize the self-synchronous theory of dual-mass vibrating machine which allows to compress radial size of the vibrocorer. Actuating motors, whose power are supplied by 36V DC lithium battery, rotating in opposite directions can generate vertical, horizontal, or alternative vibrations. The configuration of vibrocorer is 270 mm in maximal radial size, 7.5m in total length and 300kg in total weight, which aims to get the sediment core with max 6m in length and 108mm in diameter. The vibrocorer has been proved to work functionally during laboratory testing and is prepared for field testing in the season 2017-2018 at the Ekströmisen, Dronning Maud Land, Antarctica.
A Shallow Hot-water Drill

Gang Liu1,2 (gangliu16@mails.jlu.edu.cn), Pavel Talalay1,2, Rusheng Wang1,2, Xiaopeng Fan1,2, Jialin Hong1,2, Bowen Liu1,2, An Liu1,2, Sysoev Mikhail1,2

1Jilin University, Polar Research Center, Changchun, China, 2Jilin University, College of Construction Engineering, Changchun, China

To get shallow access holes in high mountain glaciers and polar ice caps and sheets, the hot-water drilling is a meaningful method for temperature observation, ice dynamics study, etc. Hot-water drill is considered as one of the most effective non-core drilling methods in ice because of the high rate of penetration and low environment impact. However, there is no complete theoretical base for designing of hot-water drilling systems and for choosing of optimal drilling parameters. Thus, the drilling process is mainly controlled by the experience of drillers. Theoretical estimations were done to predict hot-water temperature at the bottom of the borehole, diameter of the borehole, rate of penetration, required power for ice melting and the total pressure loss in water circulation system. The shallow drill system, designed and produced in Polar Research Center, includes a high-pressure washer, a winch with 100 m high-pressure hose, mast, dead weight, nozzle and sensors (temperature sensors, load cells, encoder, flowmeter, and pressure gauge). Experiments with shallow hot-water drill were taken at the low temperature test drilling facility with the main aim to find relationship between rate of penetration and borehole diameter from diameter and type of nozzle, water temperature and flow rate. Theoretically, the drill is capable to produce access borehole with diameter near 100 mm at rate of 30 m/h. These parameters have been proved during testing in 10 m deep ice-well.
Subglacial rocks and ice-rock interface plays a key role in the dynamics of the overlying ice sheet. Samples of basal and subglacial material can give unique information for paleo-climatic and paleo-environmental records, microbiological study, geology and tectonics. Hot water drilling system is considered to be the fastest way to reach the target depth. To get core sample, the drill nozzle will be changed to the coring part combination, positive displacement motor (PDM) with core barrel and drill bit. PDM motor is used to transform hydraulic pressure of hot water flow to the rotation and torque, and also balanced by anti-torque system. Core barrel is used to protect the core samples from the hot temperature environment and mechanical erosion. The type of drill bits will be chosen according to the material being drilled. Gravity chips chamber will be included into downhole assembly while coring the ice with rock or soil. If only ice coring, the system can work without chips chamber, because the hot water circulation will melt all ice chips. It is planned to test the temperature and flow rate distribution in the system on the testing stand. The detailed concept of ice and subglacial bedrock PDM corer is being worked out.
Arctic under present climatic changes brings new opportunities for industrial developments (oil and gas resources, fish and fisheries management, shipping in the Arctic ocean, etc.). Urbanisation and development all technological support for human life is one of the most globally urgent tasks for future. Low temperature biotechnology and explore the biotechnological potential of polar and other low temperature adapted cyanobacteria and microalgae (micro-algae), which can produce valuable metabolites in Central European non-summer and Arctic conditions is a great challenge for Czech Science. Microalgae and cyanobacteria are a rich source of bioactive molecules with many potential uses such as components in human/animal nutrition, pharmaceuticals, nutraceuticals, cosmetics, biopesticides, phytohormones, etc. Many of metabolites from microalgae have been shown to possess varied bioactivities. Microalgal bioactive molecules thus hold a bright and promising future in scientific research including a great opportunity for drug discovery. In proposed lecture, the non-marine environmental conditions in Arctic environments and microalgal adaptations will be introduced with respect to possible biotechnological applications. The presentation also provides a survey of the possible compounds to be exploited from Arctic microalgae. Possible constructions of photobioreactors for mass cultivation of microalgae are proposed for operations in the Arctic.
Hydraulic fracturing initiated by increasing the fluid pressure in the borehole to the point where the smallest principal stress at the borehole becomes tensile has been used commercially as a stimulation technique in the petroleum industry since the early fifties. The same situations potentially can happen under condition when drilling fluid pressure exceeds ice pressure at certain depth while drilling in ice sheets and glaciers. We propose an estimation of overpressure that causes the hydraulic fracture in ice on the base of theory of rocks fracturing. This estimation reveals the critical relationship between the drilling depth and density of the drilling fluid at which hydraulic fracturing occurs and provides the theoretical basis of adjusting the density of drilling fluid. Several hydraulic fracturing tests were carried out to simulate ice fracturing on the borehole wall with artificial ice samples under a special three-axis hydraulic fracturing test system. Based on combining with theory consideration and experimental results, this study supports the hypothesis that hydraulic fracture is a plausible mechanism for the possible phenomenon in ice drilling borehole.
Experimental Research of Hot-water Ice Coring Drill

An Liu\(^1\), Rusheng Wang\(^1\), Pavel Talalay\(^1\)
\(^1\)Jilin University, College of Construction Engineering, Changchun, China, \(^2\)Jilin University, Polar Research Center, Changchun, China

How to acquire ice cores efficiently is becoming an increasingly key problem due to abundant information of climatic variation in intact ice cores. Compared with the traditional coring drill by armor cable, hot water drilling has its unique advantages: drill rapidly and environmental friendly. This paper proposed a hot-water ice coring drill, which is used in combination with the hot-water drilling system and can get ice cores at any depth. The hot water is supplied by the same hydraulic hose that is used for the hot-water drilling. 3.25m long drill includes core barrel, guiding tubes, core catchers and drill head with 36 nozzles 1mm in diameter. The core barrel (96 mm inner diameter) is 3m long. The hot water passes through 4 guiding tubes (4mm inner diameter) fixed along outside of the core barrel to the drill head. The prototype of the drill is produced and experiments in ice drill testing facility are carried out. The ice cores are obtained successfully with a special optimal drilling parameter.
To drill through ice and bedrock in Antarctic, a new, modified version of the cable-suspended Ice and Bedrock Electromechanical Drill (IBED) was designed and tested in Polar Research Center, Jilin University. The IBED can drill in ice, debris-rich ice and rock by changing different module that permits the accomplishment of two different tasks: (1) an ice-core drill; and (2) a bedrock core drill. The upper part is almost the same and includes four sections: cable termination; a slip-rings section; an antitorque system; and an electronic pressure chamber. The ice drill could penetrate successfully 800 mm of artificial ice with nearly 100% recovery rate. The cutting load was about 400 N, and the average ROP - 12.7 m/h. Testing of bedrock drill on drilling of granite samples showed that the toothed diamond drill bit could penetrate 1m and at a rate of 1-1.5 m h$^{-1}$ at low load (< 2 kN) and torque (< 30 N m). In addition, tests of the double drill pipe was questionable as the drill was stuck after penetration of 300-400 mm. The reason of sticking was not clear, and additional tests are planning in the near future.

An Introduction to a New Inland Traverse Project (2017 - 2026) by KOPRI

Jong Ik Lee¹ (jilee@kopri.re.kr), Ji Woong Chung¹, Seong Joon Jun¹, Won Sang Lee¹, Joohan Lee¹, Yeadong Kim¹
¹Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of

Korea Polar Research Institute (KOPRI) opened the second Antarctic research station, Jang Bogo Station, at Terra Nova Bay, Ross Sea area in 2014, and many scientific expeditions are currently operated including geology (KAGEX), geophysics (EGG), meteorite searching (KOREAMET), ecosystem monitoring (CEMP) and shallow ice coring. From 2017, KOPRI started a new inland traverse project during ten years with multidisciplinary purpose. The project includes 1) finding a safe and reliable traverse route, 2) developing a 2,000m hot water drilling co-project with British Antarctic Survey for subglacial lake expedition and 3) developing a 3,000m deep ice core drilling technology. Using previous results by satellite altimetry and airborne radar surveys, the existence of subglacial lakes at the upstream of David Glacier is getting clear. During 2017 austral summer season, a traverse team will approach the possible candidate lake site and conduct a ground radar survey. The results of 2017 season expedition and long-term project plan will be presented at the meeting.
Experiments on Electric-heated Hotpoints for Boring in Ice

Yazhou Li¹ (jluyazhouli@163.com), Xiaopeng Fan¹, Mikhail Sysoev¹, Pavel Talalay¹
¹Jilin University, Polar Research Center, Changchun, China

The electric-heated hotpoints are used for boring in ice to install ablation sticks, to determine ice thickness, to locate englacial and subglacial streams, to deploy sensors and tools under ice shelves, to measure temperatures, closure rates and other internals of glaciers like variation with depth of ice flow velocity, identification of dust layers, video observation and so on. Recently, interest in hotpoint using was rekindled in connection with proposed projects for subglacial environment exploration at the Earth and other planets.

Hotpoint melting rate depends on the following variables:
(1) input power;
(2) cross-sectional area of the thermal tip;
(3) axial load (in the limited range);
(4) temperature of the drilled ice and
(5) design features like material and shape of the tip, properties of thermal element, etc.

To study relationship between input power, axial load and shape of the thermal tip, a 0.8-m long hotpoint with changeable thermal tips and computer-controlled testing stand were designed. Series of tests were carried out in artificial ice with temperature of -20 °C. Totally, 14 copper melting tips with different shapes and the same outer diameter of 55 mm were tested. The heat was provided by five diametrically installed cartridge heaters with total rated power of 2.4 kW. The results of the presented experiments provide the prominent reference for hotpoint optimization.
Keynote Lecture VII
The need for coordinated observations to inform responses to rapid Arctic change

Hajo Eicken (heicken@alaska.edu)
International Arctic Research Center, University of Alaska Fairbanks, Fairbanks, AK, USA

Rapid Arctic change poses challenges from the local to the global scale, whether it involves Arctic residents and ecosystems adapting to changing land-, sea-, and icescapes or the development of global policy frameworks to mitigate drivers of change such as greenhouse gas forcing. Informed responses to Arctic change require sustained, coordinated observations of essential variables that describe the present state of the system, inform predictions of future states, and serve as indicators of major transitions or changes in state, and support policy and decision-makers.

Over the past decade or so, a rich diversity of different implementation approaches, networks, and platforms has emerged, covering a range of observational scales from the local to the regional to the pan-Arctic. A key question – central to the Arctic Observing Summit 2018 – is how to foster structured coordination of these efforts, whether driven by bottom-up aggregation of, e.g., community-based monitoring or top-down organization through, e.g., global observing system frameworks.

This presentation illustrates how such structured coordination may be brought about by (i) drawing on toolkits developed for the design of regional or global observing systems, (ii) translating to the local scale the broader concept of societal benefits derived from services provided by the Arctic system, and (iii) focusing on the aim of informed response as a way to encourage convergence of different activities and approaches.
Keynote Lecture VIII
The Southern Ocean – globally important, surprisingly unknown

Anna Wåhlin (anna.wahlin@marine.gu.se)
Department of Marine Sciences, University of Gothenburg, Sweden

The Southern Ocean is fundamental to global climate, marine biomass, and sea-level change. Its storage of heat and carbon and its redistribution of physical and biogeochemical properties affects all oceans. It is also one of the least known sectors of planet Earth with large unexplored areas. The fate of the West Antarctic Ice Sheet is considered the greatest remaining unsolved problem when predicting future global sea level. This giant ice sheet is drained by glaciers that terminate in the ocean, where they form floating ice shelves overlying vast sub-ice cavities. Physical processes in these cavities are key for the melting and break-up of the ice sheet. However, due to the lack of data for boundary conditions, forcing, and validation of theories and models, these environments are still very poorly understood. Another main knowledge gap is the seasonally sea-ice covered parts of the Southern Ocean, an area larger than the South American continent. The Southern Ocean accounts for about 50% of the oceans uptake of CO2. Observations of the ice-covered regions remain mostly non-existent because of its remoteness and harsh environment. The ice prevents satellite-based remote sensing of the sea, available in other regions. Data is obtained at great logistical cost and elevated risk, and it is vital that the international community work together to create sustainable and efficient observing systems in this area. Without a clear understanding and long-term observations of the air-sea-ice fluxes, we are unable to supply climate models with correct process descriptions and validation. As a result, we currently hold a poor understanding of the key ocean processes. This presentation will outline major knowledge gaps existing in the Southern Ocean and recent advances addressing them within the Southern Ocean Observing System (SOOS).
Long-term Dietary Trends and Resiliency of Pacific Walruses to Climate Change

Alexander Thornton\(^1\) (alexander.e.thornton@gmail.com), Lara Horstmann\(^1\), Nicole Misarti\(^2\)

\(^1\)University of Alaska Fairbanks, College of Fisheries & Ocean Sciences, Fairbanks, United States, \(^2\)University of Alaska Fairbanks, Water & Environmental Research Center, Fairbanks, United States

Sea ice loss threatens Arctic species, such as Pacific walruses (Odobenus rosmarus divergens). Long-term dietary studies are useful in assessing impacts of climate change. We obtained stable isotope data ($\delta^{15}$N, $\delta^{13}$C) from cementum growth layers in walrus teeth to assess diet variability. By documenting changes over individual lifetimes and population-wide trends, we investigate resiliency and vulnerability of walruses to environmental change. Partnering with museums and subsistence users, we chose teeth collected from 1880-2016. A generalized additive model shows $\delta^{15}$N and $\delta^{13}$C decrease over time, while expressing cyclical, but inverse patterns. Walrus trophic level reached a low in the 1960s and peaked in the 1990s, followed by a recent decline; this may correlate with population size. When sexes were analyzed separately, this pattern was different for females, who reached a $\delta^{15}$N peak in the 1980s. Declines in $\delta^{13}$C through time may link with large-scale environmental trends and mirror observations in marine species in other biogeographic regions, including Antarctica. Autocorrelation functions show short- and long-term oscillations of $\delta^{15}$N and short-term oscillations of $\delta^{13}$C through time, suggesting biotic influences on diet (e.g., mollusk depletion and repopulation). High variability in $\delta^{13}$C and $\delta^{15}$N indicates walruses are generalist predators consuming varying proportions of pelagic and benthic prey. Walruses may thus have potential resiliency in the face of climate change.
Antarctic fur seals, *Arctocephalus gazella*, breed on sub-Antarctic islands around the continent. This discrete, yet circumpolar, distribution is an ideal natural laboratory for exploring genetic selection. All of the islands inhabited by *A. gazella* are near the polar front, but they differ in key parameters, notably in the composition of available prey and in the degree of commercial harvesting each colony experienced. In terms of prey, krill form the majority of *A. gazella*’s diet in West Antarctica, whereas further east myctophid fish form the bulk of the diet. In terms of harvest pressure, more readily accessible islands, such as South Georgia, suffered high rates of exploitation during sealing, while more remote and inaccessible islands, such as Bouvetøya, were harvested at much lower levels. How then have these disparate pressures driven genetic selection in *A. gazella*? To address this question, we sequenced 100,000 loci across the genomes of 97 individuals from 8 major colonies across the circumpolar breeding distribution. By comparing the frequencies of genetic changes, and mapping changes back onto annotated genomes, we can begin to unravel the effects of these natural and anthropogenic selective forces on *A. gazella* at a molecular level. Understanding the evolutionary consequences of sealing, and the ongoing selective pressure of different prey regimes may provide insight to guide management of this species within a rapidly changing Southern Ocean.
Post-weaning Dispersal of Antarctic Fur Seal young of the Year

Michael E. Goebel¹ (mike.goebel@noaa.gov), Jeremy T. Sterling², Noel A. Pelland², Daniel P. Costa³, Birgitte I. McDonald⁴, Douglas J Krause¹, Jefferson T. Hinke¹
¹NOAA, Antarctic Ecosystem Research Division, La Jolla, United States, ²NOAA, National Marine Mammal Laboratory, Seattle, United States, ³University of California Santa Cruz, Santa Cruz, United States, ⁴Moss Landing Marine Labs, Moss Landing, United States

First-year survival (FYS) is a critical parameter driving trends in abundance and recruitment in vertebrate populations and can be a substantial driver of life-time reproductive success. FYS of Antarctic fur seals (AFS) in the South Shetland Islands is highly variable and declining. Newly-weaned AFS are shallow divers that likely depend upon highly productive areas with high-density prey to survive an abrupt transition to nutritional independence. This critical time in pinniped life history is under-studied. Our objective was to investigate habitat use and dispersal patterns for AFS young-of-the-year using satellite-linked telemetry. We instrumented 39 AFS pups over three years. Pups were tracked from their natal colony on average 64 d (±67.0). Over 21,000 ARGOS locations were processed with a continuous-time correlated random walk model. One pup which was recaptured the following year spent 93.2% of its winter migration (251d) south of the Polar Front. Some pups spent their post-weaning months in the Bransfield Strait, the location of an extensive and growing winter fishery for Antarctic krill. The overlap between this critical period in AFS life history and the winter krill fishery is a concern for the conservation of this and other krill-dependent species. More studies of distribution and foraging ecology of young of the year are necessary to understand the full extent of the impact of the fishery.
Acoustic Monitoring of Top Predators in the Ross Sea Marine Protected Area (MPA)

Alexa Hasselman¹ (alexa.hasselman@pg.canterbury.ac.nz), Regina Eisert¹, Michael Hayes², Andrew Wright³, Andrew Wright⁴
¹Gateway Antarctica, University of Canterbury, Christchurch, New Zealand, ²College of Engineering, University of Canterbury, Christchurch, New Zealand, ³University of Canterbury, Gateway Antarctica, Christchurch, New Zealand, ⁴Bedford Institute of Oceanography, Fisheries and Oceans, Dartmouth, Canada

The Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) is expected to officially declare the Ross Sea region Marine Protected Area (MPA), located in a pristine and ecologically important area of the Southern Ocean, in December 2017. CCAMLR requires ongoing monitoring of the MPA to ensure objectives are met, specifically prevention of ecosystem effects as a result of fishing for Antarctic toothfish. The focus of proposed research and monitoring for the MPA is on toothfish predators, including Weddell seals and Type-C killer whales. These and other top predators are valuable indicators of ecosystem status, since their presence, diversity, and abundance integrate multiple external drivers acting on the ecosystem.

The aim of our study was to establish the methodology for comprehensive passive acoustic monitoring of marine mammals in the MPA. During January 2018, we deployed a series of ‘sound traps’ with a 288KHz sample rate in an area used by killer whales and other marine mammals to generate presence/absence data, diel activity patterns, and abundance information. Concurrent video was also obtained using underwater ‘camera traps’ to correlate various calls to observed behaviors, individual identity, and group structure. The findings obtained will inform the design of passive acoustic monitoring networks in the Ross Sea region MPA and greatly contribute to our understanding of the ecology of key top predators in that ecosystem.
Assessing Global Change Influences on the Distribution of Antarctic fur Seals

Mary-Anne Lea1,2 (maryanne.lea@utas.edu.au), Ben Arthur1,3, Marthan Bester4, PJ de Bruyn4, W. Chris Oosthuizen5, Michael Sumner1,5, Simon Wotherspoon1,5, Mia Wege4, Mark Hindell1,2

Antarctic fur seals are a numerous, adaptable and far-ranging circumpolar species. While krill forms a significant component of their diet in the South Atlantic, individuals in the southern Pacific and Indian Oceans rely on mesopelagic fish and squid. Over the last ten years, we have studied the winter habitat requirements of Antarctic fur seals at Marion Island. One of the primary aims has been to assess how the predicted southwards movement of Southern Ocean fronts and the intensification of westerly winds (positive Southern Annular Mode) may influence the distribution and foraging success of pelagic Southern Ocean marine predators. Since 2008, the post-breeding movements of over three hundred female Antarctic fur seals from Marion Island have been studied using flipper-tag geolocation tags. Movement analysis of this unique and extensive time series has been conducted using freely available, customised software (bsam and SGAT R packages). This approach has enabled the detection of key individual and aggregated annual foraging areas during this ten-year period (2008-2017). Predicted inter-annual southwards shifts in prime foraging areas were assessed in relation to mean and annual frontal positioning and sea-ice extent. Understanding how changes in the foraging behaviour and success of higher trophic level species relate to signals of global change, will enable better predictions of ecosystem change and population level response in the Southern Ocean into the future.
Life in the Fast Lane: Fur Seal Foraging at the Edge of their Distribution

Renato Borras-Chavez\textsuperscript{1}, Michael E Goebel\textsuperscript{2} (mike.goebel@noaa.gov), Stella Villegas-Amtmann\textsuperscript{3}, Luis Huckstadt\textsuperscript{3}, Daniel P Costa\textsuperscript{3}, Carla N Rivera\textsuperscript{1}, Jose M Fariña\textsuperscript{1}, Francisco Bozinovic\textsuperscript{1}

\textsuperscript{1}Catholic University of Chile, Center of Applied Ecology and Sustainability-CAPES, Santiago, Chile, \textsuperscript{2}National Oceanic and Atmospheric Administration, Antarctic Ecosystem Research Division, San Diego, United States, \textsuperscript{3}University of California Santa Cruz, Department of Ecology and Evolutionary Biology, Santa Cruz, United States

At its most southerly breeding range, the Antarctic fur seal (AFS) operates at its highest field metabolic rate in an environment challenging the physiological limits for energy acquisition. Currently, we have little understanding on how edge colonies, already coping with high environmental variability, may deal with additional variation contributed by specific atmospheric events. By using a combination of diet estimates and biologging we evaluated how additional environmental variability (2014/15 EL NINO year against regular years) may affect the behavior of these colonies. Foraging behavior was compared between all years using 18 variables that represent five categories: trip duration, recovery time (time ashore and surface time), diving effort, habitat use and diet. Differences were found in trip duration (longer trips), recovery time (shorter time ashore) and habitat use between 2014/15 and normal years. No differences were found in diving effort since colonies are already operating at their physiological maximum. Diet was no different between years. This suggest that, in critical years, individuals will not take decisions that may risk the success of capturing prey (longer but close to shore trips and shorter time ashore) differing from other AFS colonies under critical conditions. Adaptive mechanisms may be shaping the behavior of these colonies highlighting the importance of research on evolutionary patterns in colonies living constantly in the fast lane of life.
We present quantitative reconstructions of past temperature change from Antarctic and sub-Antarctic lake sediments using temperature-sensitive membrane-spanning glycerol dialkyl glycerol tetraether (GDGT) lipids of Archaea/Bacteria, and examine Holocene palaeoclimate change and the deglaciation of ice-free areas on the Antarctic Peninsula (AP) and South Georgia (SG). Global GDGT calibrations do not perform well for low temperature/high latitude lake sediments because GDGT presence, type and provenance is largely unstudied. To address this, we quantified modern-day environmental controls on GDGT compositional abundance in surface sediments of 38 (sub-)Antarctic lakes. GDGT compounds were found in 37 lakes, with branched GDGT (brGDGT) compounds dominant. Mean summer air temperature (MSAT) explained most variance in the brGDGT data allowing development of a new brGDGT-summer temperature calibration for (sub-)Antarctic lakes with significantly improved statistical performance at low temperatures. Reconstructed summer temperatures from three strategically-located palaeolimnological records reveal that deglaciation near to present limits was likely completed by or during a late Holocene temperature maxima, centred on c. 4-3 ka, with a significant cooling trend into, and minor glacial readvances during, the C16-19th Southern Hemisphere (SH) 'Little Ice Age'. We link Holocene temperature shifts and regional lags to variations in SH insolation and Westerly wind strength.

Lakes situated in polar regions are quite sensitive to slight variations in the climate, and therefore can be effectively used to reconstruct past variations in the environmental conditions arising due to climate change. Schirmacher Oasis (SO) is one of the ice-free regions in East Antarctica and is bestowed with several freshwater lakes. In this work, we present a multi-proxy work carried out on a 79-cm sediment core from L-49 Lake. The core has an age-span of ~43 cal ka B.P. which is constrained by five AMS radiocarbon dates. A range of environmental magnetic measurements were made in addition to estimation of the total organic matter content for the samples. The iron-bearing minerals are mainly derived from the catchment as there is no obliteration of the magnetic signal due to magnetic dissolution, bacterial magnetite and authigenic greigite. The magnetic properties are high during the last glacial period indicating a fairly high concentration of coarse-grained magnetite. Such high values are indicative of extremely cold climatic conditions in the SO. During the Holocene, the values are quite low, suggesting relatively warmer climatic conditions. This is also supported by the high values of organic matter content indicating an increase in productivity in the lake system. Deglaciation in the SO began at around 20 cal ka B.P. which is fairly consistent with other paleoclimatic records from the region as well as other ice-free regions in East Antarctica.
Groundwater and Thaw Legacy of a Large Paleolake in Taylor Valley, Antarctica

Krista Myers¹ (kmyer19@lsu.edu), Peter Doran², Neil Foley², Slawek Tulaczyk², Hilary Dugan³, Esben Auken⁴, Jill Mikucki⁵, Ross Virginia⁶

¹Louisiana State University, Geology and Geophysics, Baton Rouge, United States, ²University of California, Santa Cruz, Earth and Planetary Sciences, Santa Cruz, United States, ³University of Wisconsin - Madison, Center for Limnology, Madison, United States, ⁴Aarhus University, Department of Geoscience, Aarhus, Denmark, ⁵University of Tennessee, Knoxville, Department of Microbiology, Knoxville, United States, ⁶Dartmouth College, Institute of Arctic Studies, Hanover, United States

The McMurdo Dry Valleys (MDVs) in East Antarctica contain a number of perennial ice-covered lakes fed by ephemeral meltwater streams. Paleodeltas and paleoshorelines throughout Fryxell Basin in Taylor Valley provide evidence of significant lake level change occurring since the Last Glacial Maximum (LGM). During the LGM, grounded ice in the Ross Sea extended into the eastern portion of Taylor Valley, creating a large ice dammed paleolake referred to as Glacial Lake Washburn (GLW). Airborne resistivity data collected by SkyTEM, a time-domain airborne electromagnetic sensor system, was used to map groundwater systems in the lake basin. A large low resistivity region indicative of liquid water extends hundreds of meters away from the modern lake extent which is consistent with the presence of a degrading thaw bulb from GLW. As lake level in Fryxell Basin fell to modern levels, the newly exposed saturated sediment surrounding the lake began to freeze. We hypothesize that this process is ongoing and will continue until equilibrium is reached between the geothermal gradient and atmospheric temperatures.

Though groundwater systems were previously thought to be minimal or nonexistent in the MDVs, regional resistivity data now show that extensive reservoirs exist beneath these lakes. The presence of deep groundwater systems beneath MDV lakes has important implications for hydrologic and ecosystem connectivity in an environment largely driven by the availability of liquid water.
Assessing the Impacts of Antarctic Bases on Fildes Peninsula Aquatic Ecosystems

Santiago Giralt¹ (sgiralt@ictia.csic.es), Dermot Antoniades², Roberto Urrutia³

¹Institute of Earth Sciences Jaume Almera (ICTJA-CSIC), Barcelona, Spain, ²Centre d’Études Nordiques, Université Laval, Québec, Canada, ³University of Concepción, Concepción, Chile

The Fildes Peninsula (King George Island, South Shetland Islands) has been the site of year-round human presence since the construction of Bellingshausen Station in 1968. The peninsula is now home to six permanent bases, creating one of Antarctica’s densest human concentrations. Substantial infrastructure supports these bases, including an airport, roads, pipelines, and diesel generators. The construction and operation of these facilities has caused considerable disturbances, although the precise nature of the effects on most ecosystems is still poorly understood.

In 2016 and 2017, eight lakes were sampled to determine nutrient and metal concentrations as well as basic water column properties. Short sediment cores were also retrieved to determine lake conditions prior to human presence on the peninsula, and to develop records of how anthropogenic pollutants have affected the lakes since bases were established. XRF core scanner, x-ray diffraction, and CT-Scan images have been used to determine how the deposition of pollutants to the lakes has changed in the past. Biological indicators, including diatoms and fossil pigments, will be employed to determine how aquatic communities have changed over time and if they been affected by local human activities. By comparing our study lakes situated near and distant from bases, we will determine what observed changes can be attributed to natural changes and thus quantify anthropogenic effects on Fildes Peninsula aquatic ecosystems.
Reconstructing Westerly Wind Variability Using Sub-Antarctic Lake Sediments

Krystyna Saunders1,2 (krystyna.saunders@ansto.gov.au), Stephen Roberts3, Bianca Perren4, Christoph Butz2, Christoph Dätwyler2, Raphael Neukom2, Louise Sime4, Martin Grosjean2, Hodgson Dominic3

1Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia, 2University of Bern, Institute of Geography, Bern, Switzerland, 3British Antarctic Survey, Cambridge, United Kingdom

The position and strength of the Southern Hemisphere westerly winds (SHW) is important for temperature and rainfall variability from the mid- to high-latitudes of the Southern Hemisphere. The SHW also influence Southern Ocean circulation, regulate ocean-atmosphere CO2 degassing, and influence sea ice extent around Antarctica. While observations since the 1950s show the winds have strengthened and shifted southwards, this period is too short to understand their natural variability, especially as stratospheric ozone depletion and rising greenhouse gases from anthropogenic activities are considered to be driving these changes. Here, we present SHW strength reconstructions spanning the last 12,000 years from sub-Antarctic Macquarie Island (54°S, 158°E) based on independent proxies that track the changing inputs of sea salt aerosols and minerogenic particles into lake sediments. Our reconstructions show close agreement with temperature, sea ice and atmospheric CO2 records from Antarctic ice cores for the last 12,000 years, and southern South American temperature for much of the last Millennium.
Sub-antarctic Peats as Recorders of Westerly Wind Changes. Preliminary Results

Peatlands are important terrestrial archives of past environmental change and human impact. Some peatlands are only fed by atmospheric inputs and therefore have the potential to record a more global or hemispheric signature than other continental deposits. Easily datable, they can produce high-resolution, precisely dated records covering the Holocene and beyond. Peatlands located on high-latitude sub-Antarctic Islands are heavily influenced by the prevailing Southern Hemisphere Westerly winds (SHW) and provide excellent archives in areas of the Southern Ocean where terrestrial paleorecords are otherwise scarce. In particular, they are excellent traps for particulate material (dust) transported in the atmosphere and provide information about past changes in the SHW. Changes in the relative strength and latitudinal position of the SHW are thought to be both spatially- and temporally-variable, influencing the Southern Ocean circulation and controlling how much carbon-rich deep water reaches the ocean surface. To better understand changes in the SHW and its impact on carbon exchange between the ocean-atmosphere over millennial-centennial timescales, we sampled peatlands from several islands located within the SHW core belt. Here, we reconstruct past (decadal to millennial) changes in the SHW position and strength from proxy records of wind-driven particulates and develop a more complete understanding of how the SHW modulate the oceanic uptake of CO₂.
Functional Succession from Ice to Developed Soils in the Arctic

Alexandre Anesio¹ (a.m.anesio@bristol.ac.uk), Maisie Nash¹, Gilda Varliero², Gary Barker², Martyn Tranter², Liane G. Benning³,⁴,⁵
¹University of Bristol, School of Geographical Sciences, Bristol, United Kingdom, ²University of Bristol, School of Life Sciences, Bristol, United Kingdom, ³German Research Centre for Geosciences, Potsdam, Germany, ⁴University of AberdeenLeeds, School of Earth & Environment, Leeds, United Kingdom, ⁵Free University of Berlin, Department of Earth Sciences, Berlin, Germany

Glaciers in the Northern Hemisphere are retreating and their forefields present a unique opportunity to investigate the initial phases of soil weathering/formation and microbial succession in terrestrial cold habitats. In Arctic environments, the relative importance of primary autotrophic microbial colonisers (e.g. cyanobacteria and chemolithotrophs), input of allochthonous sources and recycling of ancient organic carbon during the initial phase of soil establishment is still debated. In this study, the functional microbial diversity of four Arctic glacier forefields was investigated using metagenomic analysis. In total, 72 soil samples were collected and sequenced using the Illumina Next-Seq 500. The annotated assembled metagenomes were used in a newly developed pipeline to provide a quantitative approach to investigate selected ecologically relevant genes. Our study shows a succession of processes with age, whereby communities in soils previously overridden ice, strongly represented by a C-fixation metabolism, are gradually replaced by a metabolism involved in the degradation of complex organic carbon. Genes associated with N-fixation were significantly high only in forefields where total nitrogen content was low. The metabolic diversity observed in our chronosequence gives insights into feedback mechanisms between geochemistry and microbial colonisation during soil development after glacial retreat.
Temperature Sensitivity of the High Alpine Soil Microbiome

Johanna Donhauser¹ (johanna.donhauser@wsl.ch), Pascal Niklaus², Beat Frey¹
¹Swiss Federal Research Institute WSL, Birmensdorf, Switzerland, ²University of Zurich, Department of Evolutionary Biology and Environmental Studies, Zurich, Switzerland

Climate change leads to rapid warming of arctic and alpine environments with strong impacts on the soil microbiome. However, the effects of elevated temperature on soil microbial diversity and functions and the link between them are still poorly understood.

To assess the temperature adaptation, we incubated eight high-alpine soils adapted to different altitudes and aspects at five temperatures between 4 - 35 °C for one month. Sequencing of the bacterial 16S rRNA gene at the DNA and RNA level as well as 3H-leucine incorporation as a measure for bacterial growth were used to investigate shifts of abundance, activity and optimal growth temperature.

All soils intrinsically exhibited an optimal temperature for bacterial growth of 25 - 30 °C. Only incubation above 25 °C led to a shift of the growth optimum towards the incubation temperature. Conversely, preliminary results indicate a gradual shift of the bacterial community structures in response to temperature over all incubation temperatures. Changes at the DNA level might indicate enrichment of taxa adapted to the respective treatment temperature in the community as they may gain a selective advantage leading to enhanced turnover relative to less well adapted taxa. On the contrary, shifts in abundance at the RNA level only suggest increase and decrease of activity without concurrent turnover as an important mechanism of temperature adaptation.

Greenhouse Gas Fluxes and Microbial Activities in Dry and Wet High-arctic Soils

Aline Frossard1 (aline.frossard@wsl.ch), Vivien Hotter2, Ramona Kern2, Bjorn Tytgat3, Christophe Seppey4, David Velazquez5, Pascal Niklaus6, Antonio Quesada5, Ulf Karsten2, Mette Svenning4, Elie Verleyen3, Beat Frey1
1Swiss Federal Research Institute WSL, Birmensdorf, Switzerland, 2University of Rostock, Rostock, Germany, 3Ghent University, Ghent, Belgium, 4The Arctic University of Norway, Tromso, Norway, 5Autonomous University of Madrid, Madrid, Spain, 6University of Zurich, Zurich, Switzerland

High-arctic tundra-soil ecosystems are particularly sensible to global changes due to their proximity to freezing, snow cover, light availability and scarcity of vegetation. Hydrological fluctuations in these soils are also important, where drier soils are expected to be less buffered to temperature, directly impacting the soil biological activity. Yet, little is known on the effects of soil moisture in the regulation of microbial activities in high-arctic soils and their impact on greenhouse gas exchanges with the atmosphere. In a study part of the CLIMARCTIC consortium, the fluxes of greenhouse gases (CO2, CH4 and N2O) were assessed along a moisture gradient (30 - 70 %) in high-arctic tundra soils near Ny-Ålesund (Svalbard) and linked to microbial activities and community structures. Fluxes of CO2 were highest in dry soils, indicating higher respiration compared to wetter soils in which CO2 fixation was more important than respiration. Methane (CH4) was mostly consumed except for the wettest soils where CH4 was emitted. Comparing these results with microbial functional diversity such as abundance of functional genes or extracellular enzymes activities involved in C and N-cycling will allow to highlight the importance of soil moisture in tundra soils for microbial activities and their impact on greenhouse gases fluxes.
The Microbiome of the High-alpine Permafrost and its Response to Warming

Carla Pérez Mon¹ (carla.perezmon@wsl.ch), Aline Frossard¹, Beat Stierli¹, Beat Frey¹
¹WSL Swiss Federal Institute for Forest Snow and Landscape Research, Zurich, Switzerland

The microbiome of temperate mountain permafrost is still poorly understood. Here we present the results of a pioneering metagenomic study on the permafrost microbial communities from the Swiss Alps. Samples taken in the ridge of “Muot-da-Barba-Peider” (N 46.49634 E 9.93145, 2979 m. a. s. l) revealed a unique, highly diverse microbial community enriched in bacterial members of the novel Patescibacteria superphylum and with a significant proportion (14%) of poorly characterized fungi. Based on these results, we established an in situ experiment in which permafrost soils at a depth of 1.6m were placed into the surface active layer in order to simulate thawing of permafrost as a consequence of warming. After one year, DNA content as a proxy for microbial biomass in the transferred permafrost soil increased. This may imply changes in the microbial community structures and functions with potential impacts on the C- and N- cycles in these soils. All together our results contribute to a better understanding of the future status of the permafrost microbiome subjected to warming and its implications for the high mountain ecosystem functioning.
Biostimulation of Antarctic Soil on a Freeze-thaw Regime: A Promising Approach

Hugo Emiliano de Jesus¹ (hugoemil@gmail.com), Charles K. Lee¹, S. Craig Cary¹, Raquel S. Peixoto², Alexandre S. Rosado²

¹University of Waikato, Faculty of Science and Engineering, Hamilton, New Zealand, ²Federal University of Rio de Janeiro, Institute of Microbiology, Rio de Janeiro, Brazil

Several studies have applied and evaluated bioremediation treatments on Antarctic soils; however, most of them take place during the summer to take advantage of higher temperatures. The Antarctic continent is constantly subject to temperature fluctuations, and summer periods are short and not enough to achieve the biodegradation goals. Recently, a few studies have shown the possibility of developing a bioremediation treatment over freezing periods with significant hydrocarbon degradation ratios. However, none of those studies compared a conventional summer bioremediation treatment against a freeze-thaw cycle (FTC) with temperatures varying between negative and positive, which frequently occur in Antarctica. A 75-day experiment was performed aiming to evaluate the differences in bacterial communities in a nutrient-amended treatment (BS) at 4°C against a FTC nutrient-amended treatment (FBS) (temperatures from -20 to 4°C) in contaminated soil by diesel oil. Our results revealed that 35.9% of OTUs found in FTC samples were shared between control and nutrient-amended treatments, relative to 4.3% of OTUs for the same treatments in unfrozen soils. Predicted functional pathways analysis showed that 12 out of 16 related xenobiotic biodegradation pathways were at least twice higher in FTC nutrient-amended soil compared to all other treatments. Based on the results, FBS treatment might represent a new effective, fast, and conservative strategy for bioremediation in Antarctica.
Methane Producing Archaea in Siberian Permafrost and their Response to Thaw

Stine Holm1 (stine.holm@gfz-potsdam.de), Susanne Liebner1, Fabian Horn1, Christian Knoblauch1, Dirk Wagner1
1Helmholtz Centre Potsdam - GFZ German Research Centre for Geosciences, Section 5.3. Geomicrobiology, Potsdam, Germany, 2Helmholtz-Zentrum Potsdam, Section 5.3. Geomicrobiology, Potsdam, Germany, 3Universität Hamburg, Department of Earth Sciences, Hamburg, Germany

Methane production in thawing permafrost can be substantial but often evolves after long lag phases or is lacking, potentially a result of low or absent methanogenic community or limited substrate. We investigated samples of a permafrost core of Kurungnakh Island, Siberia, seeking an explanation on the contrasting evolution of methane production after permafrost thaw. Subsamples were incubated anaerobically at 4°C for 7 years. The enumeration of methanogenic mcrA gene copies was performed by quantitative PCR (qPCR), and the community composition was determined by amplicon based sequencing. The initial community of the upper layer of the core, formed during cold and dry conditions was dominated by Thaumarchaota. These samples did not show methane production by the end of the incubation experiment. In contrast, the layers below 9m deposited under warm and wet conditions established methane production and were dominated by Euryarchaeota, with a high abundance of methanogens (47-78%). During the incubation the diversity of these samples decreased to a dominance of Methanomicrobiales. Based on methane production, community analysis and qPCR results, we conclude that thaw stimulated methanogenesis in permafrost environments where an initial active methanogenic community was present. The response of the methanogenic community appears to depend on the conditions, under which the soil was formed, with warmer and wetter conditions enhancing the activity of methanogens after thaw.
Human Hemoglobin and Hematocrit Values at Varying Altitude

Max Gassmann1 (maxg@access.uzh.ch)
1University of Zurich, Physiology, Zurich, Switzerland

Living at and travelling to high altitude including Antartica is a physiological challenge. While lowlanders have to acclimatize to reduced oxygen supply (and cold) by increasing red blood cell production, highlanders living in different regions of the world have developed various adaptive mechanisms to cope with these harsh conditions. Indeed, in contrast to South American Highlanders (Quechua and Aymaras), Tibetans only moderately elevate their hematocrit and hemoglobin at high altitude. We recently asked the question if an elevation lower than 1500 m above sea level shows an impact on Hb levels in men. To answer this question, we analyzed blood from 70,000 Swiss men aged 18-22 years and observed a significant increase of Hb values for every 300 meters of augmented altitude. Our data provides convincing evidence that even altitudes below 1500 m must be considered when defining normal hemoglobin and hematocrit values.
Regulating Iron and Hemoglobin Levels at High Altitude

Martina Muckenthaler¹ (martina.muckenthaler@med.uni-heidelberg.de)
²University of Heidelberg, Heidelberg, Germany

At high altitude erythropoiesis is increased to allow for the elevated demand of oxygen. In red blood cells oxygen is bound to iron within the hemoglobin molecule to circulate in the human body. Thus, iron levels have to be sufficient to maintain adequate tissue oxygenation at high altitude. Iron metabolism is controlled by hypoxia at various levels that will be discussed in my presentation. The level of hemoglobin defines anemia that adversely affects various aspects of human health including cognitive performance, work productivity as well as complications during pregnancy affecting mother and fetus. We analyzed ‘high altitude’ as a well-established modifier of Hb concentration and show that Hb values in South American inhabitants increase more dramatically with altitude compared to all other regions of the world. By contrast, individuals of Tibetan origin show a significantly lower Hb concentration at all altitudes. All other ethnicities studied showed a comparable increase of Hb in response to altitude. We provide a multiple meta-regression-model revealing the change in hemoglobin concentration with increasing altitude in dependence of sex and ethnicity in adults.
Lactate Metabolism in Tibetans

Mauro Marzorati1 (mauro.marzorati@ibfm.cnr.it)
1Consiglio Nazionale delle Ricerche, Istituto di Bioimmagini e Fisiologia Molecolare, Segrate, Italy

Upon acclimatization to severe hypoxia, Caucasian lowlanders undergo an apparent blunting of anaerobic glycolysis, the so-called “lactate paradox” (LP) (the finding that at the same fraction of the maximum work rate, blood lactate increases at high altitude to a lesser extent than at sea level attaining lower peak levels ([La\textsubscript{b}]\textsuperscript{peak}) at voluntary exhaustion. With regard to high-altitude natives, [La\textsubscript{b}]\textsuperscript{peak} at altitude has been reported to be lower in Sherpas and in Quechuas and in the same range of that of acclimatized lowlanders. Moreover, the persistence of low [La\textsubscript{b}]\textsuperscript{peaks} 6 weeks after descent from altitude to sea level, has induced to hypothesize that in Quechuas the LP may have become a fixed metabolic feature.

In order to gain a better insight into the glycolytic capacity of altitude natives, we have assessed blood lactate concentration at exhaustion in Tibetans with different altitude exposure history: a) in a group of native Tibetans living at Shegar (4,300 m); b) in a group of Tibetan highlander migrants born and living between 3,500 and 4,500 m until 2-32 days prior to the descent to Kathmandu (Nepal, 1,300 m); c) in a group of Tibetan lowlanders, born and living in Kathmandu.

In all investigated groups, [La\textsubscript{b}]\textsuperscript{peak} values were of the same order of magnitude as those observed in Caucasians at sea level (10 to 13 mM). The present results seem to indicate that the LP might not be a constant feature of high altitude acclimatization.
The Effect of Normobaric and Hypobaric Hypoxia on Peripheral Perfusion

Adam C. McDonnell\textsuperscript{1} (adam.mcdonnell@ijs.si), Ola Eiken\textsuperscript{2}, Pietro E. di Prampero\textsuperscript{3}, Igor B. Mekjavic\textsuperscript{1,4}

\textsuperscript{1}Jozef Stefan Institute, Department of Automation, Biocybernetics and Robotics, Ljubljana, Slovenia, \textsuperscript{2}KTH Royal Institute of Technology, Department of Environmental Physiology, Swedish Aerospace Physiology Centre, Stockholm, Sweden, \textsuperscript{3}University of Udine, Department of Medical and Biological Sciences, Udine, Italy, \textsuperscript{4}Simon Fraser University, Department of Biomedical Physiology and Kinesiology, Burnaby, Canada

According to the equivalent air altitude (EAA) theory, the physiological responses observed during exposure to normobaric and hypobaric hypoxia are similar. This study evaluated the EAA theory on the basis of the circadian rhythm of proximal-distal skin temperature gradient. Specifically, we assessed the effect of hypoxia on daytime and nocturnal peripheral perfusion and whether the effect was modified by the ambient pressure. Data from three separate experimental trials were analysed:

1) Acute trial: 10-day (N = 14 males) confinement in a normobaric hypoxia (simulated altitude = 4170m);

2) Adaptation trial: 21-day (N = 11 males) confinement to a normobaric hypoxia (simulated altitude = 4,000m, and

3) Chronic trial: 12-month assignment (N=16 males and 2 females) at the Antarctic research base Concordia.

We monitored the proximal-distal skin temperature gradient (\(\Delta T_c-t\)), an index of peripheral perfusion, during the day and night. Nocturnal \(\Delta T_c-t\) was not different between the groups and was below the vasoconstriction threshold, thus reflecting a tendency for nocturnal cutaneous vasodilation. Sleep onset is highly dependent on peripheral skin temperature, and as there was no difference in \(\Delta T_c-t\) between the groups, there appears to be no effect of ambient pressure on nocturnal peripheral perfusion.
Cerebral Deoxygenation and Cognitive Performance in Different Hypoxic Conditions

Mathias Aebi1,2 (mathias.aebi@gmail.com), Nicolas Bourdillon2, Philip Noser1, Denis Bron1, Grégoire Millet2
1Aeromedical Center, Dübendorf, Switzerland, 2University of Lausanne, Institute of Sport Sciences, Lausanne, Switzerland

Introduction: Mountaineers and pilots are regularly exposed to hypobaric hypoxia (HH) conditions. For safety reasons, it is paramount to investigate how concentration and cognition may be affected and the influence of cerebral deoxygenation. The aim of this study was to investigate how cognitive performance was altered and its relation with cerebral oxygenation in different normobaric and hypobaric hypoxic conditions.

Methods: Sixteen pilots trainees (26 ± 4 years old) performed a concentration test (KLT) in five randomized conditions [Normobaric Normoxia, NN; HH at 3000m and 5500m; Normobaric Hypoxia NH and Hypobaric Normoxia HN at 5500m]. During each KLT, tissue oxygenation index (TOI) was measured by near-infrared spectroscopy. Cerebral oxygen delivery (cDO2) was calculated with measured cerebral middle artery velocity by transcranial Doppler, hemoglobin concentration and earlobe oxygen saturation.

Results: Percentage of error (%Err) on KLT was higher at 5500m in HH (16.3 ± 13.3%, P=0.002) and NH (14.2 ± 9.2%, P=0.025) but not in NN (6.8 ± 6.0%) and 3000m HH (10.4 ± 11.1%), compared to NN (7.2 ± 3.9%). TOI was impaired at 5500m in HH (68.2 ± 7.1, P< 0.001) and in NH (72.2 ± 6.3) but was similar between all other conditions (NN: 80.8 ± 6.5; 3000m HH: 77.2 ± 6.1 and 5500 HN: 79.7 ± 6.6). cDO2 was similar in all conditions. No significant relationships between percent change from NN to any condition in cDo2 or TOI and %Err was observed, suggesting a complex regulation.
Crewmembers of polar expeditions often face difficulties initiating and maintaining sleep and show decreased rapid eye movement (REMS) and slow-wave sleep, as well as circadian phase delays, poor sleep quality and increased sleep fragmentation. 13 males took part in a winter-over campaign at Dome C and completed 8 measurement cycles every 6 weeks including a.o. polysomnography (PSG), actigraphy, subjective sleep, sleepiness and fatigue assessments and psychomotor vigilance testing. A control group (n=13; 2 females) performed a single measurement cycle in normobaric normoxia. Overall, results indicate that Hivernauts present with increased sleep onset latencies and reduced sleep efficiency. Latencies to REMS appear to be shorter, REMS duration increase and light sleep decreases. Hivernauts all show periodic breathing, significantly impacting sleep fragmentation. Cognitive speed is reduced in Hivernauts and associated to higher sleep fragmentation. Phase-delays are observed in crewmembers subjected to fixed bedtimes, while the remainder show free-running sleep-wake activity. Situational sleepiness is moderate in Hivernauts, but higher than in controls. Except increased obstructive respiratory events towards the end of the campaign, sleep, sleepiness and psychomotor performance variables, show to be fairly robust and stable over time. Results from the largest PSG dataset to date in Antarctica suggest that the sleep-related individual differences are phenotypic in nature.
What Is Important to Get Right When Modelling the Greenland Ice Sheet?

Ruth Mottram\(^1\) (rum@dmi.dk), Peter Langen\(^1\), Christian Rodehacke\(^{1,2}\), Fredrik Boberg\(^1\), Jens Hesselbjerg Christensen\(^3\)

\(^1\)Danish Meteorological Institute, Copenhagen, Denmark, \(^2\)Alfred Wegener Institute, Bremerhaven, Germany, \(^3\)University of Copenhagen, Nielse Bohr Institute, Center for Ice and Climate, Copenhagen, Denmark

Ice sheet and glacier models need accurate surface mass balance inputs to reproduce ice sheet extent and likely evolution. Different regional climate models (RCMs) produce subtly different estimates of ice sheet surface mass balance (SMB) for the Greenland ice sheet. While the total ice sheet SMB number is similar, there can be substantial differences spatially and in terms of the components of surface mass balance: precipitation, melt, runoff, retention and sublimation with potentially large knock-on effects for ice sheet dynamical models. Similarly, SMB generated from coarser resolution GCMs is often used (for example in ISMIP6) to force ice sheet models using simplified SMB schemes.

We use the Devon Ice Cap as a model glacier to show that ice sheet dynamical models are strongly sensitive to choices made in producing SMB forcing when using the same climate model. Similarly, using carefully designed sensitivity experiments we explore the importance of albedo, orography and retention parameter choices in calculating SMB using output from a GCM, EC-Earth and an RCM, HIRHAM5, run at 5km resolution over Greenland. The experiments emphasise that albedo remains a significant source of uncertainty in estimates of rates of melt and runoff and sea level rise but also that accounting for topographic changes on centennial to millennial timescales is likely to be important in estimating the rate of ice sheet mass loss.
Interest of a Regional Climate Model for Doing future Projections over Greenland

Xavier Fettweis¹ (xavier.fettweis@ulg.ac.be), Alison Delhasse¹, Cecile Agosta¹, Charles Amory¹, Christoph Kittel¹, Charlotte Lang¹  
¹University of Liège, Geography, Liège, Belgium

With the aim of evaluating the added value of a regional climate model in downscaled future projections over the Greenland Ice Sheet, we have compared the surface fields (snowfall and summer near-surface temperature) coming from the “best” CMIP5 and CMIP6 global models (GCMs) with these fields simulated by the MAR model forced by the same GCMs. These “best” GCMs were selected according to their ability to simulate the summer temperature at 700 hPa and the general circulation at 500 hPa over Greenland with respect to ERA-Interim over 1980-1999. However, despite their ability to correctly represent the free atmosphere, the selected GCMs present significant biases at the surface of the ice sheet. The comparison shows that MAR is however able to strongly reduce these GCM surface biases. We then forced the lateral boundaries of MAR with ERA-Interim to which we applied temperature corrections of +1°C and +2°C. The outputs were compared to MAR forced by GCM future projections corresponding to a climate about 1 and 2°C warmer than the current climate. The results of the different GCM-forced runs and sensitivity experiments are very similar to each other as the GCMs do not project general circulation changes. Moreover, the sensitivity experiments forced by modified ERA-Interim reveal that the projected SMB decrease is exponentially amplified if the increased occurrence of blocking events over Greenland in summer that has been observed since the 2000’s continues in the future.
Reduced Firn Refreezing Capacity Endangers Arctic Glaciers and Ice Caps

Brice Noël1 (b.p.y.noel@uu.nl), Willem Jan van de Berg1, Stef Lhermitte2, Horst Machguth3,4, Bert Wouters1, Nicole Schaffer5, Michiel R. van den Broeke1
1IMAU/UU, Utrecht, Netherlands, 2TU Delft, Department of Geoscience and Remote Sensing, Delft, Netherlands, 3University of Zurich, Department of Geography, Zurich, Switzerland, 4University of Fribourg, Department of Geosciences, Fribourg, Switzerland, 5Universidad de La Serena, Centro de Estudios Avanzados en Zonas Áridas (CEAZA), La Serena, Chile

Melting of the Greenland ice sheet (GrIS) and its peripheral glaciers and ice caps (GICs) significantly contributes to ongoing sea level rise. Exploiting a novel, 1 km surface mass balance product, statistically downscaled from the output of the regional climate model RACMO2.3 and evaluated against in-situ and remote sensing data, we identify 1997 as a tipping point for GICs mass balance. That year marks the onset of a rapid deterioration in the GICs firn capacity to refreeze meltwater. Consequently, GICs runoff increases faster than meltwater production, tripling the pre-1997 mass loss.

Similar processes are at play in the neighbouring Canadian Arctic Archipelago (CAA). During the last two decades, ice masses in northern and southern CAA have experienced warmer conditions resulting in enhanced surface melt, tripling and doubling the pre-1996 mass loss, respectively. While the interior of the northern ice caps can still buffer most of the additional melt in extensive accumulation zones, the lack of a perennial firn area over the low-lying southern glaciers caused uninterrupted mass loss since the 1980s.

In the absence of significant refreezing, this indicates inevitable disappearance of these highly sensitive Arctic glaciers and ice caps in the near future.
Separating Cryospheric and Oceanic Mass Changes in GRACE Monthly Solutions

Andreas Groh1 (andreas.groh@tu-dresden.de), Martin Horwath1, Benjamin D. Gutknecht1
Technische Universität Dresden, Dresden, Germany

For the period 2002 - 2017, mass changes in the Earth’s subsystems can be derived from time-variable gravity field solutions provided by the GRACE mission. We present a regional integration approach based on directly tailored sensitivity kernels, derived by a formal optimization procedure that minimizes the sum of propagated GRACE solution errors and leakage errors. This approach ensures consistency between mass change estimates for individual regions (e.g. ice sheet drainage basins) and the corresponding estimates for their aggregations. The proposed approach has been successfully applied within ESA’s Climate Change Initiative (CCI) projects on the Antarctic Ice Sheet and the Greenland Ice Sheet for the mass change products for both ice sheets. The CCI products comprise mass change time series for individual drainage basins and aggregations (basin products). In addition, time series of mass change grids with a formal resolution of 50x50km² (gridded product) are derived. The algorithm has been adapted for oceanic applications in the frame of the CCI Sea Level Budget Closure project. Special emphasis is placed on the separation of mass signals at the ice-ocean interface. Therefore, a-priori information on the spatial mass change patterns to be expected in both sub-systems is introduced into kernel tailoring algorithm. First results of the ocean mass change time series and grids, which are consistent with the latest CCI ice sheet products, are presented and discussed.
Ice Sheet - Solid Earth - Climate Interactions during the Last Deglaciation

Florian Ziemen\textsuperscript{1} (florian.ziemen@mpimet.mpg.de), Marie Kapsch\textsuperscript{1}, Virna Meccia\textsuperscript{1}, Thomas Riddick\textsuperscript{1}, Meike Bagge\textsuperscript{2}, Volker Klemann\textsuperscript{2}, Uwe Mikolajewicz\textsuperscript{2}

\textsuperscript{1}Max Planck Institute for Meteorology, Hamburg, Germany, \textsuperscript{2}GFZ German Research Centre for Geosciences, Potsdam, Germany

We study the last deglaciation in a new modeling system that encompasses a wide range of interactions between ice sheets, their mass balance, the solid Earth and the climate. The system consists of the modified Parallel Ice Sheet Model (mPISM), the Viscoelastic Lithosphere and Mantle model (VILMA), and the Max Planck Institute Earth System Model (MPI-ESM). The surface mass balance of the ice sheets is computed with an energy balance model, shelf basal melt from temperature and salinity of the adjacent ocean. By applying VILMA, sea-level change due to ice loads is calculated considering surface deformation, eustasy and geoid change. In MPI-ESM, glaciers, topography, rivers, coastlines and bathymetry adapt to changes in ice sheets and topography. The model system is forced only with transient orbital parameters and greenhouse gas concentrations.

In our experiments, the retreating ice sheets leave behind vast periglacial lakes and marginal seas. Gigantic ice sheet surges into these basins lead to the formation of large ice shelves with low surface elevations causing strong melt. Where the basins are connected to the open ocean, basal melt and calving increase the ice loss at the shelves. Over time, the retarded sea-level response shrinks the periglacial basins again. This study presents first experiments that include the full range of interactions between ice sheets, solid Earth, atmosphere and ocean circulation.
The Land-ice Contribution to SLR Since 1992

Jonathan Bamber1 (j.bamber@bristol.ac.uk), Stephen Chuter1, Richard Westaway1, Bert Wouters2, Ben Marzeion3
1University of Bristol, Bristol, United Kingdom, 2Utrecht University, Utrecht, Netherlands, 3Bremen University, Bremen, Germany

Within several projects aimed at constraining the mass balance of glaciers, ice caps (GIC) and the ice sheets, we have developed consistent, rigorous estimates of land ice mass trends over the satellite era from the early 1990s to the present day. Our results combine satellite laser and radar altimetry including ERS, ENVISat, ICESat and CryoSat, along with GRACE data from 2003 onward. We have separate time series for Greenland, Antarctica and North Atlantic GIC. The latter represents about half the GIC contribution to SLR over the period of interest. For GIC outside of this region, we utilise existing analyses of ICESat and GRACE data combined with terrestrial geodetic methods and modelled surface mass balance to extend the time series backwards.

For 2003-2015, we obtain mean rates of 84±22 Gt/yr, 269±18 Gt/yr and 135±15 Gt/yr for Antarctica, Greenland and Arctic GIC respectively. Our preliminary estimate for other GIC contributions is 140 Gt/yr giving a total land ice contribution of 623 Gt/yr, which has a sea level equivalent of 1.73 mm/yr. This is, however, not necessarily the same as the contribution to sea level rise, nor the ocean mass trend measured by GRACE, for example land-locked GIC may or may not contribute to SLR. We note that the trend in mass exchange with the ocean is not linear in time. Finally, we present the trends from the early 1990s, which have larger uncertainties and assess these estimates in relation to the sea level budget for the same time period.
An inherent challenge of interdisciplinary work is that it requires us to engage with data and information collected and analyzed by other researchers who specialize in different types of data analysis. Doing so can be laborious, requiring extended explanation and discussion of each domain's assumptions, resulting in barriers to large-scale, temporally deep analysis. dataARC is attempting to support interdisciplinary work by developing a data discovery tool that provides intentionally interdisciplinary search result sets and contextualizes the results from each domain - including archaeology, paleoecology, and the humanities - within a shared conceptual model. In practice, the project is creating a data discovery tool that provides results directly related to a search and connected results, and provides explanations for the links between them. The creation of structured and contextualized, intentionally interdisciplinary result sets requires that we define the levels of granularity at which data elements operate, connections among data elements to form basic ideas, and connections among specific ideas and broader, overarching concepts. This paper presents the data structure and knowledge model developed within the dataARC project and discusses the challenges encountered in operationalizing these structures to produce useful, intelligible search results that can enable interdisciplinary teams to share their data and understandings of that data with more confidence and clarity.
Atmospheric River Impacts on Greenland: A Self-organizing Map Analysis

Kyle Mattingly¹ (kmatt842@uga.edu), Thomas Mote¹
¹University of Georgia, Geography, Athens, United States

The Greenland Ice Sheet (GrIS) has been losing mass during the past few decades in part due to negative surface mass balance (SMB). Several recent episodes of rapid GrIS mass loss have coincided with anomalous poleward moisture transport by atmospheric rivers (ARs). ARs likely contribute to GrIS melt through the greenhouse effect of water vapor, radiative effects of clouds, latent heat release within upstream air masses, and energy from liquid precipitation. ARs may also provide positive inputs to SMB through snow accumulation. We compile a long-term record of moisture transport events affecting Greenland by applying a self-organizing map (SOM) classification as well as a conventional object-based AR identification algorithm to integrated water vapor transport (IVT) data from multiple atmospheric reanalyses. We then analyze AR effects on GrIS melt and SMB using passive microwave melt data and the Modèle Atmosphérique Régional (MAR) regional climate model.

The SOM and object-based AR results closely agree on the temporal and spatial variability of moisture transport affecting Greenland. AR events result in widespread anomalous GrIS melt during the warm season, and there is a robust relationship between annually accumulated IVT and melt. Moisture transport impacts on SMB are more complex, as ARs induce strong negative SMB anomalies in the warm season ablation zone but enhance accumulation in higher elevations during the warm season and everywhere during the cold season.
Antarctic Legacy of South Africa (ALSA) Preserve Human Data, what is the Value?

Ria Olivier¹ (riaolivier@sun.ac.za)
¹Stellenbosch University, Botany and Zoology, Stellenbosch, South Africa

ALSA’s main aim is to preserve information/data of the human involvement from South Africa by maintaining a digital data repository. This presentation will show the criteria for assessment and selection of historical data of personal and official nature for the digital repository. The following questions will be answered; do human personal experiences add any value and significant meaning to environmental research? Is digital material such as narratives, images, maps and diaries easy accessible? Will the material add to the visualization and interpretation of information? In order to answer these questions, the presentation will look at a few examples to illustrate the value of human experiences. It will emphasise the importance to ensure that personal experiences are documented and preserved for the legacy of a country, but also to preserve it for the substantial amount of scientific deductions and analysis that can be gained from preserving the information. Therefore, the personal data has to be discovered, retained and be made accessible for mining of information. An in depth look into the preserving through a digital repository will be done and to demonstrate that new possibilities and additions can be added on as needs change and differ in the future. The contributions of human involvement therefore is much more than just a few pictures and diaries left behind, their work and life can enhance our perceptions of the environment in the polar regions to preserve the future.
Creation of a Historical Southern Ocean Climate Dataset from Ships' Logbooks

Praveen Teleti1 (prt31@cam.ac.uk), W. G. Rees1, J. A. Dowdeswell1
1Scott Polar Research Institute, University of Cambridge, Dept of Geography, Cambridge, United Kingdom

Historical ship’s logbooks can provide meteorological observations in the Southern Ocean (SO), one of the largest climate data-deficient regions on Earth. In this study, we capture data from logbooks of whaling ships operating in the Weddell Sea and Indian Ocean sector of the SO, from the 1930s to the 1960s. We attempt to extract meteorological information and create a gridded climate dataset. We discuss the effectiveness of various data extraction techniques used to deal with historical climate documents, and develop new and improve existing methods for working with historical data. Meteorological variables such as wind strength and direction, air and sea temperatures are standardised and converted into consistent modern units of measurement. Extensive quality checks are made for completeness and accuracy, and to eliminate known measurement bias from the observations. Cross-validation of the data is possible when independent observations were found for ships in close proximity. Finally, the dataset is structured according to the internationally accepted International Maritime Meteorological Archive format, which includes the most commonly reported meteorological variables, including the time, location, and ship related metadata. Further analysis of resulting meteorological dataset is useful to understand long-term changes in SO climate. Dataset can be fed as forcing and boundary conditions to global climate models to improve parametrisations, hence simulated results.
Documentary Evidence of 19th c. Sea Ice Extent in the Davis Strait & Baffin Bay

Matthew Ayre¹ (matthew.ayre@ucalgary.ca), Patricia Wells¹, Ravi Sankar¹, Maribeth Murray¹
¹University of Calgary, Arctic Institute of North America, Calgary, Canada

Historical observations obtained from British Arctic whaling logbooks kept during voyages in the Arctic waters of the Davis Strait & Baffin Bay constitute a rare subset of environmental data that provide a unique view of the regions past climate. Approximately 6000 voyages left British ports to engage in Arctic whaling over the 300 years it was practiced. The latter part of this enduring endeavour, executed throughout the 19th and into the early 20th c. was focussed in in this locality; less than 150 documents from this period are known to exist. British whalers circumnavigated this region annually between April and October, actively seeking out the sea ice edge; for it was here they pursued their prize - the bowhead whale (*Balaena mysticetus*). These surviving documents contain detailed, daily observations of meteorological conditions (wind direction/speed, precipitation), sea ice, icebergs and fauna encountered. This research has made near exhaustive use of the known surviving collection with 117 documents (1809-1911) from British whaling in the region being identified and digitally imaged. Digitization of the ~25000 days of observations has been completed with the assistance of citizen science volunteers. Preliminary results illustrate that ice observations can be used to reconstruct average monthly sea ice edge positions for the entire summer melt season, extending the current known seasonal sea ice climatology for the region back to the early 19th century.
Polar regions are key components of the climate system whose understanding can largely benefit from merging observation-based estimates with advanced numerical models. Global and regional Ocean Reanalyses (ORA) products are increasingly used in polar research. To assess the quality of ORA products in representing the sea ice-ocean state over recent decades, the Polar ORA Intercomparison Project has been established, following on from the ORA-IP project.

Ten selected ORAs (among which 7 include sea ice data assimilation) are considered, extensively analysed and evaluated in the Arctic and Antarctic regions by comparing snow, sea ice, ocean transports and hydrography with available data sets. This is the first time that most sea ice diagnostics are performed for such a large set of ORAs. This presentation presents sea-ice diagnostics, while the presentation by Uotila and co-authors focuses on liquid ocean diagnostics. ORA product biases against observed data and their mutual spread are quantified, and possible reasons for discrepancies investigated. Particular attention is given to the comparison of the MultiModel ensemble Mean (MMM) with individual products and the identifications of outliers, aiming to identify physical mechanisms causing common and individual ORA sea-ice biases. Monthly data for the 1993-2010 period are considered. The importance of the atmospheric forcing, air-ocean coupling protocol and sea-ice data assimilation for the sea-ice performance is also discussed.
By Stein Sandven and Hanne Sagen

INTAROS is a research and innovation action under the H2020-BG-09 aiming to develop an integrated Arctic Observation System (iAOS). INTAROS will extend, improve and unify existing systems in the different regions of the Arctic. The project has focus on integration of data from atmosphere, ocean, cryosphere and terrestrial sciences, provided by institutions in Europe, North America and Asia. Satellite earth observation (EO) data plays an increasingly important role in such observing systems, because the amount of EO data for observing the global climate and environment grows year by year. EO data will therefore be integrated into iAOS based on existing products and databases. In situ observing systems are much more limited due to logistical and technological constraints. The sparseness of in situ data is therefore the largest gap in the overall observing system. INTAROS is currently assessing strengths and weaknesses of existing observing systems and contributes with more sensors and platforms to enhance the in situ network. Building sustainable Arctic observing systems requires coordination, mobilization and cooperation between available infrastructures, modeling communities and relevant stakeholder groups. INTAROS also includes development of community-based observing systems, which are combined with scientific data. Thereby, INTAROS will contribute to better-informed decisions related to economic activities, environmental regulations and development in local communities.
1495

Exploitation of the Existing Arctic Observing Systems under the INTAROS Project

Roberta Pirazzini\textsuperscript{1} (roberta.pirazzini@fmi.fi), David Gustafsson\textsuperscript{2}, Michael Tjernström\textsuperscript{3}, Andreas Ahlströem\textsuperscript{4}, Ingo Schewe\textsuperscript{5}, Hanne Sagen\textsuperscript{6}, Stein Sandven\textsuperscript{6}

\textsuperscript{1}Finnish Meteorological Institute, Meteorological Research, Helsinki, Finland, \textsuperscript{2}Swedish Meteorological and Hydrological Institute, Norrköping, Sweden, \textsuperscript{3}Stockholm University, Department of Meteorology, Stockholm, Sweden, \textsuperscript{4}Geological Survey of Denmark and Greenland, Copenhagen, Denmark, \textsuperscript{5}Alfred Wegener Institute, Bremerhaven, Germany, \textsuperscript{6}Nansen Environmental and Remote Sensing Centre, Bergen, Norway

In the framework of the H2020 project “Integrated Arctic Observation System” (INTAROS), the existing Arctic observing systems and selected in situ and satellite data products are assessed, exploited, and standardized to enable their delivery to a multidisciplinary, integrated Arctic Observing System (iAOS) through established databases. The assessment and exploitation addressed observations of the ocean, atmosphere, cryosphere and land including physical, chemical, and biological parameters.

Strengths, weaknesses, gaps in spatial/temporal coverage, missing monitoring parameters, sustainability, and data management of the existing in situ observation networks are analyzed. Moreover, coverage, resolution, timeliness, uncertainty, format, and metadata of selected in situ and satellite data collections are assessed with respect to the requirements needed for applications within weather prediction and sea ice services, hazard risk assessment and prevention, climate, environmental protection. The quality and the processing of selected datasets are improved to meet the highest standards set by the European and international organizations. New products resulting from the exploitation of available data are provided, and sparse data are made accessible through the existing repositories.

The main result is the enhanced quality, quantity, accessibility and documentation of existing Arctic observations, which are then ready to be ingested into the iAOS.
CryoNet forms the core of the Global Cryosphere Watch (GCW)’s surface network, leveraging on existing cryospheric observatories and promoting the upgrade of other suitable facilities. The aim is to build a sustained network of environmental observing stations, that will yield routine high-quality data and are committed to comply in its methods, quality control and data dissemination with agreed GCW practices. To ensure consistent quality data within CryoNet, the GCW is currently developing best practices for its observatories, including those for sea ice. These Best Practices will form the official recommendations on necessary sea ice variables required for the science and operational sea ice community and WMO sampling requirements. For the Sea-Ice Best Practices a set of required and desired variables has been compiled, acknowledging that remotely-sensed products are the only effective means to provide information on some of the sea-ice variables. Here we present observational rules for key sea-ice parameters and how to obtain consistent long-term data while reducing measurement uncertainties. We also discuss challenges of observing sea ice, which seasonally and regionally is highly variable and covers large expanses. Using the example of the ASPeCt and ASSIST underway sea-ice observations we demonstrate the virtue of accepting Lagrangian observatories into CryoNet as well as how digital data recording reduces recording errors while enabling near-real time data distribution.
Connecting CryoNet Stations with WMO Systems, an Interoperability Effort of GCW

Joel Fiddes\textsuperscript{1,2} (joelfiddes@gmail.com), Matthias Bavay\textsuperscript{3}, Charles Fierz\textsuperscript{3}, Rodica Nitu\textsuperscript{4}, Øystein Godøy\textsuperscript{5}
\textsuperscript{1}University of Oslo, Oslo, Norway, \textsuperscript{2}World Meteorological Organization, Geneva, Switzerland, \textsuperscript{3}WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland, \textsuperscript{4}World Meteorological Organization (WMO), Geneva, Switzerland, \textsuperscript{5}Norwegian Meteorological Institute, Oslo, Norway

The WMO Global Cryosphere Watch (GCW) is an international mechanism for supporting all key cryospheric in-situ and remote sensing observations. To meet the needs of WMO Members and partners in delivering services to users a global network of “CryoNet” stations is being established. These stations monitor the state of the cryosphere and report to the GCW dataportal. Data are identified through discovery metadata which includes access mechanisms for data. The GCW data management is decentralised in the sense that the data centres of the CryoNet stations host the data, but expose discovery metadata to central catalogue which makes these searchable. The GCW Data Portal will also serve real-time data from the stations into WMO Information System (WIS/GTS) if required by the user community.

To date 120 stations have been approved as CryoNet and Contributing stations of the GCW surface observing network; more than 50\% of these are operated by universities and research organizations, which are not familiar with the WMO metadata and data exchange mechanisms and do not have the resources to adopt them. These are often significant barriers to entry.

Here we present a data interoperability tool that enables GCW to add value by being the "blackbox" whereby research scientists are not exposed to operational details (and costs) of WMO while WMO receives a standardised product and is not exposed to the true diversity of formats, standards etc. at the individual station level.
The International Arctic Systems for Observing the Atmosphere (IASOA) Framework

Taneil Uttal¹ (taneil.uttal@noaa.gov), Sara Morris²
¹NOAA Earth System Research Laboratory, Physical Science Division, Boulder, United States, ²Cooperative Institute for Research in Environmental Sciences, NOAA/ESRL/PSD, Boulder, United States

The International Arctic Systems for Observing the Atmosphere (www.iasoa.org) was launched during the International Polar Year and is a consortium that combines the observing assets and expertise from multiple Arctic Observatories distributed around the Arctic Ocean. Three significant facilitating tools developed by IASOA include a data portal that has informed and been coordinated with the data portal developed by Global Cryosphere Watch, development of graphical datagrams that substantially extend the information about the end-to-end collection/processing of in-situ instruments and support of thematic science working groups that produce concrete outcomes such as processed, calibrated, interoperable datasets and collaborative cross observatory research results. The IASOA framework is described and proposed as a template for new international coordination programs such as T-MOSAiC (land-based studies during the MOSAiC Arctic Ocean Campaign). The general theme discussed is the task of creating effective, high yield, networked observing systems in the Arctic - requirements and challenges.
Nowadays, many countries with a National Polar Research Program require all data collected within that program to be submitted to a National Polar Data Centre (NPDC). These NPDCs carry out different roles. For data originating from the domain of the data centre, the NPDC will manage the data. For data from other domains for which a national domain specific data centre exists, the NPDC will play a coordinating role, while for data without a domain-specific host the NPDC will perform basic data management tasks. As a result, the NPDC will have a complete overview of all polar data within a national Polar program.

The NPDC is also the gateway to various international data access infrastructures, offering the user access to a wealth of integrated data from all disciplines. NPDCs from around the world cooperate in SCAR’s Standing Committee on Antarctic Data Management (SCADM) and IASC-SAON’s Arctic Data Committee (ADC). These two committees manage and maintain data access infrastructures for the Antarctic resp. Arctic regions. This presentation will describe the work done by SCADM and ADC and will specifically address how data are distributed using portals such as the Antarctic Master Directory (AMD). Current initiatives for further data integration will be highlighted.
Microplastic Pollution in the Greenland Sea and Selective Intake by a Seabird

Françoise Amélineau1,2 (francoise.amelineau@gmail.com), Delphine Bonnet3, Olivier Heitz4, Valentine Mortreux3, Ann Harding5, Nina Karnovsky6, Wojciech Walkusz7, Jérôme Fort1, David Grémillet2
1Université de La Rochelle, Laboratoire Littoral, Environnement et Sociétés, La Rochelle, France, 2CEFE, CNRS - Université Montpellier, Montpellier, France, 3Université de Montpellier, Laboratoire MARBEC, Montpellier, France, 4Université de Montpellier, Institut Universitaire de Technologie de Montpellier-Sète, Sète, France, 5Alaska Pacific University, Environmental Science Department, Anchorage, United States, 6Pomona College, Department of Biology, Claremont, United States, 7Fisheries and Oceans Canada, Winnipeg, Canada

Microplastics (MPs) are found everywhere on earth. Despite Arctic remoteness from major sources of plastics, recent studies suggest that Arctic sea-ice is a sink for MPs, and several Arctic seabirds are already contaminated. However, very few data exist for this area. Our aims were to quantify MPs in little auk (Alle alle) foraging area and diet. Little auks are zooplanktivorous and dive between 0-50m. They are expected to be less contaminated than filter or surface feeders. Our study was conducted in East Greenland where data on MP were inexistent, for two breeding seasons with different sea-ice concentrations (SIC): 2005 (high SIC) and 2014 (low SIC). Despite the Arctic origins of the water masses in our study area, MP abundances were similar to those of other oceans, with 0.99 ± 0.62m⁻³ in 2005 (high SIC), and 2.38 ± 1.11m⁻³ in 2014 (very low SIC). MP rise between 2005 and 2014 might be linked to a global increase in plastic pollution or to lower SIC in 2014, if MPs are released to the water column once sea-ice melts. All chick meals contained plastic filaments, with 9.99 and 8.99 pieces per meal in 2005 and 2014 respectively. Importantly, little auks ate more light colored MPs than darker ones, strongly suggesting an active contamination with birds mistaking MPs for their prey. Overall, we stress the great vulnerability of Arctic marine ecosystems to MP pollution in a warming Arctic, where sea-ice melting could release high amounts of trapped debris.
Sea ice in polar oceans has been identified as a potential sink for microplastics. In the context of a changing climate, these sea ice sinks can possibly function as microplastic sources when the ice melts. Assessments regarding microplastics in sea ice are particularly important as they provide an understanding of the microplastics that polar organisms may be exposed to in the future. The present study, investigated the abundance, distribution and composition of microplastics in sea ice and water beneath ice in the Arctic Central Basin. During the Arctic Ocean 2016 expedition onboard Swedish icebreaker Oden, there were twenty-five stations at which sea ice cores were retrieved and water pumped from beneath the ice was filtered. Cores were sectioned, melted and filtered. Potential microplastics from samples are in the process of being isolated and analyzed using Fourier Transform Infrared Spectroscopy (FT-IR).
Microplastics in the Surface Ocean of the Canadian Arctic Archipelago

Kirstie Jones-Williams¹² (k捏es79@bas.ac.uk), Victoria Peck¹, Tamara Galloway², Matthew Cole³, Clara Manno¹
¹British Antarctic Survey, Cambridge, United Kingdom, ²Exeter University, Exeter, United Kingdom, ³Plymouth Marine Laboratory, Plymouth, United Kingdom

The Arctic is already one of the most environmentally stressed regions in the world owing to the rate of ocean warming, acidification and sea ice melt. This makes the Arctic marine ecosystem particularly vulnerable to the additional threat posed by plastic pollution. Approximately 12.7 million tonnes of plastic litter enter the World’s oceans each year. Whilst data on the spatial and temporal spread of plastics in the Canadian Arctic Archipelago is limited, recent studies have shown plastics present in surface waters at both a visible and microscopic scale. Microplastics (< 5mm) have been shown to be bioavailable and entering the ecosystem by ingestion from small zooplankton. On CCGS Amundsen Expedition 2017 Leg 2B, surface waters were opportunistically sampled to collect microplastics from seven stations using a HydroBios Neuston net (300 µm aperture mesh) within Baffin Bay and the Canadian Archipelago. This study aims to provide insight into the concentration of plastics and properties of different polymer types in the region. Secondly, based upon counts of amphipods versus microplastics found in each sample, we will present a ratio of zooplankton: microplastics, providing environmental context for microplastics occurrence. These findings come at a time of vital importance for developing a baseline for monitoring the extent of plastic pollution in the Arctic.
The 'Mother-ships' of Microplastics on Sub-Antarctic beaches

Juliana Assunção Ivar do Sul1,2 (juliana.ivardosul@io-warnemuende.de), Renata Portis1

1Federal University of Rio Grande, Rio Grande, Brazil, 2Leibniz Institute for Baltic Sea Research Warnemünde (IOW), Rostock, Germany

Beaches in King George and Elephant Islands, South Shetland Islands, were opportunistically sampled for macroplastics (>0.5 cm) during expeditions from the Brazilian Antarctic Program in 2014 (OPERANTAR XXXII, Project Penguins & Skuas) and 2016 (OPERANTAR XXXV, Project INTERBIOTA). 608 items were counted, measured and analysed in relation to the type of material, degradation and biofouling. Ordinary plastics (PET, PP; 60%), expanded polystyrene (27%) and rubber (11%) were mostly sampled. All are synthetic materials that slowly break down and accumulate in the environment. 73 items were whole objects measuring 32±101 cm and included PET bottles and packaging, but also nautical ropes and buoys. Few are labelled indicating their origins; others accumulated organisms in their surfaces, suggesting long-range transport in the sea. However, 88% were fragments from larger objects, measuring 5±8 cm. Polystyrene pieces were recurrent on beaches, as also observed in other sub-Antarctic islands. Potential sources are nautical buoys and protective packaging from electronic equipment. On beaches, these fragments will eventually become microplastics (< 5 mm) with rounded shapes, small enough to be ingested by organisms in marine food chains. As source identification is one of the major challenges on microplastic pollution research, the positive recognition of their 'mother-ships' allow the implementation of effective measures to minimize microplastic releases into the Antarctic environment.
It is estimated that there are up to 5 trillion pieces of plastic in the oceans (Erikssen et al., 2014). Microplastic pollution (particles < 5mm) is recognised as a major problem in the world ocean, with much of it accumulating in oceanic gyres (Cozar et al., 2014). Antarctica is generally thought of as a pristine and isolated wilderness, free of most of the anthropogenic stressors found in populated regions of the world. However, recent studies in the Southern Ocean have reported microplastics in deep-sea sediments (Van Cauwenberg et al., 2013) and surface waters (Cincinelli et al., 2017). We present our predictions of microplastic contamination in the Southern Ocean, based on quantifiable data from research stations, cruise ships and fishing effort. Our findings suggest that at an Ocean basin level concentrations should be insignificant, but that at point sources the contamination may be high. We report the detection of the first microplastics in shallow benthic sediments close to a number of research stations on King George Island. Worryingly, our predictions of primary microplastic concentrations from local sources are five orders of magnitude lower than levels reported in published sampling surveys, some of which were comparable to levels found in highly populated areas of the world (Erikssen et al., 2014; Adventurescience, 2016). We speculate that plastic contamination originating outside the Southern Ocean is crossing the Polar Front and contributing to the problem.
Plastic Pollution Around Antarctica: Preliminary Results from the ACE Expedition

Giuseppe Suaria1 (giuseppe.suaria@sp.ismar.cnr.it), Jasmine Lee2, Vonica Perold3, Tommy Bornman4, Stefano Alani1, Peter Ryan1
1CNR-ISMAR, Institute of Marine Sciences - Italian Research Council, Lerici, Italy, 2University of Queensland, Centre for Biodiversity Conservation Science, St Lucia, Australia, 3University of Cape Town, Percy FitzPatrick Institute of African Ornithology, Rondebosch, South Africa, 4South African Environmental Observation Network, Elwandle Coastal Node, Port Elizabeth, South Africa

The Antarctic Circumnavigation Expedition (ACE) sampled micro, meso and macroplastic litter around Antarctica from December 2016 to March 2017. No mesoplactic items were found in plankton samples collected with a 200 µm Neuston net and only 22 macrolitter items were observed floating south of the Subtropical Front in almost 15,000 km of transect counts, confirming that the Southern Ocean is the ocean least polluted by plastics globally. Nevertheless, anthropogenic debris was found in two seabed Agassiz trawls and macroplastic items were recovered from most beach landings, though quantity varied with location. Small numbers of fibers were found in beach sediments from Antarctic and sub-Antarctic sites and synthetic microfibres were detected in virtually all bulk water samples collected around Antarctica. Surprisingly, there was no marked gradient in these fibres as we approached continental source areas. Confirmation of the identity of these fibres is still pending, but if they prove to be synthetic, they suggest that all the world’s surface waters apparently carry low concentrations of microfibre pollutants, at a density of ~0.1-1 fibres per litre.
Towards Producing a Daily Snow-on-Sea Ice Data Set

Julienne Stroeve\textsuperscript{1} (j.stroeve@ucl.ac.uk), Glen Liston\textsuperscript{2}, Andrew Barrett\textsuperscript{3}

\textsuperscript{1}University College London, Earth Sciences, London, United Kingdom, \textsuperscript{2}Glen.Liston@colostate.edu, Cooperative Institute for Research in the Atmosphere, Fort Coling, United States, \textsuperscript{3}University of Colorado, National Snow and Ice Data Center, Boulder, United States

Estimates of ice thickness across the Arctic Ocean have become available over the past 20 years based on data from ERS-1/2, Envisat, ICESat, CryoSat-2 satellites and Operation IceBridge aircraft campaigns. However, the different measurement approaches, sensor technologies and spatial coverage present formidable challenges in producing a comprehensive view of long-term sea ice thickness changes. Key among these is that measurement techniques do not measure ice thickness directly - retrievals also require snow depth and density. A sophisticated snow accumulation model is tested in a Lagrangian framework to map daily snow depths across the Arctic sea ice cover using different atmospheric reanalysis data as input. Accuracy of the snow accumulation is assessed through comparison with Operation IceBridge data and ice mass balance buoys (IMBs).
Assessing Precipitation and Snow Accumulation in the Arctic and Southern Oceans

Linette Boisvert1 (linette.n.boisvert@nasa.gov), Melinda Webster1, Alek Petty1, Thorsten Markus1
1NASA Goddard Space Flight Center, Greenbelt, United States

Precipitation over the Arctic and Southern Oceans is a key component of the ocean fresh water budget, while the magnitude of snow accumulation over sea ice controls the strength of the snows insulative properties. However, precipitation from reanalysis over the polar regions show large uncertainties in both frequency and magnitude, due to the lack of in situ data for validation in these regions and differing model schemes representing cloud physics. Introducing problems for those modeling snow accumulation on sea ice, specifically for use in estimating sea ice thickness from laser altimetry data.

In recent years, the Arctic has become warmer and wetter, which leads to the questions: Is more precipitation falling and more of this as rain in the Arctic, is more precipitation or rainfall also occurring in the Antarctic? What are the implications of more frequent rainfall on modeling snow depth on sea ice? For example, rain events will modify the existing snow pack by causing large changes in the insulating properties and surface albedo.

In this work we compare precipitation from 8 different reanalysis: MERRA, MERRA2, NCEP-R1, NCEP-R2, ERA-Interim, CFSR, ASR and JRA-55 over the Arctic and Southern Oceans. We assess the annual, seasonal, and regional differences and compare results with Ice Mass Balance Buoy data to explore sources of discrepancies between products during observed snowfall and rainfall events in the Arctic and Southern Oceans.
A New Snow on Sea Ice Budget Model and Snow Depth Dataset over the Polar Oceans

Alek Petty\textsuperscript{1,2} (alek.a.petty@nasa.gov), Melinda Webster\textsuperscript{1}, Linette Boisvert\textsuperscript{1,2}, Thorsten Markus\textsuperscript{1}

\textsuperscript{1}NASA Goddard Space Flight Center, Greenbelt, United States, \textsuperscript{2}University of Maryland, ESSIC, College Park, United States

Poor knowledge of snow on sea ice over the polar oceans provides a key source of uncertainty in our understanding of freshwater budgets and the estimation of sea ice thickness from satellite altimetry. Here we present a new, open-source, two-layer Eulerian snow budget model developed to improve the representation of snow on sea ice across both poles. The model includes several parameterizations to represent various sources and sinks of snow on sea ice through the accumulation season (September through April), e.g. wind compaction and blowing snow lost to leads. The model is forced with daily reanalysis-derived snowfall and winds, and satellite-derived ice concentration and drifts. We explore the sensitivity of the modelled snow depths to the input forcing data and model parameters, and compare the results with observations where possible (e.g. field data from 1979-1991, 1997-1998, buoy data from 2000-present and NASA’s Operation IceBridge data from 2009 to present). We demonstrate the utility of the new snow depth product (available daily) to produce updated sea ice thickness estimates from ESA’s CryoSat-2 mission (2008 onwards) and look ahead to the upcoming launch of ICESat-2 (summer 2018). It is our hope that the open source framework will encourage community involvement in possible improvements and additions to the model physics (e.g. rain-on-snow, snow ice formation, snow melt processes), especially as new forcing/validation datasets are made available.
A Dynamic Snow Load Model for Satellite Altimeter Sea Ice Thickness Retrievals

Rachel Tilling1 (r.tilling@leeds.ac.uk), Andy Ridout2, Isobel Lawrence2, Michel Tsamados2, Sammie Buzzard2, Julienne Stroeve2, Andrew Shepherd1
1University of Leeds, Leeds, United Kingdom, 2University College London, London, United Kingdom

Satellite radar altimeter data are now widely used to produce estimates of sea ice thickness across the Arctic Ocean. However, these estimates rely to varying degrees on the use of a snow climatology in the conversion of sea ice freeboard to thickness. The application of a climatological snow load is currently the largest source of uncertainty in the ice thickness estimates that we produce at the UK Centre for Polar Observation and Modelling (CPOM) from CryoSat-2 data. To reduce this uncertainty, we have developed a dynamic snow load for application with our sea ice processor that enables us to account for inter-annual and spatial variations in the snow cover. The dynamic snow load model is initialised using precipitation and evaporation data from reanalysis, and developed with a dependence on sea ice concentration, drift, and atmospheric temperature. When applied to CryoSat-2 sea ice observations, the dynamic snow load results in a decrease in ice thickness compared with climatological estimates by up to 70 cm in regions of seasonal ice cover such as Baffin Bay and the Siberian Shelf Seas. This demonstrates the ability of CryoSat-2 to measure ice thickness over thinner (< 0.5 m) ice regimes than previously thought. Here we summarise the development of our dynamic snow load, and evaluate using in situ campaign data. We then assess its impact on spatial and inter-annual variations in Arctic-wide sea ice thickness and volume estimates compared with a snow climatology.
The Role of Snow Distribution on the Antarctic Sea Ice Mass and Energy Balance

Nander Wever¹ (nwever@gmail.com), Katherine Leonard²,³,⁴ Ted Maksym⁵, Kevin Manning⁶, Jordan Powers⁶, Seth White⁶, Jan Lenaerts¹

¹University of Colorado, Department of Atmospheric and Oceanic Sciences (ATOC), Boulder, United States, ²École Polytechnique Fédérale de Lausanne (EPFL), School of Architecture, Civil and Environmental Engineering, Lausanne, Switzerland, ³WSL Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland, ⁴University of Colorado, Cooperative Institute for Research in Environmental Sciences (CIRES), Boulder, United States, ⁵Woods Hole Oceanographic Institution (WHOI), Woods Hole, United States, ⁶National Center for Atmospheric Research (NCAR), Mesoscale and Microscale Meteorology (MMM) Laboratory, Boulder, United States

Snow on sea ice is increasingly recognized as a key component of the sea ice system. The snow cover substantially impacts the mass and energy balance of sea ice, but exhibits high variability in space and time. As in-situ measurements are scarce and many remote sensing products show large uncertainties, the use of physics-based snow and sea ice models is attractive. Here, we present spatially explicit simulations of the snow-sea ice system using the recently developed sea ice module for the physics based SNOWPACK model for three floes of different age, that were visited in July and August 2013 in the Weddell Sea. Terrestrial laser scans of the snow surface, combined with highly spatially resolved ice thickness and snow depth measurements, are used to initialize the model. The simulations are then forced by meteorological observations provided by weather station buoys left on the ice, augmented by AMPS Polar WRF reanalysis data. The resulting simulated sea ice energy and mass balance is verified by Ice Mass Balance (IMB) buoys installed on the floes. Results show that the snowpack provides a strong control on the energy and mass balance and that taking into account the snow cover distribution enables an accurate simulation of the total sea ice mass balance. Simulated ice growth rates correspond well with the IMB buoy data. These results illustrate that physics based models of the snow-sea ice system provide accurate assessments of the spatial and temporal evolution of sea ice.
Satellite Remote Sensing of Large-scale Arctic Sea Ice Thickness and Snow Depth

Lu Zhou\(^1\) (zhou-l15@mails.tsinghua.edu.cn), Shining Xu\(^1\), Jiping Liu\(^2\)
\(^1\)Tsinghua University, Beijing, China, \(^2\)State University of New York at Albany, Albany, United States

Large-scale retrieval is carried out for sea ice thickness (Hi) and snow depth over sea ice (Hs), based on concurrent radar altimetry of CryoSat-2 satellite and L-band (1.4 GHz) passive radiometry based on SMOS satellite. Two physical models, the L-band radiation model for the sea ice cover, and the hydrostatic relationship based on buoyancy model, are adopted. Verification for the retrieval is carried out with CryoVEx airborne data, which co-registers with CryoSat-2 tracks. Results also show reduced uncertainties for both Hi and Hs. Especially, the uncertainty involving the climatological snow loading and the potential lack of efficacy for radar altimetry in current era is addressed, with much lower and spatially uncorrelated uncertainty and better estimation of ice volume. The retrieved large-scale Hi and Hs fields provide new perspective for investigating Arctic climate change.
Basal Ice Properties in Two-million-Year-old Allan Hills Cores

Yuzhen Yan1 (yuzheny@princeton.edu), John Higgins2, James Menking3, Aron Buffen2, Ed Brook2, Heather Clifford4, Andrei Kurbatov3, Paul Mayewski3, Jessica Ng4, Jeffrey Severinghaus4, Michael Bender1

1Princeton University, Princeton, NJ, United States, 2Oregon State University, Corvallis, OR, United States, 3University of Maine, Orono, ME, United States, 4University of California San Diego, La Jolla, CA, United States

Currently the longest continuous ice core record, capped at 800 thousand years (kyr) old, comes from the EPICA Dome C. Concerted efforts in the ice core community are underway to find and retrieve stratigraphically continuous deep ice cores older than 800 kyr. A complimentary approach to deep coring is shallow drilling in Blue Ice Areas (BIAs), where ancient ice is brought to the surface by a combination of glacial flow and subglacial topography. Discontinuous ice as old as two million years has been found in two adjacent drill holes in the Allan Hills BIA. Here we report the elemental and isotopic composition of the trapped gases (N2, O2, Ar, and CO2), along with high-resolution stable water isotopes, in > 2 million year old basal ice from the two cores. Our data indicate that the ice is deformed and that mixing takes place at sub-meter length scales. In addition, although much of the ice older than 800 kyr appears to contain pristine greenhouse gases, the oldest basal ice contains both elevated CH4 and CO2 as high as 1200 ppm. High CO2 samples are associated with depleted (< -10 ‰) δ13C of CO2, consistent with contributions from the respiration of organic carbon (δ13C ~ -25‰). Alternative approaches for determining paleo-atmospheric CO2 (e.g. Δ17O of O2) will be discussed.
Is there 1.5 Million-year Old Ice Near Dome C, Antarctica?

Frédéric Parrenin¹ (frederic.parrenin@univ-grenoble-alpes.fr), Marie G. P. Cavitte²,³, Donald D. Blankenship², Jérôme Chappellaz², Hubertus Fischer⁴, Olivier Gagliardini¹, Valérie Masson-Delmotte⁵, Olivier Passalacqua¹, Catherine Ritz¹, Jason Roberts⁶,⁷, Martin J. Siegert⁸, Duncan A. Young²

¹CNRS/IRD/UGA, Institut des Géosciences de l’Environnement, St Martin d’Hères, France, ²University of Texas at Austin, Jackson School of Geosciences, Institute for Geophysics, Austin, United States, ³University of Texas at Austin, Jackson School of Geosciences, Department of Geological Sciences, Austin, United States, ⁴University of Bern, Physics Institute & Oeschger Centre for Climate Change Research, Climate and Environmental Physics, Bern, Switzerland, ⁵CEA-CNRS-UVSQ/IPSL, Laboratoire des Sciences du Climat et de l’Environnement, Gif-sur-Yvette, France, ⁶Australian Antarctic Division, Kingston, Australia, ⁷University of Tasmania, Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia, ⁸Imperial College London, Grantham Institute and Department of Earth Science and Engineering, London, United Kingdom

Ice sheets provide exceptional archives of past changes in polar climate, regional environment and global atmospheric composition. The oldest dated deep ice core drilled in Antarctica has been retrieved at EPICA Dome C (EDC), reaching ~800,000 years. Obtaining an older paleoclimatic record from Antarctica is one of the greatest challenges of the ice core community. Here, we use internal isochrones, identified from airborne radar coupled to ice-flow modelling to estimate the age of basal ice along transects in the Dome C area. Three glaciological properties are inferred from isochrones: surface accumulation rate; geothermal flux; and the exponent of the Lliboutry velocity profile. We find that old ice (>1.5 Myr, 1.5 million years) likely exists in two regions: one ~40km south-west of Dome C along the ice divide to Vostok, close to a secondary dome that we name “Little Dome C” (LDC); and a second region named “North Patch” (NP) located 10-30 km north-east of Dome C, in a region where the geothermal flux is apparently relatively low. Our work demonstrates the value of combining radar observations with ice flow modelling to accurately represent the true nature of ice flow, and understand the formation of ice-sheet architecture, in the centre of large ice sheets.
An Essay to Reconstruct MIS-11 Climate from 4 Water Isotopologues in Vostok Ice

Alexey Ekaykin¹² (ekaykin@aari.ru), Arina Veres¹², Anna Kozachek¹, Vladimir Lipenkov¹, Aleksandra Skakun¹, Diana Vladimirova¹²
¹Arctic and Antarctic Research Institute, Saint Petersburg, Russian Federation, ²Saint Petersburg State University, Institute of Earth Sciences, Saint Petersburg, Russian Federation

A strong limitation of the stable water isotope method to reconstruct past temperature changes is related to the fact that the isotopic composition of a polar ice core depends both on local conditions and conditions in the moisture source. There have been attempts to use a second-order parameter, \( ds = dD \cdot 8d^{18}O \), in parallel to the isotopic composition itself (\( dD \) or \( d^{18}O \)), in order to discriminate between both factors. It has been shown that the results strongly depend on the sensitivity of \( ds \) to the condensation temperature, which is poorly known. Recently a new parameter, \( 17O\text{-excess} = \ln(d^{17}O) - 0.528 \ln(d^{18}O) \), has been developed, that was initially thought to depend only on the air humidity in the moisture source. However it was soon demonstrated that the variability of \( 17O\text{-excess} \) in deep Antarctic ice cores would imply unrealistically strong humidity oscillations in the past, which means that other factors (primarily, local conditions during condensation in ice clouds) play a role, too. Here we present a new, detailed isotopic record for the MIS-11 epoch (370-440 ka BP) reconstructed from the Vostok ice core, and for the first time attempt a climatic paleo-reconstruction based on 3 independent parameters (\( dD \), \( ds \) and \( 17O\text{-excess} \)). Our results (including the past variability of air humidity in the moisture source) are consistent with the published data, and demonstrate that this approach has the potential to improve the ice core-based paleo-reconstructions.
Temperature and Circulation Changes in the Ross Sea over the Last 1000 Years

Anais Orsi¹, Barbara Stenni² (barbara.stenni@unive.it), Amaelle Landais¹, Martin Werner³, Nancy Bertler⁴,⁵
¹LSCE (UMR 8212 CEA-CNRS-UVSQ/IPSL), Université Paris Saclay, Gif Sur Yvette, France, ²Ca’ Foscari University of Venice, Department of Environmental Sciences, Informatics and Statistics, Venice, Italy, ³Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, ⁴Victoria University of Wellington, Antarctic Research Centre, Wellington, New Zealand, ⁵GNS Science, Lower Hutt, New Zealand

The Antarctic has an unusual climate history compared to other continents for the past 2000 years: unlike other regions, the last 50 years are not unusually warm, and the period around 1850 is not unusually cold. All of Antarctic 2000-year climate records are derived from water isotopes from ice cores. Could it be that water isotopes are not a faithful temperature recorder, or is it that Antarctica has a distinct climate variability over this time period?

Here we compare a temperature reconstruction derived from the analysis of inert gas isotopes ($\delta^{15}$N and $\delta^{40}$Ar) with water isotopes to provide multiple constraints on the climate history of the past 1000 years at Talos Dome, Antarctica. Talos Dome is a peripheral dome located in the South Pacific/Ross Sea sector of the East Antarctic Plateau. It receives air masses mainly from the Indian and secondarily from Pacific sectors of the Southern Ocean. As a result, its climate presents similarities both to West Antarctica and to the East Antarctic plateau sites of Dome C and Vostok.

We find that inert gas isotopes indicate a long term cooling trend at the site, which is not recorded in the $\delta$D signal. We use the climate model ECHAM5-wiso to link the d-excess to change in the atmospheric circulation over the Ross Sea, which can explain the discrepancy between $\delta$D and temperature. These results provide new constraints on the changes in the circulation associated with the Little Ice Age cooling in West Antarctica.
Characterisation of AIM Events in the Ross Sea Region from the RICE Ice Core

Abhijith Ulayottil Venugopal¹ (abhijith.uv@vuw.ac.nz), Nancy Bertler², James Lee², Giuseppe Cortese³, Rebecca Pyne³
¹Victoria University of Wellington, Antarctic Research Centre, Wellington, New Zealand, ²Oregon State University, Corvallis, United States, ³GNS Science - Institute of Geological and Nuclear Sciences Ltd., Wellington, New Zealand

The last glacial in Antarctica is punctuated by several episodes of warm events, when air temperature rose between 1-3°C, which are referred to as ‘Antarctic Isotope Maxima’ (AIM) events. The comparison of Antarctica and Greenland ice core records shows an out of phase relationship between AIM events and their northern counterparts- Dansgaard/Oeschger events, referred to as the ‘Bipolar Seesaw’. Possible explanations include oceanic teleconnections via a shift in strength of the Atlantic Meridional Overturning Circulation and Antarctic Bottom Water formation.

Roosevelt Island is a local ice rise at the northern edge of the Ross Ice Shelf. A 764m deep Roosevelt Island Climate Evolution (RICE) ice core was obtained between 2011-2013. Due to its proximity to Ross Sea, the RICE records have the potential to provide new insights into the drivers and consequences during the evolution of AIM events.

Here, we present the highly resolved major ion record of the RICE core spanning the time period between 83,000 to 25,000 years B.P., presented on the RICE17 age scale. The major ion record, including sodium, methyl sulphonic acid, and calcium provide useful indicators of past environmental conditions such as changes in sea ice extent, primary productivity and latitudinal shifts in circumpolar westerlies. The record will also be correlated with existing Antarctic ice cores to gain insights into the regional heterogeneity in the environmental conditions during the evolution of AIM events.
Glacial-interglacial transitions are recorded in various climatic archives over the Quaternary. The EPICA Dome C (EDC) ice core provides high latitude climate reconstructions based on water isotopes as well as global proxy records such as greenhouse gases concentrations, and low latitudes tracers $\delta^{18}$O$_{atm}$ (i.e. $\delta^{18}$O of atmospheric O$_2$) or d-excess over the last 800 ka. These high-resolution records illustrate the variety of glacial-interglacial transitions observed under different orbital and sea level contexts.

We present here new detailed measurements of $\delta^{18}$O$_{atm}$, $\delta^{15}$N and d-excess on the EDC ice core over Terminations II and III. First, we analyze the millennial variability superimposed to the orbital signal in the different isotopic records, and describe the different sequences of events for these two deglaciations. Termination III is associated with several millennial-scale events while Termination II is depicted by only one major Heinrich event. Second, we compare our new high-resolution $\delta^{18}$O$_{atm}$ profile to East Asian $\delta^{18}$O$_{calcite}$, which presents similar orbital and millennial variations related to the monsoon activity or shifts in the InterTropical Convergence Zone position to propose an improved way of using $\delta^{18}$O$_{atm}$ to constrain ice core chronologies. Finally, we present such an application refining the ice core dating of MIS5.
Role of Polar Anticyclones for Arctic Sea Ice Melting in Summer

Heini Wernli\(^1\) (heini.wernli@env.ethz.ch), Lukas Papritz\(^2,3\)
\(^1\)ETH Zurich, Zürich, Switzerland, \(^2\)University of Bergen, Geophysical Institute, Bergen, Norway, \(^3\)Bjerknes Centre for Climate Research, Bergen, Norway

Annual minima in Arctic sea ice extent and volume are decreasing rapidly since the late 1970ies, with substantial interannual variability. It was shown that summers with a particularly strong reduction of Arctic sea ice extent are characterized by anticyclonic flow anomalies from the surface to the upper troposphere. Here we adopt a weather-system perspective to investigate the origin of these seasonal circulation anomalies and show that they are caused by an increased occurrence of episodic upper-level induced Arctic anticyclones. Sea ice reduction is systematically enhanced during these transient episodes with Arctic anticyclones and the seasonal reduction of sea ice volume correlates with the area averaged frequency of Arctic anticyclones poleward of 70°N (correlation coefficient of 0.57). A trajectory analysis reveals that these anticyclones result from extratropical cyclones injecting extratropical air masses with low potential vorticity into the Arctic upper troposphere. Our results emphasize the fundamental role of extratropical cyclones and associated diabatic processes in establishing Arctic anticyclones and in turn seasonal circulation anomalies, which are of key importance for understanding the variability of summertime Arctic sea ice melting.
Airmass Transport and Dynamical Drivers of an Extreme Arctic Winter Warm Event

Hanin Binder¹² (binder@lmd.ens.fr), Maxi Boettcher², Christian M. Grams²³, Hanna Joos², Stephan Pfahl², Heini Wernli²

¹Laboratoire de Météorologie Dynamique/IPSL, École Normale Supérieure, Paris, France, ²Institute for Atmospheric and Climate Science, ETH Zurich, Zurich, Switzerland, ³Institute of Meteorology and Climate Research (IMK-TRO), Karlsruhe Institute of Technology, Karlsruhe, Germany

During a one-week episode at the turn of the years 2015/2016, maximum surface air temperature in the Arctic reached record high values of more than 0°C, which led to pronounced, widespread sea-ice melting in the middle of the cold season. In this study, we adopt a Lagrangian perspective to investigate the origin of the warm air masses and the meteorological processes that allowed them to reach the North Pole. We show that (i) the extreme event resulted from a complex chain of extraordinary dynamical and physical processes, (ii) three fundamentally different airstreams contributed to the high Arctic temperatures, of which two airstreams were initially extremely cold and located either in the Arctic lower troposphere and subsequently heated by intense surface fluxes, or in the midlatitude upper troposphere and subsequently heated by adiabatic compression, (iii) the poleward transport of these warm airstreams occurred along an exceptionally intense low-level jet that established between a sequence of Icelandic lows and a strong Scandinavian anticyclone, and (iv) the setup and persistence of this dipolar pattern was supported by continuous warm conveyor belt ascent into the upper part of the anticyclone. The findings emphasise the combined role of multiple transport processes and transient synoptic-scale dynamics for establishing an extreme Arctic heat and melt event.
In the marginal ice zone (MIZ), it is expected that the turbulent fluxes of momentum and sensible heat are dependent on a number of surface characteristics and processes that impact the surface roughness and the stability in the atmospheric surface layer. These include ice concentration, ice thickness, ice freeboard, floe sizes, and ocean wave characteristics (height and period). The range of length scales over which these parameters vary in the MIZ is large. The relationship between some of these characteristics and the turbulent fluxes are represented by recent bulk flux parameterization schemes (e.g., Andreas et al, 2010; Lüpkes et al 2012; Lüpkes and Gryanik 2015). During the Sea State field program in the Beaufort and Chukchi Seas from Oct 3 to Nov 5, 2015, direct covariance and inertial dissipation measurements of the turbulent fluxes were made from the bow of the icebreaker R/V Siquliak, while many of the surface characteristics were also measured from various platforms on board. Hence, this data set provides a good opportunity to explore the relationships between surface characteristics and the turbulent fluxes in the advancing marginal ice zone. This presentation will show the complex surface environment encountered during Sea State, and demonstrate the extent to which existing bulk flux parameterizations can represent the directly measured turbulent fluxes of sensible heat and momentum in this environment.
Cold air Outbreaks in the Nordic Seas: Climatology and Link to Large-scale Flow

Lukas Papritz1,2, Thomas Spengler1,2, Christian M. Grams3,4
1Geophysical Institute, University of Bergen, Bergen, Norway, 2Bjerknes Centre for Climate Research, Bergen, Norway, 3Institute for Atmospheric and Climate Science, ETH Zurich, Zurich, Switzerland, 4Institute for Meteorology and Climate Research (IMK-TRO), Karlsruhe Institute of Technology, Karlsruhe, Germany

Marine cold air outbreaks (CAOs) at high latitudes are harbingers of severe weather such as polar lows and they lead to intense air-sea heat fluxes. We first present a 35-year long Lagrangian climatology of wintertime CAO air masses in the Nordic Seas including the Irminger and the Barents Seas. Based on this climatology we study

(1) the origin and pathways of CAO airmasses,
(2) their thermodynamic evolution, and
(3) their contribution to winter mean air-sea heat fluxes.

Specifically, we show that CAOs in the Nordic Seas originate largely in the interior Arctic, entering the Nordic Seas via Fram Strait. In addition, also flows across southern Greenland and katabatic drainage contribute. As we show further, the spatio-temporal variability of CAO air masses is essentially dictated by the frequency of CAOs. Second, we investigate the linkage of CAO formation with the low-frequency variability of the large-scale flow using a weather regime classification. We show that each regime is characterised by a typical CAO frequency anomaly pattern and a corresponding imprint in CAO airmass pathways and air-sea heat fluxes. Thereby, the strength and location of the storm tracks in each regime are found to be decisive for the pathways of CAO air masses and, thus, for CAO occurrence. The mechanistic linkage between CAOs and weather regimes may help to better understand variability in open ocean convections, as well as forecasting the occurrence of polar lows.
Formation of Convergence Zones in Cold Air Outbreaks

Shun-Ichi Watanabe¹ (watanabe-s@aori.u-tokyo.ac.jp), Hiroshi Niino¹, Thomas Spengler²
¹Atmosphere and Ocean Research Institute, University of Tokyo, Kashiwa, Japan, ²University of Bergen, Bergen, Norway

During cold air outbreaks, low-level atmospheric convergence zones often emerge over relatively warmer seas downstream of coastlines, sea ice edges, and mountains. We investigate the formation mechanism of such convergence zones using idealized numerical experiments and analytic theory. In the numerical experiments, a cold air outbreak is simulated in a simplified setup including a coastline and a mountain, where the former has a kink. The numerical simulations show that varying the angle of the kink in the coastline as well as changing the height of the mountain, or removing it, cause a difference in the fetch (traveling distance over sea) of the cold airmass. A warm wedge is formed due to the difference in the fetch, because the longer fetch causes more warming by the sensible heat flux. Hydrostatically, this results in a low pressure trough, which induces a pressure gradient force towards the warmest area. The turbulent momentum transport in the convectively mixed layer is important for the formation of the convergence zone, because it enhances frictional convergence into the pressure trough. The moisture enhances the convergence by intensifying vertical motion due to diabatic heating. We also present an analytic model for the setup with the kink in the coastline using the basic state flow and the bulk formula for the surface sensible heat flux. The theoretical estimates of the pressure trough and convergence agree well with the results of the numerical experiments.
Excursions of cold air masses from the ice-covered high-latitude area into oceanic regions are frequently accompanied by the development of intense mesoscale cyclones. This particular ocean-atmosphere configuration exhibits favorable conditions for relative large surface turbulence exchange of momentum, moisture, and heat. In this study, we examine the impact of this air-sea-exchange on the development of polar lows.

We utilise an idealised numerical channel model to gain insight into the role of surface heat and moisture fluxes on the dynamical evolution of polar lows. The initial setup consists of a baroclinic jet in thermal wind balance. To mimic cold air outbreaks we prescribe sea surface temperatures that are higher than the low-level air temperature. This setup enables a systematic investigation of the relative contributions from surface sensible and latent heat fluxes on polar low development by varying the intensity of the initial baroclinicity, moisture, and air-sea temperature difference. In addition we investigate the relative role of sensible and latent heat fluxes by gradually changing the intensity of surface exchange in a set of sensitivity experiments. Identification of moisture sources and sinks further illustrates the role of surface heat and moisture exchange on the intensification of polar lows.
Habitat Suitability and Conservation of McMurdo Dry Valley Soil Biodiversity

E. Ashley Shaw¹ (elizabeth.shaw@colostate.edu), Jasmine R. Lee², Aleks Terauds³, Diana H. Wall¹

¹Colorado State University, Department of Biology, Fort Collins, United States, ²University of Queensland, Centre for Biodiversity and Conservation Science, Brisbane, Australia, ³Australian Antarctic Division, Kingston, Australia

Antarctica’s McMurdo Dry Valleys (MDV) are the continent’s largest ice-free area, containing soil biodiversity that has not been considered in conservation planning. This biodiversity consists of soil-inhabiting microbes, nematodes, rotifers, tardigrades, springtails and mites. While specific habitat requirements vary by species, abiotic factors (e.g., water and carbon availability, temperature, and soil geochemistry) are known to drive distributions. Yet, soils are highly heterogeneous and these abiotic factors vary greatly landscape-wide. Furthermore, climate-driven changes in lake and stream hydrology are already occurring, producing immediate impacts on surrounding soil environment and communities. Given their vulnerability to such changes, including soils and dependant biodiversity in conservation planning is critical.

We obtained an Antarctic Science International Bursary to undertake a collaborative project to examine the drivers of soil biota in the MDV and build habitat suitability models to predict current and future distributions. Soil biodiversity and chemistry data were gathered from the MDV Long Term Ecological Research Project (US NSF) and compiled into a spatially explicit dataset. With this dataset, we modelled habitat suitability by taxon, confirming that environmental drivers of species distributions vary. We used the models to spatially predict species distributions and then combined them to identify sites of conservation priority across the MDV.
Soil Changes in 10 Years of Environmental Change in Victoria Land (Antarctica)

Nicoletta Cannone¹ (nicoletta.cannone@uninsubria.it), Mauro Guglielmin², Dirk Wagner³
¹Università degli Studi dell’Insubria, Science and High Technology, Como, Italy, ²Università degli Studi dell’Insubria, Varese, Italy, ³GFZ German Research Centre for Geosciences, Potsdam, Germany

In Victoria Land, continental Antarctica, across a latitudinal gradient between Apostrophe Island (73°) and Finger Point (77°S) in the period 2002-2013 were detected significant environmental changes involving climate, active layer thickness, vegetation abundance and composition and soil chemistry. In particular, despite air temperature did not change, there was an increase of incoming radiation and active layer thickness. In response to these environmental change, soils exhibited a large decrease of water content (more pronounced at deeper depths), and a general pH increase associated to an increase of conductivity (more pronounced in ornithogenic soils). Opposite trends were observed for most inorganic compounds comparing ornithogenic and not-ornithogenic soils. The changes in soil chemistry reflect concomitant changes in climate and active layer and vegetation cover, with a decrease of mosses and a concomitant increase of lichens in most sites. These changes may be due to soil evolution processes or to different dynamics of the active layer. The observed changes in soil chemistry did not appear to be strictly related to the aeolian dust deposition or to the Southern Oscillation Index.
Climate change in polar regions has negatively affected top predator species such as the polar bear and has caused the expansion of higher plant communities, but the effects of altered temperature and water availability on microbes at the bases of polar food webs, such as the fungi, which drive vital ecosystem processes, have largely been ignored. Here, 16 fungi, including the widespread *Pseudogymnnoascus pannorum*, were isolated from soil collected from the Arctic and Antarctic and screened for the production of enzymes. The data obtained from the growth rate experiments suggested that increased temperature and reduced water availability have differing effects on the growth and enzyme production of the fungal species tested.
Penguins as Drivers of Microbial Diversity in Maritime Antarctic Soils

Mafalda Baptista¹,² (mafaldasbaptista@gmail.com), Maria Monteiro², Charles Lee², Catarina Magalhães¹, Craig Cary²
¹University of Porto, Interdisciplinary Centre of Marine and Environmental Research, Porto, Portugal, ²University of Waikato, International Centre for Terrestrial Antarctic Research, Hamilton, New Zealand

Penguin activity affects microbial communities in Antarctica soils. Previous studies have shown distinct microbial communities in penguin-colonized ornithogenic soils, in relic ornithogenic soils, and in mineral soils. At Cape Adare, northern Victoria Land, we conducted a survey across Ridley beach (the site of the largest Adélie penguin rookery in Antarctica) to test the hypothesis that within a penguin colony distinct patterns of microbial communities could be seen. Analysis of prokaryotic community composition were based on sequencing of 16S rRNA gene PCR amplicons, and analysis of soil geochemistry were based on ammonium, phosphate, C and N content, electrical conductivity (EC), and pH in a total of 26 sites. The highest concentrations of phosphate, EC, C, and N were seen at the beach’s central sites, radially decreasing towards the Adare Peninsula and the ocean. These parameters were strongly positively correlated and were significant environmental drivers of community composition. Ordination of the sampling sites showed they could be separated into two groups: those for which the most abundant OTU had a relative abundance higher than 20% and the ones for which it was lower. Up to six different OTUs were present at a given site with an abundance >20%, highlighting a high level of plasticity in a geographically confined place with homogeneous soil geochemistry, and suggesting a differentiating penguin influence across the sites of a rookery.
Long-term Ecological Research on King George Island, Antarctica

Hong Kum Lee¹ (hklee@kopri.re.kr), Seok Cheol Kim², Chang Uk Hyun³, Hyun-Ju No¹, Marc Oliva³, Ji Hee Kim¹, Kyu Song Lee², Hyun-Cheol Kim¹, Ok-Sun Kim³, Sang Hee Kim¹, Hyoungseok Lee³, Soon Gyu Hong³

¹Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of, ²Gangneung-Wonju National University, Gangneung, Korea, Republic of, ³Universidade de Lisboa, Lisbon, Portugal

Baton Peninsula, King George Island (KGI) is the focus of a Korean-lead study on the effects of environmental changes on the terrestrial ecosystem since 2009. It harbors diverse organisms and micro-ecosystems including representative local ecosystems: wet coastal environments with diverse mosses and lichens; dry inland environments with only a few lichen species; and patterned ground with exposed mineral soil and limited vegetation on rocks. In 2015, a vegetation base map was developed for Barton Peninsula using satellite images, UAV images, and field surveys. As well as diversity of microorganisms and invertebrates, our long-term monitoring includes microclimate, light intensity, soil temperature and moisture. Different micro-environments act on different genotypes of the same lichen species. While water availability is the most important factor for all organisms, photosynthetic lichens and mosses are also affected by snow cover due to its protection from sunlight and light availability. Lake sediment core records of during last 3,000 years revealed the variation of abundant fungi, microalgae and invertebrate depending on the depth. It implies KGI in the Antarctic Peninsula is one of the most vulnerable ecosystems in a changing climate. As a hotspot of ANTOS and LAPES, the map and database of KGI long-term monitoring as well as biological responses in molecular level will allow a comprehensive understanding of ecosystem in space and time in environmental changes.
Survivors or Colonizers? Case Study of the Freshwater Copepod Boeckella poppei

Claudia Maturana¹, Jennifer Jackson², Peter Convey², Elie Poulin¹ (epoulin@uchile.cl)
¹Institute of Ecology and Biodiversity, University of Chile, Santiago, Chile; ²British Antarctic Survey, Natural Environment Research Council, Cambridge, United Kingdom

The Quaternary brought numerous cycles of ice sheet extension and contraction across the Antarctic continent, resulting in major disruption of terrestrial habitats and the extinction of diverse taxa. Currently there are two main hypotheses to explain the present-day occurrence of freshwater biota in Antarctica: (1) recent colonization from lower latitudes during inter-glacial periods; (2) persistence in refugia within Antarctica.

The genus Boeckella has a Gondwanan distribution, and B. poppei is unique as the only terrestrial or freshwater invertebrate that occurs in all three of the generally recognized Antarctic biogeographic regions. We describe population structuring and divergence times across the maritime Antarctic, sub-Antarctic South Georgia and Patagonia. We used a combination of molecular approaches targeting one mitochondrial fast-evolving (cox1) and two nuclear slow-evolving markers (28S and ITS), and traditional morphological taxonomy. Our data clearly support the refugial hypothesis, with two independent regional recolonization events from putative refugia in the southern Antarctic Peninsula and the South Orkney Islands. Molecular phylogenetic reconstruction showed two distinct clades,

(1) Patagonian and
(2) Antarctica, separating 3 Mya.

Within Antarctica two haplogroups were present,

(1) sub-Antarctic + southern Antarctic Peninsula and
(2) northern Antarctic Peninsula, separating 1 Mya.
Terrestrial flora of Antarctica's frozen continent is dominated by bryophytes (mosses, liverworts) restricted to the limited ice-free areas. These plants constantly battle against sub-zero temperatures, extreme winds, reduced water availability and high levels of damaging ultraviolet radiation due to reduced stratospheric ozone; all impacting the ability of Antarctic species to survive and grow. Thus, it is imperative that we monitor Antarctic flora in response to changes in climate, in particular to ozone depletion. Furthermore, there is a substantial need for regional climate proxies given the sparse distribution, limitations and short record of Antarctic meteorological stations. As resilient plants with simple structures, mosses are suitable candidates for proxy development as they can preserve long-term records of their immediate microclimate in their chemical signatures; for example, sunscreen compounds preserved in their cell walls. We aim to develop and use Antarctic mosses as biological proxies for climate around the Antarctic coast. This includes analysing sunscreens and stable isotopes of a range of Continental and Maritime mosses that have been dated using the radiocarbon bomb-pulse method. Long-term regional climate records, such as moss water availability and ozone levels, could be locked away as chemical signatures within old-growth moss shoots of up to 420 years old.
The Circumpolar Shrub *Cassiope tetragona*: an Archive of High Arctic Climate

Stef Weijers¹ (weijers@uni-bonn.de)
¹University of Bonn, Department of Geography, Bonn, Germany

High Arctic instrumental meteorological data are often discontinuous and represent only a few decades, which limits interpolation and upscaling of climatic data in this part of the Arctic and reconstructions based on reliable climate proxies are needed to fill in observational gaps. Annual growth of the evergreen circumpolar dwarf shrub species *Cassiope tetragona* represents such a climate proxy. Annual shoot length growth of this species can be accurately measured through the presence of so-called *wintermarksepta* (WMS), dark bands of meristem tissue in the white pith that demarcate the end of a growing season. WMS-distances offer an alternative to ring widths in the High Arctic, where trees and tall shrubs are absent. The growth chronologies developed for this long-lived (>150 years) species are the longest developed for the High Arctic so far. Intact subfossil specimens have been found, and small stem fragments found in soil cores may offer the possibility for longer-term reconstructions. Annual growth of *C. tetragona* was found to be strongly limited by growing season temperatures at many High Arctic sites in experimental warming and dendroecological studies. Annual growth parameters of the species thus form a reliable proxy for past temperatures. Several examples of studies on *C. tetragona* as climate proxy will be presented, including from High Arctic sites such as the world’s northernmost polar desert in North Greenland and sites in Svalbard.
The Siberian Margin in the Context of Holocene Sea Level Rise and Climate

Henning A. Bauch

1 Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, c/o GEOMAR, Kiel, Germany

After the Holocene sea-level highstand some 5-6 ka ago, a time of sedimentary stabilization commenced on the Siberian shelves. Drastic decreases in sedimentation rates in the Laptev Sea occurred at water depths >30 meters whereas in the inner shelf region deposition continued due to input from rivers and coastal erosion. Compared with that latter process, the Lena Delta should comprise a region of sediment catchment where aggradation wins over erosion. However, little is known about the detailed history of this delta during the second half of the Holocene. To gain more insight into this issue several islands within the Lena Delta were studied. All of these are comprised of massive peat of several meters in thickness. Using discrete specimens of water mosses, detailed radiocarbon-based chronologies of these peat sections were established. These show that the islands' history above the present-day delta sea level is c. 4000 yrs. old. Moreover, a major change in peat growth occurred after 2500 yrs BP in both, accumulation and species composition. Because these changes also correlate well in time with major shifts in ocean circulation and sea ice drift patterns elsewhere the environmental developments at the Siberian margin reflect the overall climate development witnessed around the Arctic during the late Holocene.
The Potential for Using Arctic Carbonate Microfossils as Paleo-pH Proxies

Emily Osborne¹ (emily.osborne@noaa.gov), Thomas Cronin², Laura Gemery², Catherine Davis³, Jeremy Mathis¹, Robert Thunell³

¹National Oceanographic and Atmospheric Administration, Oceanic and Atmospheric Research/Arctic Research Program, Silver Spring, United States, ²United States Geological Survey, Eastern Geology and Paleoclimate Science Center, Reston, United States, ³University of South Carolina, School of the Earth, Ocean, and Environment, Columbia, United States

Modern ocean time-series indicate the Arctic Ocean is experiencing ocean acidification at an accelerated rate, and it is expected to experience the largest net decline in seawater pH globally during the coming century. Modern pH observations are especially limited in the Arctic Ocean, highlighting the importance of paleo-pH reconstructions from sediment records. Recent developments in boron-based paleo-pH proxies provide opportunities to reconstruct past carbonate chemistry of seawater but have yet to be applied to the Arctic sedimentary record. This work evaluates the pH proxy potential of boron to calcium (B/Ca) ratios in Arctic foraminifera and ostracodes preserved in Pacific Arctic surface sediments. B/Ca results are compared to in situ bottom water pH and saturation state (Ω) to develop modern species-specific calibrations that can be applied to paleo-pH reconstructions. The calibration sample set includes nearly 80 sediment core-tops distributed along a latitudinal gradient (62°N to 73°N) in the Bering and Chukchi Seas. The sampling locations represent a range of bottom water temperature (-1.5 to 4.9 °C) and pH (7.7 to 8.1) conditions, ideal for calibrating relations between various oceanographic parameters and shell chemistry. Results include trace element data for multiple species of benthic foraminifera (Elphidium incertum and Nonion labradorica) and ostracodes (Sarsicytheridea bradii and Krithe spp.) that are broadly distributed across the Arctic environment.
Seafloor Methane Seepage at NW Svalbard Since the Last Glacial Maximum

Andrea Schneider¹ (andrea.schneider@uit.no), Giuliana Panieri¹, Aivo Lepland², Chiara Consolaro³, Antoine Crémière², Matthias Forwick¹, Joel E. Johnson⁴, Andreia A. Plaza-Faverola¹, Simone Sauer⁵, Jochen Knies²
¹UiT The Arctic University of Norway, Tromsø, Norway, ²Geological Survey of Norway, Trondheim, Norway, ³Plymouth University, Plymouth, United Kingdom, ⁴University of New Hampshire, New Hampshire, United States, ⁵Ifremer, Plouzané, France

The amplification of global warming in the Arctic raises concern about the role of methane, a powerful greenhouse gas. A large amount of methane is present in continental margin sediments worldwide that may be released into the water column and atmosphere during future climate warming. Therefore, it is important to evaluate the character, timing, and triggers of past seafloor methane seepage to better understand future seepage dynamics.

Vestnesa Ridge, located at 79°N in 1200 m water depth offshore NW Svalbard, is one of the northernmost known active methane seep sites and is characterised by a subseafloor fluid flow system, numerous seafloor pockmarks, and gas flares in the water column.

Our study applies multiple proxies in the geological record to reconstruct past methane seepage variability on Vestnesa Ridge:

i) geochemical data from diagenetically altered fossil foraminiferal tests,
ii) mineralogical and stable isotope composition of methane-derived authigenic carbonate, and
iii) sediment geochemistry of multiple sediment cores.

We observe several seepage events that coincide with the Last Glacial Maximum extent of the Svalbard Barents Sea Ice Sheet, with the Heinrich Event 1 (ca. 18.5 cal ka BP), and multiple events in the early Holocene. Geological evidences for enhanced methane flux and seafloor methane seepage imply that glacio-isostatic adjustments during ice sheet advance and retreat may have triggered methane seepage at Vestnesa Ridge.
Paleodynamics in Thaw Lakes: Accumulation of Aquatic vs Permafrost Carbon

Josefine Lenz1,2 (josefine.lenz@awi.de), Katey M. Walter Anthony2, Christopher V. Maio3, Guido Grosse1,4
1Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Periglacial Research Section, Potsdam, Germany, 2University of Alaska - Fairbanks, Water and Environmental Research Center, Fairbanks, United States, 3University of Alaska - Fairbanks, Department of Geosciences, Fairbanks, United States, 4University of Potsdam, Institute of Earth and Environmental Science, Potsdam, Germany

Permafrost deposits preserve organic matter which is decomposed and potentially released as greenhouse gases (CO2 and CH4) during thermokarst processes and in particular thaw lake development. Younger near-surface and older organic matter from slumping and expanding lake shores are deposited in the lake basin and contribute to the lacustrine carbon cycle. Bioproductivity within the lakes complements carbon accumulation in lacustrine deposits and provides an additional source of young carbon and greenhouse gases.

A set of lake sediment cores from Goldstream Valley in the discontinuous permafrost zone of Interior Alaska was studied for their origin of organic matter during the Holocene. With the aim to distinguish the provenance (terrestrial or aquatic) of carbon contributions to sediments over time, core samples were analyzed for their total organic carbon/total nitrogen ratio (C/N) as well as stable carbon isotopes. The case study of Goldstream Valley Lake located in yedoma permafrost, indicates a dominance of aquatic plant material in the littoral zone with a mean C/N ratio as low as 8.7. Although a similar signal is found for sediments in the lake's central basin, a clear shift to a terrestrial carbon signal (C/N of 22) is presumably indicating the trash layer of the initial lake phase. Further, ongoing organic matter decomposition in talik sediments proves to be crucial to assess the contribution of thaw lakes to future climate change by mobilizing Pleistocene soil carbon.
The increased melt of ice in areas of retreating glaciers in High Mountain and polar environments creates new ecosystems and changes existing ones. Particles and attached compounds such as nutrients are released from the glacier and enter the fluvial system including glacier-fed lakes, which become impacted in their physical and chemical habitat properties. The disappearance of glaciers may fundamentally change these systems with unknown consequences on organismic diversity, nutrient cycling and resilience towards further changes. To understand the importance of glaciers for alpine lake ecosystems, we compared glacier-fed and permafrost-influenced lakes at three locations in the Swiss Alps in two field campaigns in 2016/2017. We analyzed microbial diversity as well as physical and chemical properties in lakes and in glacier forefields. Glacier-fed lakes had a higher turbidity, suspended sediment concentration, and conductivity than permafrost-influenced lakes. In contrast, nutrients (nitrate and phosphate) did not differ between the two. Microbial mats were found in both lake types, but microbial community compositions differed markedly. In glacier-fed streams they were similar to each other independent of the source glacier. In contrast, permafrost lakes showed high variability in microbial community compositions. Future work aims to better understand changes in the fluvial properties and project responses of High Mountain aquatic ecosystems in a possible post-glacial era.
The link between carbon cycling and weathering in recently deglaciated areas may result in important feedbacks on global warming and biogeochemical element cycles, particularly since glaciers are predicted to retreat at increasing rates in the future. In addition, recently deglaciated areas are unique environments to study the initial development soils and their associated terrestrial microbial ecosystems.

In newly formed proglacial soils, the scarcity of carbon and nutrients is thought to be the dominant limiting factor for microbial colonization and development. However, the processes controlling carbon and nutrient cycling in such settings remain poorly understood. To address this gap, we studied the functional linkages between soil mineralogy, weathering parameters carbon and nutrient distributions and microbial communities along a 150 years chronosequence in the glacier forefield of Fláajökull, south-east Iceland.

Our results show a clear decrease in pH, conductivity and soil grain size along the chronosequence which is accompanied by an increase in clay size contents. In this contribution, we will discuss the links between changes in weathering parameters and microbial community development along the chronosequence with the aim to better quantify the development of new soils upon glacier retreat.
Microbial Communities and Ecological Function in Dry Valley Lakes, Antarctica

Ok-Sun Kim¹ (oskim@kopri.re.kr), Miye Kwon¹, Jaejin Lee¹, John Priscu², Jongik Lee¹, Soon Gyu Hong¹
¹Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of, ²Montana State University, Montana, United States

Permanently ice-covered lakes in the McMurdo Dry Valleys of Antarctica are physicochemically stratified along depth and have significant biological gradients. Despite the long-term ecological researches on these extreme environments, there remains a paucity of studies on microbial community structure and its ecological function. We conducted the comprehensive analysis of bacterial communities and additional biogeochemistry with depth profiles in five ice-covered lakes. Specific assemblages were confined exclusively to a certain environment. In Lake Bonney, 30 m depth of the East and West Lobe was dominated by two distinct Firmicutes classes. Candidate division WM88 occurred at 15 m depth of Lake Fryxell, whereas lineages of Chlorobi are detected only at the depth of 18 m in Lake Miers. Furthermore, Lake Fryxell was dominated by various uncultured bacterial lineages belonging to Bacteroidetes, Actinobacteria, Planctomycetes and candidate divisions JS1, WM88, and SAR 406. To study their ecological roles, shotgun metagenomics was carried out in all depths sampled and here we present significant results in order to implicate the microbial ecological function in this hypersaline ecosystem, Antarctica.
Climate change is rapidly altering the arctic sea and landscape to forms and functions not previously observed while our understanding of the importance of arctic microbial communities is just beginning. Molecular methods (i.e. through the use of extracted DNA, RNA and proteins) are playing a critical role in deciphering the current and changing function of these microbial communities by identifying members of the communities and their potential and expressed functions. The heterogeneity of the microbial community structure and the homogeneity of certain functions define an ecosystem with specific interactions that are currently being modified under selective pressure of the changing environment. The difficulties and rewards of exploring arctic microbial communities through molecular methods will be described with examples evaluating the role of atmospheric microorganisms in the snow and ice, the dynamics of the snow microbial communities, and the spatial heterogeneity of these arctic microbial communities. The functional future of these microbial communities will have a direct impact on the role of the Arctic in global geochemical cycling and arctic foodwebs.
Monitoring Climate Change: Lichens do it Well in Antarctica

Leopoldo Sancho1 (sancholg@farm.ucm.es), Ana Pintado1, Theodore Gannutz2, Steven Frishman3, Allan Green1,4, Catherine Beard5, Ian Hogg4,6, Mercedes Vivas1, Craig Cary4
1Universidad Complutense, Departamento de Biologia Vegetal II, Madrid, Spain, 2Private, Loysville, United States, 3Private, Yerington, United States, 4Waikato University, Hamilton, New Zealand, 5Department of Conservation, Hamilton, New Zealand, 6Polar Knowledge Canada, Canadian High Arctic Research Station (CHARS), Cambridge Bay, New Zealand

Lichens grow on snow free sites throughout Antarctica from the Maritime to 85°S in the Ross Sea region, a span of round 22 degrees latitude. Lichens show two orders of magnitude difference in growth rate from the slowest yet known, 0.36 mm/century in the Dry Valleys (77.5°S) to around the fastest, 87 mm/century at Livingston Island (62.4°S). As a result, lichen growth rate appears to be possibly the best biological indicator of climate in Antarctica. Temperatures have been changing rapidly in the maritime Antarctic, increasing until 1998 and now declining. Lichen growth has tracked these changes and results from growth measurement over 38 years shows that they respond strongly to warming (26% increase over a 0.58° temperature rise for Usnea antarctica, 45% per 1°C increase). However, falling temperatures cause almost catastrophic declines not just from lower growth rates but with loss of complete thalli of some species due to snow kill. The latter follows loss in productivity when lichens remain covered in snow for long periods. Evidence suggests that snow kill may be an important factor forcing lichen community change throughout the continent. We also present a new data set from Cape Hallett that spans 51 years, one of the longest in Antarctica, and which is an important intermediate site between the two extremes. Whilst longer active periods from increasing precipitation probably drive productivity, actual growth rate is likely to be a response to temperature.
Aerobiology over Antarctica

David Pearce¹ (david.pearce@northumbria.ac.uk)
¹Northumbria University, Applied Sciences, Newcastle-upon-Tyne, United Kingdom

The rate of dispersal to an ecosystem can significantly influence ecosystem dynamics. Aerial transport has also been identified as an important source of biological input to remote locations. However, the contribution of aerial dispersal in shaping patterns of biodiversity and ecosystem function remains poorly understood, mainly due to the lack of coordinated efforts in gathering data at appropriate temporal and spatial scales. In this study, circum-Antarctic samples were collected during the ACE cruise, to map aerobiological diversity around Antarctica, to identify the main input routes and sources, potential biodiversity hotspots and areas of special concern for biological conservation. This unique sample set has enabled the investigation of Antarctic atmospheric ecology from regional to continental scales.
Person-Environment Fit: Needs and Challenges in Antarctica

Cyril Jaksic1 (cyriljaksic@hotmail.com), Gary Steel1, Emma Stewart1, Kevin Moore1
1Lincoln University, Christchurch, New Zealand

Working in an isolated and confined environment (ICE), such as the Antarctic, presents a range of challenges for those who work there. While everyone copes differently with isolation and confinement, some key indicators might allow identification, prior to the deployment, of those better equipped to adjust well. In the present research, a Person-Environment fit theory, drawn from organisational psychology, has been used to investigate the interaction between the individuals' deployed to work at various Antarctic stations and the environment's characteristics, and how this interaction relates to measures of adjustment. The research included two studies. The first study (n=14) used a series of self-report questionnaires to gather data from winter-overs throughout their stay. The second study (n=59) employed a single, self-report questionnaire to record former winter-overs' recollection of their experience. Analysis of these data revealed the important role of needs for affiliation, intimacy and privacy, and their relationships to social adjustment within the station. Results also supported the hypothesis that such adjustment is negatively related to winter-over syndrome and positively related to job satisfaction. Overall, the results suggest that theoretical approaches that consider interactions between personal characteristics and defining environmental features lead to better understanding of human adaptation to extreme environments.
Expeditioner Adjustment to Antarctic Employment: Does One Size Fit All?

Clare Hawkes1, Kimberley Norris1 (kimberley.norris@utas.edu.au), Jeff Ayton2, Douglas Paton3
1University of Tasmania, Psychology, Hobart, Australia, 2Australian Antarctic Division, Polar Medicine, Kingston, Australia, 3Charles Darwin University, Darwin, Australia

Limited research has been conducted outside the theoretical paradigm of the third-quarter phenomenon to examine patterns of expeditioner adjustment to Antarctic employment, and whether this is a primarily homogeneous experience. As such, an exploratory paradigm adopting latent growth curve analysis was utilised within the current research to determine whether such patterns could be quantitatively identified. 423 expeditioners within the Australian Antarctic Program provided data regarding mood prior to departure for Antarctica, each month they were ‘on the ice’, and upon return to Australia. The findings supported the long-standing postulated notion that the psychological adjustment in Antarctic expeditioners is primarily homogeneous. These finding can be utilised to guide the development of a new theoretical model to help explain the pattern of psychological adjustment in Antarctic expeditioners, as well as assist in development and implementation of intervention and prevention programs for Antarctic expeditioners.
Background: Medical provisions for BAS bases are ordered on an annual basis from the UK, and transported to the bases by non-refrigerated ship spending 1-2 months in the tropics enroute (approx 25-30°C, RH 80-90%). Due to supply chain and expiry dating, products are often approaching expiry by the time of arrival on base and many expire prior to the following year’s resupply. The lowest average temp is at Halley Station (-10°C in the summer, down to -55°C in the extreme).

Aim: To consider the use of expired drugs in a remote environment.

Methods:

1) Two separate literature reviews to establish current evidence on A) stability of expired drugs and B) stability of drugs stored outside recommended conditions.

2) Results of testing of stability of expired drugs returned from Antarctica by HPLC or RP-HPLC.

Five expired agents, returned from Antarctica, were analysed using stability indicating methods. These drugs may have been exposed to sub-zero temperatures on transporting from ship to base and back, and on the occasional periods when building temperature may drop below freezing, for example during power cuts. They were transported by sea through the tropics twice and were 15-51 months post-expiry date.

Stability indicating HPLC or RP-HPLC analysis was used for each agent.

Results: There are several studies providing evidence that many drugs are stable post-expiry. Heat tends to lead to more drug degradation than cold. All tested drugs were stable 15-51 months post-expiry.
This paper concerns the results of the quantitative and qualitative analysis of the interviews and tests administered to the crews that took part, from 2004 to 2016, at the winter expeditions to Antarctica, at Concordia Station. The winterers are multicultural groups because they include Italian and French people. They are selected and trained by Italian and French specialists through specific psychological tests and training methods. Particularly there will be presented the results of some psychological tests used for the aptitude evaluation of Italian subjects who have participated in the last thirteen winter Expeditions to Antarctica and who have remained in a confined environment for one year at Concordia Station. Also there will be presented the results of the debriefing with the crewmembers of the last expeditions to Concordia Station. The debriefing was made using questionnaires, tests and interviews to assess the winterer's perception of psychological adaptation, coping strategies, feelings and mood. They were asked about what they found different from their expectations, what they preferred and what they didn't like, the quality of the interpersonal relationship, the existence of sub-groups, their evolution with time, the relationship with the leader and the outside environment (research's investigators, logistic support, etc.) The objective was to identify what is useful to do to improve future missions.
“Ice-tronauts:” Antarctica as a Space Exploration Analog for Team Functioning

Steven Kozlowski¹ (stevekoz@msu.edu), Chu-Hsiang Chang¹, Jessica Webb¹, Jeffery Olenick¹, Jeff Ayton²
¹Michigan State University, Psychology, East Lansing, United States, ²Australian Antarctic Division, Polar Medicine, Kingston, Australia

The isolated, confined, and extreme (ICE) conditions that characterize polar exploration and research are excellent analogs for studying the effects of ICE stressors that will affect individual and team psycho-social functioning during long duration space exploration missions to the moon and Mars. This is critical because, although team effectiveness has been studied for well over 60 years, most of the research is static. While much is known regarding the psycho-social factors that contribute to team effectiveness (i.e., team cohesion, affect, conflict), relatively little is known about how they vary or fluctuate over time, trends that characterize long term changes, and factors that account for variance in psycho-social functioning. Our research, funded by NASA, is investigating ICE team functioning in winter-over and summer scientific missions in Antarctica (in collaboration with the Australian Antarctic Division and others), as well as in two NASA mission simulations. Mission durations range from a matter of a few weeks to upwards of one year, depending on the analog. The protocol across all analogs captures daily ratings on psycho-social factors which are analyzed to identify within person and within team variability, long term trends, and factors that account for changes. The presentation will discuss findings across these research locations, focusing on polar settings as an excellent analog for understanding space team functioning for long duration exploration missions.
It is beyond doubt that a stay in space affects human physiology and health. Besides increased radiation levels and reduced gravity, health problems can be caused by other stress factors e.g. isolation and confinement and disturbed sleep. So far, the mechanisms of human adaptation to these environments are unknown. Since the number of space experiments is limited, ground-based platforms are useful to recreate aspects of the extreme space environment. Within IMAGe, the impact of extreme conditions on human physiology will be investigated at the Belgian Princess Elisabeth Station at Antarctica (PEA). The environmental part will specifically monitor ionizing radiation doses and ozone concentrations present in- and outside PEA. In addition, immune changes, stress-related hormones and oxidative stress will be measured in blood, saliva and urine from volunteers. Furthermore, heart and oxygen saturation will be monitored. In parallel, a study assessing the microbiome with/without Spirulina supplementation will be conducted. Besides experimental research, a considerable amount of time will be devoted to dissemination and education activities. In conclusion, the IMAGe project is a unique pilot study to perform multidisciplinary bio-monitoring. Obtained data can be compared with previous Antarctic studies, and will bring more insight into physiological changes in humans exposed to the PEA environment.
Antarctic Snow Accumulation over the past 200 Years

Elizabeth Thomas1 (lith@bas.ac.uk), Jan Melchior van Wessem2, Jason Roberts3, Elisabeth Isaksson4, Elisabeth Sclosser5, TJ Fudge6, Paul Vallelonga7, Brooke Medley8, Jan Lenaerts2, Nancy Bertler9, Michiel R. van den Broeke2, Daniel Dixon10, Massimo Frezzotti11, Barbara Stenni12, Mark Curran3, Alexey Ekaykin13

1British Antarctic Survey, IDP, Cambridge, United Kingdom, 2Institute for Marine and Atmospheric research, Utrecht, Netherlands, 3Australian Antarctic Division, Hobart, Australia, 4Norwegian Polar Institute, Tromso, Norway, 5Univ. of Innsbruck, Innsbruck, Austria, 6University of Washington, Seattle, United States, 7Centre for Ice and Climate, Copenhagen, Denmark, 8NASA Goddard Space Flight Center, Maryland, United States, 9National Ice Core Research Laboratory, Wellington, New Caledonia, 10University of Maine, Maine, United States, 11ENEA, Rome, Italy, 12University of Venice, Venice, Italy, 13Arctic and Antarctic Research Institute, St Petersburg, Russian Federation

The Antarctic Ice Sheet (AIS) is the largest reservoir of fresh water on the planet, even small changes in its volume could have significant impacts on global mean sea level. Here we present Antarctic snow accumulation variability, at the regional scale, over the past 200 years based 79 ice core snow accumulation records. The records were evaluated against precipitation from ERA-interim reanalysis and converted to regional surface mass balance (SMB) by regressing onto the modelled SMB from RACMO2.3p2. Our results show that SMB for the total Antarctic ice sheet (including ice shelves) has increased at a rate of 7 +/- 0.13 Gt dec^-1 since 1800 AD, representing a net reduction in sea level of ~0.02 mm dec^-1 since 1800 and ~0.04 mm dec^-1 since 1900 AD. The largest contribution is from the Antarctic Peninsula, where the annual average SMB during the most recent decade (2001-2010) is 123 +/- 44 Gt yr^-1 higher than the annual average during the first decade of the 19th century.
Antarctic Ice Flow Line Map

Yan Liu¹ (lyxixi_2003@163.com), Liyun Zhao¹, John Moore¹, Xiao Cheng¹
¹Beijing Normal University, College of Global Change and Earth System Science, Beijing, China

We generate a complete, accurate, high-resolution, digital mosaic flow line map for the whole Antarctica by a novel automatically tracking method based on surface ice flow velocity dataset. Multi-level and up to 10200-neighborhood (101 by 101) search windows are used to track directions along flow lines with high precision, and adapt to the spatial inconsistency of the original flow directions. A set of restrictions based on physical principle of ice flow are also taken in account. The flow lines obtained are highly consistent with the ice flow features revealed by the remote sensing images. This detailed flow line map give a clear divide of the ice sheet-ice shelf systems of the whole Antarctica. This view of ice sheet motion redefines our understanding of spatial distribution pattern and characteristics of Antarctic ice streams, and has far-reaching implications and application for the reconstruction and prediction of ice sheet evolution, ice mass supply and migration.
Mechanical Modelling of Iceberg Capsize Constrained by Seismic Inversion

Pauline Bonnet1,2,3 (pbonnet@ipgp.fr), Amandine Sergeant4, Vladislav Yastrebov5, Anne Mangeney1,2,6, Olivier Castelnau3, Jean-Paul Montagner3, Eleonore Stutzmann1

1Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Seismology Group, CNRS UMR 7154, Paris, France, 2Université Paris-Diderot 7, Sorbonne Paris Cité, UFR STEP, Paris, France, 3ENSAM, CNAM, Laboratoire Procédés et Ingénierie en Mécanique et Matériaux, CNRS, Paris, France, 4ETH Zurich, Laboratoire of Hydraulics, Hydrology and Glaciology (VAW), Zurich, Switzerland, 5MINES ParisTech, PSL Research University, Centre des Matériaux, CNRS UMR 7633, BP 87, Evry, France, 6Inria, Laboratoire J.-L. Lions, ANGE team, CEREMA, CNRS, Paris, France

Iceberg calving is responsible for most of the mass loss occurring at the front of marine-terminating glaciers in Greenland. Capsizes of calved icebergs generate long-period seismic signals that are recorded by local and global stations. The emitted seismicity contains precious informations about the source mechanisms involved during the calving process. A versatile mechanical modelling of iceberg capsize has been developed by A. Sergeant et al. [2016]. Inversion of seismic signals provides constraints to the model and enables calculation of the iceberg volume and source dynamics. This model has been first tested on two particular events at the Helheim glacier, Greenland (25 July 2013 at 03:13 UTC and 31 July 2013 at 19:31 UTC) and the results are consistent with the iceberg volume measured separately using optical images. A difficulty of the capsize modelling lies in accurate models used for the strongly coupled iceberg-water interaction, as the iceberg dynamics strongly depends on the water flow initiated during the capsize. The models with and without drag force, with and without added mass will be considered, as well as models including immobile and deformable terminus. In this presentation, we will analyze how these different iceberg-ocean interaction models affect the resulting seismic signals. By comparing synthetic seismograms with data, the most adequate models will be selected.
What is the Viscosity of the Mantle Beneath Antarctica, and why Do we Care?

Pippa Whitehouse¹ (pippa.whitehouse@durham.ac.uk), Grace Nield¹, Wouter van der Wal², Douglas Wiens³, Andrew Lloyd³, Matt King⁴
¹Durham University, Durham, United Kingdom, ²Delft University of Technology, Delft, Netherlands, ³Washington University in St Louis, St Louis, United States, ⁴University of Tasmania, Hobart, Australia

In traditional studies of glacial isostatic adjustment, mantle viscosity is inferred from observations of relative sea-level change or present-day uplift that reflect the solid Earth response to past (known) changes in ice and ocean loading. In Antarctica, we lack robust constraints on the surface loading history in many regions, and therefore recent studies have sought to use independent evidence to constrain the viscosity beneath Antarctica. In this presentation we review the different methods and data sets used to determine mantle viscosities across Antarctica, and we outline the range of values that are deduced under different rheological assumptions. Finally, we discuss the implications of the emerging viscosity distribution for past and future ice sheet dynamics, and highlight areas that we recommend should be the focus of future research.
Ice Dynamic Model with Laterally Varying Relaxation Time

Wouter van der Wal¹ (w.vanderwal@tudelft.nl), Dirk Oude Egbrink¹, Pablo Vizcaino Rubio¹, Bas de Boer², Roderik van de Wal²

¹Delft University of Technology, Delft, Netherlands, ²Utrecht University, Utrecht, Netherlands

The elevation of an ice sheet controls its mass balance, either through the influence on temperature or because local sea level changes. Elevation depends on the ice thickness and the relaxation of the bedrock, which in ice sheet models is often modelled by assuming a constant relaxation time. However, it is known that mantle viscosity varies with location, hence also bedrock relaxation times will vary across the Earth’s surface. The goal of this study is to include variations in relaxation time in an ice sheet model and study the effect on the equilibrium state in areas where large variations in relaxation time are expected, such as Antarctica.

We use the ANICE ice-sheet model with a bedrock relaxation module adapted to compute bedrock deformation for a location specific relaxation time. The reference case is constant relaxation time with a value of 3000 years. For a realistic ice dynamic simulation a 3D map of relaxation times should be used. However, we only have estimates of viscosity that are derived from a global seismic model in combination with parameters for olivine rheology. Relaxation time maps are obtained by varying relaxation time to obtain the same bedrock deformation as predicted with the viscosity map in a GIA model. Results for a dynamic ice sheet based on the relaxation time maps show that the small relaxation times in West Antarctica result in a 2.5% smaller LGM ice sheet and 10% variation in ice volume that melted between LGM and present.
Recent estimates for sea level rise from Antarctica in coming centuries span near-zero to several metres, with the huge range arising largely from possible socio-economic pathways. But within any particular pathway, high rates of mass loss are driven by the controversial marine ice cliff instability (MICI) mechanism. We find MICI is not required to reproduce past Antarctic sea level rise (1992-2011; Last Interglacial, 130,000-115,000 years ago; Mid-Pliocene, 3 million years ago). With MICI, Antarctica is most likely to produce 40 cm sea level rise by 2100; without, it is unlikely to exceed this. We cannot, however, firmly rule MICI out.
The Arctic Science Agreement Propels Science Diplomacy

Paul Arthur Berkman¹ (paul.berkman@tufts.edu), Lars Kullerud², Allen Pope³, Alexander Vylegzhanin⁴, Oran Young⁵
¹Tufts University, Fletcher School of Law and Diplomacy, Medford, United States, ²University of the Arctic, Arendal, Norway, ³International Arctic Science Committee, Akureyri, Iceland, ⁴MGIMO, Moscow, Russian Federation, ⁵University of California Santa Barbara, Santa Barbara, United States

The presentation will share perspectives reported in Science magazine on 3 November 2017 (Volume 358: 596-598). The Agreement on Enhancing International Arctic Scientific Cooperation, signed on 11 May 2017 by foreign ministers of the eight Arctic States, including the United States and Russia, as well as Greenland and the Faroe Islands, is a strong signal reaffirming the global relevance of science as a tool of diplomacy, reflecting a common interest to promote scientific cooperation even when diplomatic channels among nations are unstable. Although the Arctic States are the signatories, the "Arctic Science Agreement" emphasizes that these States "may continue to enhance and facilitate cooperation with non-Parties with regard to Arctic science." This holistic (international, interdisciplinary, and inclusive) science cooperation broadens the scope of the Arctic Science Agreement beyond its defined area to address "common Arctic issues," in particular, "sustainable development and environmental protection" as established by the Arctic Council, balancing economic prosperity, environmental protection and societal well-being with the "best available knowledge for decision-making." With science defined broadly as the study of change to include natural and social sciences as well as indigenous knowledge, such science diplomacy helps to balance national interests and common interests for the lasting benefit of all on Earth with hope and inspiration across generations.
Environmental impact assessment is a central regulatory process in contemporary Antarctic governance as determined by the Madrid Protocol of 1991. The centrality of the EIA process in Antarctic affairs mirrors a broader development in which EIA has come to be the central regulatory tool in environmental policy worldwide, since its first introduction in the United States in 1969. This paper investigates the place of ideas and policies relating to ‘environmental impact’ in the Antarctic Treaty System before the signing of the Madrid Protocol in 1991. It will look at three case studies. First, the EIA process of the United States National Science Foundation in the McMurdo Dry Valleys in the 1970s. Secondly, the discussions about ‘impact’ in the CRAMRA negotiations between 1982 and 1988. And thirdly, the rhetoric and practices of impact in the Greenpeace World Park Base of the 1980s. Each of these cases will build into a larger picture of the contours and limits of the idea of ‘impact’, especially as it related to potential or actual bureaucratic processes in that period. This paper contributes not only to polar history, but to the broader discipline of environmental history to understand one of the fundamental structures of modern environmental protection that has hitherto remained under-studied.
Changing Ice at the Poles: Ramifications for Legal and Social Boundaries

Hayley Brazier
(hbrazier@uoregon.edu)

1University of Oregon, History, Eugene, United States

The problem of changing ice in the Arctic and Antarctic is central to the research of polar scientists. Yet scientists are not the only scholars who can bring critical perspectives to polar ice. Social scientists and humanities scholars, like environmental historians, can also contribute to the debate about ice and our understanding of the ice-ocean interface. This paper draws on a developing field of literature to argue that ice in the Southern and Arctic Oceans muddles the borders that legal and diplomatic institutions attempt to create. International regulatory regimes like the United Nations Convention on the Law of the Sea and the Antarctic Treaty have attempted to construct legal boundaries that do not necessarily acknowledge or adapt to the complexities of the polar environments. Ice shelves, icebergs, and sea ice undermine human-imposed boundaries when they obscure the shoreline in Antarctica, move between national jurisdictions in the North Atlantic, or melt to reveal new borders of untapped oil resources in the Arctic. When ice changes, nations are left to negotiate in terms of realpolitik the circumstances under which they may share oceanic resources. As scientists continue to study changing trends of ice at the poles, the humanities and social sciences are well positioned to determine the social and legal ramifications of such environmental change.
Defining Values: In a Word, who we Are

Gary Steel¹ (gary.steel@lincoln.ac.nz), Sira Engelbertz²
¹Lincoln University, Department of Tourism, Sport, and Society, Lincoln, New Zealand, ²University of Canterbury, Gateway Antarctica, Christchurch, New Zealand

The concept of values has been one of significant interest to polar social scientists in the last decade, yet there has been a puzzling lack of a clear and explicit definition of the concept in many of the publications and other academic output from this research. In the rare instance where a definition of “value” is offered by a researcher - explicitly or, more usually, implicitly - it can deviate markedly from those used by researchers in other disciplines. The lack of consensus for such a critical, theoretical term hinders collaborative, interdisciplinary work, and hampers direct comparison of research findings. This leads to a pervasive and regrettable inefficiency in the study of this important area. This paper presents common themes and key differences in several definitions of ‘values’ drawn from the general, social science literature and, where they can be found, more specific definitions from studies of ‘polar values’. The paper then proposes a working definition as a starting point for discussion amongst polar researchers.
Framing Antarctica as Fragile

Hanne Nielsen1,2 (hanne.nielsen@utas.edu.au)
1University of Tasmania / Institute for Marine and Antarctic Studies, Hobart, Australia, 2Association of Polar Early Career Scientists, Alfred-Wegener Institute, Helmholtz Center for Polar and Marine Research, Potsdam, Germany

Antarctica has been framed in many ways over the course of its human history: as a place for profit; a place for heroes; the ultimate testing ground; a place of purity, or a place of transformation. In recent times Antarctica has come to be cast as a fragile place. Although dominant in modern Western discourse, the view of Antarctica as a place that requires protection is not inevitable. This paper examines how the idea of Antarctic “fragility” manifests not only in a policy setting, but also the realm of cultural production. It asks how the “fragility” theme has appeared at different times, for various audiences, and uses media and advertising to trace links between public opinion, policy, publicity, and protection over the past century. By analysing representations of Antarctica in the media and contextualising these temporally and nationally, it traces how popular attitudes towards the continent have evolved over time. Gaining a comprehensive understanding of how framing of Antarctica has shifted - from a place of danger to be conquered to a place requiring protection - also reveals why we care about the place. Most people will never visit Antarctica, so their imagined versions of the far south are far more vivid than the ice itself. In the context of climate change, it is more important than ever to gain an understanding of human interactions with and conceptions of the far south. Analysis of media texts helps illuminate the discourse behind framing Antarctica as fragile.
New Critical Realities: Indigenous Film in the Time of Climate Change

Lisa Bloom¹ (lbloom2@mindspring.com)
¹University of California, Gender and Women's Studies, Berkeley, United States

This paper draws on writing done for my book project Polar Art and the Climate Crisis: Witnessing the Anthropocene. The book addresses polar art and film not just as an illustration of planetary demise and a call for action. But as a challenge to our imagination. Much of this work brings into being new forms of seeing, feeling, and sociality, that are connected to living through this kind of slow-moving disaster inflicted by environmental and climate breakdown. How very different these emotions of precariousness are from the old flag-planting heroism of explorations to “the ends of the earth” of an earlier epoch.

This presentation focuses on indigenous filmmakers to shift our view of the polar regions from the heroic to the climatic, from the white, male explorer’s perspective of remote wildernesses to the Inuit/Indigenous perspective that frames the land and the people of the land as a mix of human and non-human forces. It focuses on the experimental film, “Qapirangajuq: Inuit Knowledge and Climate Change,” (2010) by Nunavut-based director Zacharias Kunuk and Ian Munroe, the first documentary in the Igloolik-based language that explores how a northern indigenous community is affected by climate change from an indigenous perspective.

My analysis calls attention to how this film replaces the sublime aesthetic of the polar heroic age with an alternative aesthetic - one that is a counter aesthetic (anti-heroic), focuses on the everyday (quotidian), and is indigenous (Inuit).
Establishing a Data Stewardship Model for Arctic Observing through Collaboration

Peter L. Pulsifer¹ (peter.pulsifer@colorado.edu), Marten Tacoma², Stein Tronstad³
¹University of Colorado, National Snow and Ice Data Center, Boulder, United States, ²Royal Netherlands Institute for Sea Research, Texel, Netherlands, ³Norwegian Polar Institute, Tromsø, Norway

In November of 2014 the International Arctic Science Committee (IASC) and the Sustaining Arctic Observing Networks (SAON) established the Arctic Data Committee (ADC). The ADC comprises national and other organizational members who participate in working groups on a variety of different topics including federated search, vocabularies and semantics, education and others. In addition to actively engaging in working groups that directly support practice, the ADC works to ensure a better understanding of the Arctic data system as a whole and the policies, funding and societal drivers that underpin Arctic and polar data management and stewardship.

Most recently, the ADC took a leadership role in bringing together more than ten active polar data programs, initiatives and actors to focus on work planning and coordination of effort. This meeting complemented past workshops and fora (e.g., IPY, Polar Data Forums etc.) that have been effective in defining important community challenges and technical issues. The focus of the meeting was to generate detailed plans on how best to mobilise existing and pending funded activities to develop a particular international data sharing case study.

Collaboratively engaging with the diverse actors, projects and programs in the Arctic and elsewhere is the priority of the ADC moving forward.
Putting Antarctica on the Map: 25 Years of the Antarctic Digital Database

Peter Fretwell¹ (ptf@bas.ac.uk), Adrian Fox¹
¹British Antarctic Survey, Mapping And Geographic Information Centre, Cambridge, United Kingdom

The SCAR Antarctic Digital Database is a seamless compilation of international topographic data covering Antarctica south of 60°S. It is the primary source of map data for coastlines, rock-outcrop and contours, and has been used extensively for cartography, science and logistics since its launch in 1993. Over the last 25 years it has documented both the evolution of knowledge about the topography of Antarctica and major changes in the physical landscape. Here we summarise key changes captured in the ADD over the last quarter century, and current developments to ensure its relevance in the digital landscape of the next decade.

The initial baseline data came from 200+ regional scale maps from 11 national mapping agencies, later supplemented by newer vector data. Recently significant sources of new information are continent-wide, automatically-generated datasets from remote sensing. Delivery has changed from release on CD in 1993 to a web application which allows selection and download of data in a range of formats and resolutions, and provides web services for other systems. The availability of more remote sensing data has driven demand for more up-to-date information. We now intend to provide more frequent updates to capture the dynamic nature of Antarctic topography. Including continent-wide datasets from new sources has required updating metadata attributes, improving quality control procedures and more automated ways to generalize the lower-resolution datasets.
The volume and variety of Earth Observation (EO) data available for the polar regions is growing rapidly, providing opportunities for more complex investigations by the polar research community. With this increase in data and plans for new polar observing satellites, there are challenges to fully process, analyse, disseminate and exploit these new EO data.

The European Space Agency has established the Polar Thematic Exploitation Platform (PTEP) which provides the necessary collaborative computing environment for polar researchers. The PTEP projects address present challenges and opportunities in scientific data exploitation by collocating data, processing capabilities and ICT infrastructure, providing a complete cloud based work-environment.

This presentation will describe the Polar TEP concept and the range of potential uses it will support. We will present details of the platform where users can bring their algorithms and applications directly to the data. It will also cover the rich set of polar EO datasets, toolboxes and processing capabilities, plus functionality to allow deployment of user defined workflows and processing environments.

We will also outline a pilot project which demonstrates the use of Polar TEP to investigate current and future iceberg risk in Baffin Bay. The pilot project integrates a diverse set of data, processors and models, allowing investigation of linkages between iceberg trajectories, changes in ice sheet velocity and glacier calving rates.
Quantarctica 3: A Cross-platform, Full-featured Open GIS for Antarctic Research

Version 3 of the open GIS package “Quantarctica” was released in early 2018 (http://quantarctica.npolar.no). This geospatial data package is built on the free, open-source, cross-platform QGIS software, is capable of operating entirely offline, and includes a wide range of cartographic basemap layers, scientific datasets, and satellite imagery. Version 1 Quantarctica was first released in 2013, and it became a SCAR product in 2014. For this latest version, the Quantarctica Editorial Board selected peer-reviewed datasets for a wide range of Antarctic users, adding over 130 new basemap and scientific data layers and widening the thematic coverage from Glaciology and Geophysics to other themes such as Atmospheric Science, Biology, Oceanography, Social Sciences, and more. We also expanded the project’s extent and data coverage to 40°S, including sub-Antarctic islands.

Here, we briefly revisit the development process and accomplishments of the Quantarctica project, before showcasing Quantarctica 3’s expanded and deepened data coverage, new features, and practical applications in Antarctic research, logistics, education, and outreach. We also present our ongoing efforts and experiences with the Antarctic science community, including workshops, data solicitation and open data sharing, and direct engagement with Antarctic researchers in the field, in the office, and on social media.
Air temperature is an important baseline parameter for a range of scientific studies in Antarctica, e.g. climatology, hydrology or ecology. Climate stations provide sub-daily measurements, however, their low spatial density does not allow for comprehensive spatio-temporal analysis. While climate models can be used to fill these gaps, their coarse spatial resolution only allows capturing broad scale patterns. The application of remote sensing technology, on the other hand, provides fine resolution proxies for air temperature that make it possible to assess small-scale dynamics. The application of remote sensing data and methods is therefore inevitable.

This study uses time series of the MODIS Terra and Aqua sensors to estimate daily air temperature at 1 km spatial resolution. Machine learning algorithms are used to relate MODIS as well as process specific auxiliary predictors to measured air temperature recorded by 70 climate stations distributed over Antarctica. In this context, new modelling strategies are applied that account for the spatio-temporal autocorrelation in the data hence allowing for an adequate training of the model.

The resulting data set is unique as it provides daily air temperature at 1km spatial resolution for the entire continent. The new product therefore presents a baseline for temperature pattern and trend analysis at an adequate resolution to study both, regional and local scale climate variability.
The GeoMAP Dataset of Antarctic Rock Exposures

Simon Christopher Cox¹ (s.cox@gns.cri.nz), Belinda Smith-Lyttle¹, Christine Siddoway², Gianni Capponi³, Synnøve Elvevold⁴, Alex Burton-Johnson⁵, Jacqueline Halpin⁶, Paul Morin⁷, David Elliot⁸, Geomap Action Group⁹
¹GNS Science, Dunedin, New Zealand, ²Colorado College, Department of Geology, Colorado Springs, United States, ³DISTAV, Genova, Italy, ⁴Norwegian Polar Institute, Tromsø, Norway, ⁵British Antarctic Survey, Cambridge, United Kingdom, ⁶University of Tasmania/Institute for Marine and Antarctic Studies, Hobart, Australia, ⁷University of Minnesota, Polar Geospatial Center, Saint Paul, United States, ⁸Ohio State University, Columbus, United States, ⁹SCAR, Cambridge, United Kingdom

The SCAR GeoMap action group has been building a detailed digital geological dataset of Antarctica. We have been capturing existing geological map data, refining its spatial reliability, improving representation of glacial sequences and geomorphology. The initiative is aimed towards continent-wide perspectives and for cross-discipline use, our international team is collaboratively classifying and describing around 72,000 distinct areas that cover 51,000 km². The dataset will describe ‘known geology’ of rock exposures rather than ‘interpreted’ sub-ice features. Glacial deposits are an important focus for their potential to contain records of ice fluctuations of relevance to climate change. Here we present background on:

(1) Completion, or very near-completion, of the first version of a continent-wide dataset. All rock outcrops will have geological attributes assigned to them in GeoSciML suitable for use at 1:250,000 (or more-regional) scale.
(2) The large number of hard-copy geological maps and data sources, which range in scale and quality.
(3) Development of local legends, which highlight geological variation across the region.
(4) Progress towards a unified classification scheme.
(5) Bibliographic links referencing authors of key original work.
(6) Potential for the dataset to provide fresh perspectives, for example, through combined geological legends and interrogation of continent-wide time-space plots.

Arctic Sea Ice: A Transport Vehicle and Temporal Sink for Microplastic!

Ilka Peekén1 (ilka.peeken@awi.de), Sebastian Primpke2, Birte Beyer2, Julia Gütermann2, Thomas Krumpen1, Melanie Bergmann1, Laura Hehemann1, Gunnar Gerdts2

1 Alfred Wegener Institute, Helmholtz Center for Polar and Marine Research (AWI), Bremerhaven, Germany,
2 Alfred Wegener Institute, Helmholtz Center for Polar and Marine Research (AWI), Helgoland, Germany

Microplastics (MP) are a problem of growing environmental concern and have been acknowledged in polar oceans with particularly high concentrations in Arctic sea ice. Sea ice has long been recognised as a transport vehicle for contaminants from both distant and local sources. The Fram Strait represents a major gateway for both the inflow of warm Atlantic water with anthropogenic imprints, and the outflow of sea ice originating from the Siberian shelves and carried south via the Transpolar Drift. The MP content and composition from sea ice cores collected by RV Polarstern in 2014 and 2015 at five different locations along the Transpolar Drift allow for studying the various imprints of MP pollution. Through focal plane array detector-based micro-fourier-transform infrared imaging we recorded MP concentrations of up to $1.2 \times 10^7$ m$^{-3}$. Most particles were smaller than 50µm. Separate analyses of the various ice core horizons showed a strong shift in polymer distribution, depending on the source area and drifting paths of the sea ice, highlighting the transport capacities of sea ice for MP. The quantities found exceed previous reports by several orders of magnitude underlining the importance of sea ice as a temporary sink for MP. The role of focal sources versus long-range transport of MP particles will be discussed in the context of upcoming exploration of the Arctic Ocean due to climate change.
Assessment of Pollution from Two Ice Cores from Col du Dome, French Alps

Monica Arienzo1 (marienzo@dri.edu), Susanne Preunkert2, Joe McConnell1, Nathan Chellman1, Kelly Gleason1, Michel Legrand2
1Desert Research Institute, Reno, United States, 2Université Grenoble Alpes, CNRS, Institut des Géosciences de l’Environnement (IGE), Grenoble, France

Ice cores extracted from high altitude glaciers have proven to be important archives of human impacts on the free troposphere over continents. Measurements of heavy metals, sulfur, nitrate, ammonium, and black carbon in ice cores have previously been used to quantify pollution sources including coal, oil, and mining and to determine the relative contributions of pollutants with time. Here we present recent results from two ice cores extracted at the Col du Dome site (4250 m above sea level) located in the French Alps: the C10 core (126 m long) drilled in 1994 and the CDM core (140 m long) drilled in 2012. Nearly 30 trace elements and chemical species were analyzed at the Desert Research Institute via the continuous flow analysis system allowing for sub-annual resolution of many of the pollutants of interest. Based on the ammonium record that exhibits a well-marked seasonal cycle with a winter minima, seasonally resolved trends of various pollutants were determined for the 1890-2000 C.E. time period. Primary Matrix Factorization (PMF) was used to assess the apportionment of trace elements and chemical species to specific pollution sources. The PMF results are compared to available pollution emission estimates and to other ice core records to determine the influence of transport and deposition processes of pollutants to the Alps over the past.
Sunlight illumination of surface waters induces photochemical reactions with transformation of naturally occurring compounds and xenobiotics, inactivation of pathogens, and effects on biogeochemical cycles. These reactions consist of direct photolysis of sunlight-absorbing molecules, and of indirect phototransformation. In the latter case, sunlight is absorbed by naturally-occurring photosensitisers (e.g. chromophoric dissolved organic matter or CDOM, nitrate and nitrite) to produce several reactive transient species that trigger transformation reactions. The transients include, among others, the hydroxyl (·OH) and carbonate (CO$_3^-$) radicals, singlet oxygen (¹O$_2$) and CDOM triplet states (³CDOM$^*$). Their occurrence in surface waters depends on sunlight irradiance and on key water parameters such as chemistry and depth. In mountain environments, the nature and photoreactivity of CDOM is strongly affected by the vegetation surrounding the water body (forests, alpine meadows or bare rocks). Moreover, the duration of the ice-cover period could strongly affect photochemistry. As we recently demonstrated, the latter phenomenon is thought to play a key role in Antarctic lakes, also because ice protects CDOM from sunlight-induced photobleaching and ensures the occurrence of very photoreactive CDOM in lake water soon after the ice melt. Therefore, Antarctic lakes are very efficient photoreactors towards xenobiotics contained in the ice, which could reach lake water as the ice melts.
New Forensic Methods to Quantify Unseen Human Impact on Terrestrial Antarctica

Georgia Wakerley¹, Charles Lee¹ (charles.lee@waikato.ac.nz), Ian McDonald¹, Craig Cary¹
¹University of Waikato, International Centre for Terrestrial Antarctic Research, Hamilton, New Zealand

Under the Antarctic Treaty System of 1959, National Antarctic Programs and individuals have an obligation to keep the Antarctic continent in a ‘pristine’ state. The current definition of ‘pristine’ focuses on visible physical and chemical impacts without regard to the unseen remnants of human activities. The McMurdo Dry Valleys (MDV) is a microorganism-dominated ecosystem, where the effects and risks of releasing DNA from human and human-associated microbiota as part of routine activities are unknown. Using forensics-grade techniques and newly developed ultra-sensitive methodologies based on digital PCR, human trace DNA has been detected in field camps after habitation. We will present assessments of impact from human and human-associated microbial genetic materials for a range of sites, from highly impacted to previously unvisited locations. We will elucidate the relationship between the degree of detectable impact with the level of documented activities, and these results can potentially be developed as tools to detect undocumented activities and impact across the Antarctic continent. This research is part of the Dry Valley Ecosystem Resilience (DryVER) programme, funded by the New Zealand Ministry of Business, Innovation and Employment, that aims to provide evidence-based risk management of the McMurdo Dry Valleys. The data generated from these tools will be used to produce an “impact index” to inform the review of current environmental management guidelines.

**Anthropogenic Trace Elements (Bi, Cd, Cr, Pb) Emissions in the West Antarctica**

Franciele Schwanck¹ (franschwanck@gmail.com), Jefferson Simoes¹, Michael Handley², Paul Mayewski², Ronaldo Bernardo¹
¹Centro Polar e Climatico, Porto Alegre, Brazil, ²Climate Change Institute, Orono, United States

Atmospheric concentrations of trace elements are influenced by natural and anthropogenic processes. Most anthropogenic sources (fossil fuel combustion, smelting, industry, agriculture, and large-scale land use) have increased since the late 19th century becoming a worldwide issue for humans and the environment. Here, we present long-term Bi, Cd, Cr, Pb records in West Antarctica during the period 1882-2015 based on ice-core concentration analyses from Pine Island Glacier ice divide. Two Mount Johns ice cores (79°55′28″ S, 94°23′18″ W, 2100 m a.s.l.) were recovered in the austral summer of 2008/2009 (91.20 m depth) and 2015 (19.12 m depth). Trace element concentrations were determined using inductively coupled plasma mass spectrometry (CCI/UMaine). The results of enrichment factor and principal component analysis revealed that anthropogenic activities were likely important contributors to those trace element records. We find that Bi, Cd, Cr, and Pb emissions increased after 1884 reaching a maximum by 1900. Concentrations remained high until the late 1920s, with a temporary low during the Great Depression (1931) and again at the end of World War II (1948) when concentrations dropped to background levels. Concentrations increased after 1960 and remained high until the present. Concentrations during the early 21st century were lower than the peak of the 20th century concentrations but well above background levels.
Mercury in the Southern Ocean: Pathway from Primary Producers to Top Predators

José Seco¹ ² (jseco@ua.pt), João Pedro Coelho¹, José Carlos Xavier³ ⁴, Geraint Tarling⁴, Miguel Pardal⁵, Paco Bustamante⁶, Gabriele Stowasser⁶, Ryan A Saunders⁴, Sue Gregory⁴, Richard A Philips⁴, Andrew S Brierley⁶, Maria Eduarda Pereira¹

¹University of Aveiro, Centre for Environmental and Marine Studies, Aveiro, Portugal, ²University of St Andrews, Pelagic Ecology Research Group, St. Andrews, United Kingdom, ³University of Coimbra, Marine and Environmental Sciences Centre (MARE-UC), Coimbra, Portugal, ⁴British Antarctic Survey, Cambridge, United Kingdom, ⁵University of Coimbra, Center for Functional Ecology (CFE-UC), Coimbra, Portugal, ⁶Université La Rochelle, Centre de Recherche sur les Ecosystèmes Littoraux Anthropisés, La Rochelle Cedex, France

Although Antarctica is seen as the remote and pristine continent, the levels of contaminants in the Southern Ocean have increased significantly. Mercury is one of the pollutants that it's found in higher concentration than expected in Antarctic waters. With this study, we aim to better understand the concentration of mercury and its pathway along the Southern Ocean marine trophic web.

Samples were collected along several taxonomic groups from microalgae, crustacean, fish, cephalopods and top predators, between 2015 to 2017 on the Scotia Sea, one of the most productive areas of the Southern Ocean. Plankton and nekton were collected around South Georgia and South Orkneys. Predator samples were collected by colleagues in the islands.

This presentation will be focused in the path that mercury since it gets absorbed in the micro algae to the levels that it reaches in the long living top predators, using stable isotopes analyses as proxy for trophic level. Establishing the base levels of mercury in the Southern Ocean food web is crucial to better understand how this pollutant will may affect the Antarctic ecosystems.
OS-5b - The role of snow on sea ice for sea-ice parameter retrieval and variability
23.06.2018 11:00-12:30, B Jakobshorn

2106
Snow Depth and Sea Ice Thickness in the Antarctic

Ted Maksym¹ (tmaksym@whoi.edu), Ron Kwok², Katherine Leonard³,⁴, Jeffrey Mei³,⁵, Hanumant Singh⁶, Ernesto Trujillo⁷, Jeremy Wilkinson⁷, Guy Williams⁸
¹Woods Hole Oceanographic Institution, Woods Hole, United States, ²Jet Propulsion Laboratory, California Institute of Technology, Pasadena, United States, ³Swiss Federal Institute for Forest Snow and Landscape Research WSL, Lausanne, Switzerland, ⁴Univ of Colorado, Boulder, United States, ⁵Massachusetts Institute of Technology, Cambridge, United States, ⁶Northeastern University, Boston, United States, ⁷British Antarctic Survey, Cambridge, United Kingdom, ⁸University of Tasmania, Tasmania, Australia

Determining ice thickness distribution from satellites in the Antarctic is difficult in large part because of challenges with estimating the snow depth distribution. At present, current satellite ice thickness products cover a wide range of thickness estimates due to differences in how snow cover is treated. We present a comparison of NASA IceBridge snow depths and surface topography with in situ measurements of three-dimensional “layer-cakes” of surface topography, snow depth, and ice thickness for Antarctic sea ice in late spring. First, we present a method to extend sparse radar retrievals of snow depth across sea ice floes. Next, using relationships between snow freeboard, snow depth and ice thickness from the field data, we calculate ice thickness for IceBridge data in the Antarctic, with an estimate of the error. These results are compared to other methods for estimating these relationships. Consistent with prior analysis, these data suggest a significantly thicker sea ice cover in near coastal Antarctica than has been suggested from shipboard estimates of the broader pack.
Exploiting Digital Imagery for Snow Surface Retrieval on Sea Ice

Adam Steer1,2 (adam@synth3d.co), Petra Heil2,3, Jan Lieser1
1University of Tasmania, Hobart, Australia, 2Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia, 3Australian Antarctic Division, Hobart, Australia

We show how imagery from uncalibrated airborne cameras can be used to reconstruct the snow/air interface on Antarctic sea ice, using data collected on the SIPEX-II research voyage during austral spring 2012. Imagery collected by an airborne surveying package was used to develop a 3D surface model using a structure-from-motion approach. This model was validated using coincident airborne LiDAR and in situ observation of total freeboard. Our study demonstrates that equivalent surveys may be obtained using unmanned vehicles (drones) carrying only a camera and basic navigation equipment. Using this method, detailed floe-to-multifloe scale models of snow topography may be derived without logistically intensive airborne surveying programs. In turn, this allows for quick repeat surveys - simplifying the capture of a surface topography time series at any given field research site. It also allows for highly detailed analysis of relationships between surface features and how they evolve over time. Finally, we show how different surveying scenarios affect data quality and the ability to easily co-register surface models with other coincident datasets. We discuss how future surveys should be planned, which data need to be collected alongside the imagery used to generate 3D models, and where future development should be aimed at in terms of uncertainty computations and data quality assessment.
GPR for Rapid and Accurate Snow-thickness Measurements on Antarctic Sea Ice

Jan Lieser1,2 (jan.lieser@utas.edu.au), Andreas Pfaffhuber3, Christian Haas4,5
1University of Tasmania, Antarctic Climate & Ecosystems CRC, Hobart, Australia, 2University of Tasmania, Institute for Marine and Antarctic Studies, Hobart, Australia, 3NGI, Oslo, Norway, 4York University, Toronto, Canada, 5Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Bremerhaven, Germany

Snow thickness on sea ice is not known on the regional scales and to the accuracy required for climate analysis and to assess its significant role in the Earth’s cryosphere mass balance. The thickness of snow on sea ice is a largely under-sampled, but crucially important parameter when estimating sea-ice thickness from space-borne sensors. Traditional sampling methods comprise meter-stick measurements or snow probes, which yield highly accurate data but are sparse in space and time, whereas remote sensing data have the potential to cover large areas but exhibit large uncertainties. To increase the local data volume and to apply as an intermediate level for remote-sensing data validation, we present non-destructive ground-penetrating radar (GPR) snow-thickness data of remarkable accuracy (millimetre to centimetre) when compared to in-situ data. The semi-regional data collected during two Antarctic campaigns in late winter/early spring confirm the underestimation of snow thickness on sea ice using remote-sensing methods by roughly 30%. The radar wave propagation was found to be rather constant in snow (+/- 6%), supporting the applicability of GPR for regional snow thickness surveys of snow thicker than 10cm, which was the detection limit of the off-the-shelf GPR setup used in this study.
Vertical Snow Structures from Local to Regional Scale

Stefanie Arndt¹ (stefanie.arndt@awi.de), Nicolas Stoll¹,², Stephan Paul¹
¹Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Sea Ice Physics, Bremerhaven, Germany, ²University of Bremen, Institute of Geosciences, Bremen, Germany

Snow on sea ice alters the properties of the underlying ice cover as well as associated exchange processes at the interfaces between atmosphere, sea ice and ocean. As Antarctic snow cover persists during most of the year, it contributes significantly to the sea-ice mass budget due to comprehensive physical (seasonal) transition processes within the snowpack. It is therefore necessary to locate and quantify internal snowmelt, snow metamorphism, and snow-ice formation in the Antarctic snowpack on different spatial scales. Doing so, we present here in-situ observations of physical snow properties from point measurements and transect lines during recent expeditions in the Weddell Sea from 2013 to 2018, covering summer and winter conditions. Analysis of snow pit measurements on both small (< 100m) and floe-size (< 2km) scales reveal significant variations in the horizontal snowpack structure. In order to describe internal snow processes on regional scales, we grouped the observed snow conditions, differentiating for snow conditions between eastern (seasonal sea ice) and western Weddell Sea (perennial sea ice). While the thick perennial snowpack is highly metamorphous with a large number of internal layers, the seasonal snowpack is less stratified. Results of the study will improve our understanding on processes and interactions in the snowpack as well as at the snow/ice interface associated with seasonal and inter-annual variations in the sea-ice mass budget of the Southern Ocean.
Comparison of Winter Field Data to Ice Thickness from ALS, ASIRAS and CryoSat-2

Anja Rösel1 (anja.rosel@npolar.no), Jennifer A. King1, Henriette Skourup2, Sine Munk Hvidegaard3, Sebastian Gerland1, Gunnar Spreen3, Chris Polashenski4, Veit Helm5, Glen E. Liston6

1Norwegian Polar Institute, Research Department, Tromsø, Norway, 2DTU Space - National Space Institute, Lyngby, Denmark, 3University of Bremen, Inst. of Environmental Physics, Bremen, Germany, 4U.S. Army Cold Regions and Engineering Laboratory, Hanover, United States, 5Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, 6Colorado State University, Cooperative Institute for Research in the Atmosphere (CIRA), Fort Collins, United States

Current freeboard and associated sea-ice thickness retrievals from the SIRAL radar altimeter on the CryoSat-2 satellite rely on the premise that the return signal measured is from the ice surface. However, it has been indicated that where a thick, layered, wet, or saline snow cover is present this return may arise from somewhere within the snowpack rather than from the snow-ice interface. We present a case study for winter conditions in which co-located freeboard measurements from airborne laser scanner (ALS), the Airborne Synthetic Aperture and Interferometric Radar Altimeter System (ASIRAS) and CryoSat-2 are compared to ice thickness measurements from both helicopter-borne and ground based electromagnetic-sounding, and to point measurements of ice and snow properties. This case study was performed in the Arctic Ocean in April 2015 in the region north of Svalbard. This study adds to a body of evidence that documents the complexity of sea-ice freeboard retrievals from radar altimetry. It particularly highlights that radar penetration of the snow on sea ice can be low and variable even at temperatures as low as -15°C. While this knowledge can have far-reaching consequences for radar based sea-ice thickness and consequently total Arctic sea ice volume estimates, we can use this information to improve altimetry processing routines, reduce uncertainty assessments for freeboard retrievals, and thus increase the accuracy of derived ice thickness information.

Dual Frequency Airborne Radar Measurement for Potential Estimates of Snow Depth

Henriette Skourup¹ (hsk@space.dtu.dk), Alessandro Di Bella⁰, Sine Munk Hvidegaard¹, Nicolaj Hansen¹, Arne Vestergaard Olesen¹, Alex Coccia⁰, Rene Forsberg¹, Tânia Casal³, Malcolm Davidson³

¹Technical University of Denmark, National Space Institute, Kongens Lyngby, Denmark, ²MetaSensing, Noordwijk, Netherlands, ³European Space Agency/ESTEC, Noordwijk, Netherlands

Snow on sea ice is difficult to measure from space. As snow introduces one of the largest uncertainties in the error budget of the sea ice freeboard to thickness conversion, it is important to find a solution to obtain reliable Arctic wide snow depths. The ESA CryoSat-2 validation experiment (CryoVEx) 2016 airborne fall campaign was the first to fly combined Ka- and Ku-band radars on the same platform. Where the CryoVEx 2016 fall campaign was dedicated to the Greenland Ice Sheet a campaign in the spring 2017 was covering sea ice in different regions representing different sea ice types. The airborne instruments are the ESA Ku-band radar altimeter (ASIRAS), MetaSensing Ka-band radar altimeter (KAREN), together near-infrared Airborne Laser Scanner (ALS). Even though some studies has indicated that ASIRAS reflects from the air-snow surface and do not penetrate down to the snow-ice surface, as typically assumed by Ku-band radars in dry cold snow conditions, the waveform turns out to be more complex, and often show dual peaked waveforms, potentially reflecting from the air-snow and snow-ice surface. The Ka-band radar is expected to reflect from the air-snow surface. Both radars are tied together with the ALS observations of the air-snow surface. Here we present an analysis of waveforms from the Ka/Ku-band airborne radars in different sea ice regions, to investigate the potential for estimating snow depths in support of future dual-frequency satellite missions.
During 2015 and 2016 austral winters a lack of precipitation was observed in the north-eastern Antarctic Peninsula compared to previous years. This condition led to very negative mass balances in both glaciological years for Bahía del Diablo glacier. After 6 years of positive or near zero mass balances, -380 mm w. eq. (2016/17) and -605 mm w. eq. (2015/16) were determined, being the latter the highest loss registered for the whole series. Annual precipitation of ~100 mm water equivalent at sea level and ~300 mm water equivalent at 650 m a.s.l. were recorded for this both periods, which are both less than the mean for the previous 12 years of ~290 mm and ~510 mm respectively. The mass balance for Bahía del Diablo glacier has a very high negative correlation with the mean summer air temperature (MSAT) recorded by an automatic weather station nearby the glacier. During 2016 and 2017 summers the recorded values for MSAT were not between the warmest of the series and were not warm enough to be the main driver for the negative mass balances. Only the lack of precipitation was the main factor that led to the very low mass balance recorded.
We provide an overview of the development of glaciated area in the region from 45° to 56°S in South America over the last decade. With Cordillera Darwin, Gran Campo Nevado and the two Patagonia Ice Fields the region includes the major ice masses of the southern hemisphere outside the large polar ice sheets. Many of its glaciers are reported to retreat by large rates and contribute to sea level rise, however, mass balance measurements are sparse. We provide geodetic glacier mass balance measurements using InSAR products from the missions TanDEM-X and SRTM. Our database comprises digital elevation models from 2000 and 2011-2016 from which we derive surface elevation changes and convert results to mass changes. Our analysis provides glacier specific changes and hence leads to a better interpretation of on-going processes evoking the observed changes. Consistent methods also enable comparability of specific mass loss rates of the different sub-regions.
Sediment Records of Climate Variability from the Subantarctic Auckland Islands

Greer Gilmer1 (greer.gilmer@otago.ac.nz), Christopher M. Moy1, Jonathan E. Nichols2, Imogen M. Browne3, Lorelei Curtin4, Marcus J. Vandergoes5, Christopher H. F. Aebig1, Gary S. Wilson1
1University of Otago, Dunedin, New Zealand, 2Lamont-Doherty Earth Observatory of Columbia University, New York, United States, 3University of South Florida, Tampa, United States, 4Columbia University, New York, United States, 5GNS Science, Wellington, New Zealand

The Southern Hemisphere westerly winds (SHWW) are a fundamental component of global oceanic and atmospheric circulation, and play a primary role in regulating CO2 flux in the mid to high southern latitudes. Situated within the core of the SHWW, and with multiple protected fjord sub-basins, deep lakes, and peatlands, the New Zealand subantarctic Auckland Islands (50°S) are uniquely positioned for the development of high-resolution records of ocean and atmospheric change. We will present a record of SHWW variability using fjord sediment cores, supported by records from peatlands and lake cores, to create a multi-proxy and multi-site reconstruction of past climate change associated with the SHWW. Modern process and paleoclimate studies suggest that in lacustrine and fjord settings, mixing of the water column, and precipitation-driven erosion within catchments is linked to an increase in SHWW strength over the Auckland Islands. Between 13 and 9 ka, an overall increase in redox-sensitive elements in the fjord sediment cores and elevated n-alkane δD values from peatlands signal a combination of reduced SHWW strength and warmer atmospheric temperatures. Since 5.5 ka, we interpret declining n-alkane δD values to indicate enhanced SHWW flow. We will discuss these results within the context of other SHWW paleoclimate records including terrestrial records developed from southern South America and the South Island of New Zealand in order to evaluate SHWW change across the Pacific basin.
Multi Temporal Mass Balance of the NPI (1975-2016) & Links with Regional Climate

Ines Dussaillant¹² (ines.dussaillant@legos.obs-mip.fr), Etienne Berthier¹, Mariano Masiokas³, Vincent Favier², Fanny Brun²
¹LEGOS/OMP, Université de Toulouse, CNES, CNRS, IRD, Toulouse, France, ²IGE, Université Grenoble Alpes, CNRS, IRD, Grenoble, France, ³IANIGLA, CONICET, Mendoza, Argentina

The northern Patagonian Icefield (NPI) is the second largest ice mass in Patagonia (3740 km²). Several estimates of recent volume changes confirm an acceleration of ice loss in the last decades compared to the long term loss since the Little Ice Age. However, glacier-climate relationships are still poorly understood and the drivers of the accelerated mass wastage are still unclear. We will compare five digital elevation models of the Northern Patagonian Icefield (NPI) generated from the Shuttle Radar Topography Mission in 2000, SPOT5-HRS sensor for 2005 and 2012, SPOT6 and SPOT7 stereo-imagery for 2016, and earlier Chilean cartography for 1975, to assess multi-temporal mass balance changes of the 38 largest NPI glaciers. We will then analyze the glacier volume changes over these sub-periods together with climate trends observed from nearby stations and downscaled regional climate models. We will also compare the observed glacier changes with recent variations in the Antarctic Oscillation (AO) and the Pacific Decadal Oscillation (IPO), known to have an important role in modulating climate in Patagonia. Our study will improve our understanding of the climatic causes behind the recent glacier wastage in this region using up-to-date estimates of ice mass loss at the NPI.
Patagonian Surface Mass Balance Sensitivity to Regional Climatic Changes

Gabriela Collao-Barrios¹ (gabriela.collao@univ-grenoble-alpes.fr), Vincent Favier¹,², Fabien Gillet-Chaulet¹,², Hubert Gallée¹,², Xavier Fettweis³

¹Université Grenoble Alpes, IGE Institut des Géosciences de l’Environnement, Grenoble, France, ²CNRS, IGE Institut des Géosciences de l’Environnement, Grenoble, France, ³Université de Liège, Département de Géographie, Liège, Belgium

Patagonian icefields are the largest ice-covered regions in the Southern Hemisphere after Antarctica. They are under the influence of the westerlies coming from the southern Pacific Ocean. Estimations of total mass balance from different sources show the acceleration of mass losses over the last decades compared to the mean value since the Little Ice Age. In the global climate changes context, the causes of this accelerated waste are generally related to regional warming although there is still uncertainty in temperature and precipitation trends in Patagonia. Indeed, in this zone, the equilibrium line altitude (ELA) is located at an altitude that correspond to vast and flat plateaus. This characteristic makes the icefields surface mass balance (SMB) particularly sensitive to small shifts in the ELA. Here, we estimate the Patagonian Icefields SMB using the regional circulation model MAR forced with the Era-Interim reanalysis for the period 1979-2012. MAR is coupled with the surface model SISVAT that includes a snow surface module. We analyze the sensitivity of the SMB to atmospheric variables to assess the causes of glacier wastage. Particularly, we analyze the impact of temperature and moisture changes on the final SMB.
The Signature of Atmospheric Circulation Patterns in Antarctic Precipitation

Gareth Marshall¹ (gjma@bas.ac.uk), David Thompson², Michiel R. van den Broeke³
¹British Antarctic Survey, Cambridge, United Kingdom, ²Colorado State University, Fort Collins, United States, ³Institute for Marine and Atmospheric Research, Utrecht, Netherlands

We analyse the relationships between large-scale patterns of Southern Hemisphere climate variability and the detailed spatial structure of Antarctic precipitation. Linkages between the high spatial resolution (27 km) daily precipitation from the RACMO2 regional atmospheric model and four patterns of large-scale Southern Hemisphere climate variability are examined: these are the southern baroclinic annular mode (BAM), the southern annular mode (SAM), and the two Pacific-South American (PSA) teleconnection patterns. We find that variations in all four patterns influence the spatial configuration of precipitation across Antarctica, consistent with their signatures in high-latitude meridional moisture fluxes. They impact not only the mean but also the incidence of extreme precipitation events. In addition, seasonal trends in some of the circulation patterns have contributed significantly to precipitation trends in areas of the continent: for example, the SAM on the opposing wetting and drying trends on the western and eastern sides of the Antarctic Peninsula. Although current coupled-climate models are able to reproduce all four patterns of atmospheric variability, they often struggle to correctly replicate their regional impacts on Antarctic climate. Thus, linking these patterns directly to Antarctic precipitation variability may allow a better estimate of future changes in precipitation than using model output alone.
Atmospheric Response to Marginal-ice-Zone Drag Parameterisation

Ian Renfrew1 (i.renfrew@uea.ac.uk), Andy Elvidge2,3, John Edwards3
1University of East Anglia, School of Environmental Sciences, Norwich, United Kingdom, 2University of East Anglia, Norwich, United Kingdom, 3Met Office, Exeter, United Kingdom

A physically-based parameterization of atmospheric surface drag over the marginal-ice-zone (MIZ) has recently been validated and tuned based on a large set of observations of surface stress from the Barents Sea and Fram Strait. This parameterization has now been implemented in the Met Office Unified Model (MetUM) and is available for both weather and climate applications. Here we present model simulations of a collection of cold-air outbreak cases in the vicinity of the MIZ from the ‘ACCACIA’ field campaign, and for a standard global model test suite of cases. Our focus is on the response of the atmosphere to changes in surface drag. The new parameterization has a significant impact on simulated boundary layer conditions; for example changing temperatures by 2-3 K. Comparisons with aircraft observations over and downwind of the MIZ show that simulations with the new sea-ice drag scheme generally have the lowest bias and lowest root-mean-square errors. Notably the wind speed and temperature biases are reduced to less than 0.1 m s\(^{-1}\) and 0.1 K respectively. The atmospheric response is relatively widespread - impacting most of the Arctic and Antarctic sea-ice areas - with the largest changes in the vicinity of the MIZ and affecting the entire atmospheric boundary layer.
Wind Stress Forcing in the Arctic and North Atlantic Oceans

Tamas Kovacs\textsuperscript{1,2} (tamas.kovacs@awi.de), Rüdiger Gerdes\textsuperscript{1,2}
\textsuperscript{1}Alfred Wegener Institute, Bremerhaven, Germany, \textsuperscript{2}Jacobs University, Bremen, Germany

One of the key processes responsible for driving the circulation of ocean waters is the wind stress. This important air-sea interaction stands for the imparting of atmospheric momentum to the ocean. The prevailing wind patterns largely influence the velocity in the top Ekman layer in the ocean, sustaining the observed system of surface currents. Given the internal variability of the wind climate, these surface currents are subject to anomalies in space and time that can have large scale effects on oceanic processes.

This is particularly true in the Arctic and the subpolar North Atlantic oceans that play a key role in the global ocean circulation, and are influenced by variations of wind stress forcing associated with large scale atmospheric modes in these regions.

In this study we examine the sensitivity of surface currents, ice cover, freshwater and heat content in these ocean basins to wind stress forcing through numerical experiments. The tool for this is the Modini-system, a partial coupling technique that allows flexible experiments with prescribed wind stress fields for the ocean in the otherwise fully coupled Earth System Model of the Max Planck Institute. In this work we present our results investigating the role of wind stress forcing in shaping the distribution and exchanges of state variables in and between the Arctic and North Atlantic oceans by comparing our model results using external wind stress forcing with the Modini-system, and fully coupled runs.
Polar lows (PLs) are intense mesoscale cyclones (diameter of 200-600 km) that form at high latitudes during winter. Their wind speeds (above 15 m.s\(^{-1}\)) can substantially impact on and offshore activities. A previous ocean model study, where 238 PLs/month were parameterized in the surface forcing over the north-east Atlantic Ocean, indicated that the wind speeds and heat fluxes associated with PLs may have a strong impact on deep-water formation in the Nordic Seas and increase the Atlantic Meridional Overturning Circulation. To explicitly investigate this possible link, we use the 98-year high-resolution simulations (present day forcings) from the MetOffice HadGEM3-GC2 coupled climate model (horizontal resolution of 25 km in the atmosphere and 0.25° in the ocean). We first track and identify PLs in the model over the Nordic Seas. HadGEM-GC2 shows a similar representation of PLs compared to observations and reanalyses, with a mean of 2.75 PLs/month compared to 2.25 PLs/month from the CFSR reanalysis and with no obvious inter-annual or seasonal pattern or trend. A clear link is found between PLs and surface heat fluxes: the higher the PL numbers the higher the heat fluxes. However, this relationship is too weak (mean increase of +15 W.m\(^{-2}\) for high PL numbers years) to impact the ocean circulation. Subsequently, almost no correlation occurs between PL numbers and the ocean density, suggesting that the previously hypothesized mechanism is not found in HadGEM3-GC2.
Recent Regional Variabilities Reflected in Kongsfjorden: An IndARC Perspective

Divya David T1 (divyadavidt@gmail.com), Subeesh M. P2, Renjith V. R3, Ravichandran M2, Anil Kumar N2
1ESSO-National Centre for Antarctic and Ocean Research, Goa, India, 2ESSO-National Centre for Antarctic & Ocean Research, Goa, India, 3Indian Institute of Technology Mumbai, Mumbai, India

The time series IndARC multisensor subsurface mooring data from July 2014 to July 2017 and the summer-fall CTD profiles collected in a biweekly interval at Kongsfjorden (an open fjord on the north-west coast of Spitsbergen in the Svalbard archipelago with its mouth located at 79 °N and 11 °E exhibiting a sub Arctic nature) had been analyzed along with the atmospheric observations, reanalysis, model and remote sensing datasets to delineate the regional variabilities captured and to understand the dynamics. The temperature, salinity, dissolved oxygen; photosynthetically active radiation, fluorescence; turbidity and nitrate were recorded at an hourly interval while the currents at half an hour interval at defined depths below 20 meters in the mooring line. The interannual as well as intraseasonal atmospheric-fjord processes, Atlantic water intrusions, glacial melt and the interactions during the observational period had been studied in detail. Besides the prominent intraseasonal variability on a biweekly scale that was found driven by the local winds, the physical and biochemical processes showed a strong coupling even at higher frequencies as evident from the high resolution data. The present study could be considered as substantiation that showed that the regional variabilities were quite well captured in the fjord system which makes it a hotspot to conduct the climate scale regional studies.
Foehn winds generated by westerly flow across the Antarctic Peninsula have a dominant influence on the climate and surface energy balance over Larsen C Ice Shelf. Satellite observations have shown that the greatest annual ice shelf melt is found in inlets prone to the strongest foehn winds (foehn jets). However, this pattern is not reproduced in single-case numerical model experiments.

High resolution Met Office Unified Model experiments have been conducted covering two recent 6-month periods; the melt seasons of 2014-15 and 15-16. The model output is validated against new observations from an automatic weather station located in one of the major inlets. The combination of ideally-located surface observations and the extended-period simulations afford the first comprehensive characterisation of air-ice interactions in Larsen inlets.

The range of conditions - both foehn and non-foehn - responsible for leeside warming and inlet ice melt are evaluated. The variability in surface fluxes in the immediate lee of the Peninsula is examined, with links drawn to the orographically forced flow dynamics; in particular the jet/wake foehn structure. The net energy available for melt is revealed to be governed by the two large and opposite-signed surface turbulent heat fluxes (downward sensible and upward latent), the balance of which varies diurnally and spatially. Successful prediction of leeside melt is contingent on the model’s ability to correctly reproduce this delicate balance.
The response of the climate system to Drake Passage (DP) closure is examined using a coupled ocean-atmosphere-ice model. Upon DP closure the initial response is consistent with previous ocean-only studies, with an invigoration of Antarctic overturning and a collapse of North Atlantic Deep Water (NADW) production. This results in a dominance of southward heat transport and Antarctic sinking when DP is closed. However, within just a decade, the increased southward heat transport has melted back much of Antarctic sea-ice and weakened the subpolar westerlies. These effects, not captured in models without ice-atmosphere feedbacks, combine to force Antarctic Bottom Water to warm and freshen, to the point that this water mass becomes less dense than NADW. This leads to a contraction of Antarctic overturning, allowing NADW to ventilate the deep ocean once more. Poleward heat transport also settles back to values very similar to the unperturbed DP open case. Yet remarkably the equilibrium climate retains a strong Southern Hemisphere warming. Here it is ocean-atmosphere-ice feedbacks, particularly the sea-ice albedo feedback, not southern sinking, that maintain the warm polar oceans when DP is closed. We further find that DP closure leads to warming that is sufficient to inhibit ice sheet growth over West Antarctica. This highlights the importance of the DP gap, Antarctic sea-ice and the associated ice-albedo feedback in maintaining the present-day glacial state over Antarctica.
The Magmatic Evolution of the Antarctic Peninsula Crustal Block

Joaquin Bastias1 (j.bastias.silva@gmail.com), Richard Spikings1, Alexey Ulianov2, Anne Grunow3, Teal Riley4, Alex Burton-Johnson4, Urs Schaltegger1, Francisco Hervé5

1University of Geneva, Earth Science Department, Genève, Switzerland, 2University of Lausanne, Institute of Earth Sciences, Lausanne, Switzerland, 3Ohio State University, Byrd Polar and Climate Research Center, Columbus, United States, 4British Antarctic Survey, Cambridge, United Kingdom, 5Universidad de Chile, Departamento de Geología, Santiago, Chile

The interpretation of the Eastern Palmer Land Shear Zone as a suture between an autochthonous gondwanan block with an allochthonous arc that collided at ca. 105 Ma, (Vaughan and Storey, 2000) contradicts the former interpretation that the arc products of the Antarctic Peninsula were an in-situ record of the ‘Andean’ subduction during the Mesozoic and part of the Cenozoic (Suarez, 1976). In the last two decades it has been published new dataset that have argued against the consistency of the ‘accretionary model’ (e.g. Burton-Johnson and Riley, 2015). However, a dense framework of data is required to tackle such a regional-scale problematic.

We present a new dataset of geochronology, isotopic tracing and geochemical studies of the Antarctic Peninsula Batholith and the Antarctic Peninsula Volcanic Group; in localities that are spread over 1000 km. We have collected over 100 U-Pb zircon ages, 40 Ar/Ar ages in groundmass and biotite, which are combined with isotopic tracing of Sr-Nd-Pb in whole-rock and Hf in zircons. These results are also compared with the previous works conducted in the region.

The South Georgia microcontinent (SGM) is an allochthonous block from south-east Tierra del Fuego that has been transported over the past 80-100 My as part of Scotia Plate (SP) development. While its trajectory is poorly constrained, SGM is now located on the east end of the North Scotia Ridge (NSR) approximately 1600 km east of its original position. West of SGM, NSR forms the South America plate (SAP) - SP boundary. Based on Scotia Arc bathymetric morphology and geological history, SGM has been considered part of the SP, with the plate boundary along its northern side. SGM seismic activity, while very low, is concentrated along its southern border and interpreted, based on a few small thrust mechanisms, to represent underthrusting and uplift of South Georgia Island on an NSR restraining bend on the north-eastern margin of SGM. More recently, also based on this seismicity, the plate boundary has been placed on SGM’s south side, suggesting SGM has, or is being, transferred to SAP. We report on marine seismic reflection surveys north and south of the island, and results from a 4 station continuous GPS network on the island, to determine the block’s current tectonic affinity with respect to the SAP and SP, and examine SGM for internal deformation. We will present preliminary geodetic results, based on 3 years of continuous GPS data indicating SGM motion and deformation, and multi-channel seismic reflection profiles across the margins of SGM showing indications of compression.
The Scotia Arc was formed by the eastwards migration and dispersion of the continental fragments that connected South America and the Antarctic Peninsula. In this process the Drake Passage constituted a narrow gateway that facilitates the eastward flow of the mantle from the Pacific towards the Atlantic. Tierra del Fuego, northwards of Drake Passage, is a key area to study the effect in the upper mantle of this major tectonic event. 18 long period magnetotelluric sites were recorded along 2 profiles using LEMI-417 stations the 3 magnetic and 2 telluric field components in the frequency range of 4 Hz to investigate the deep crustal and upper mantle conductivity. Standard robust processing was performed yielding high quality transfer functions. The interpretation of phase tensor invariants and tipper vectors was undertaken by 3D anisotropic modeling using the Frankfurt group software based on Comsol Multiphysics 5.2™. GEBCO database was considered to take into account the effect of surrounding seawater. A main NW-SE oriented anisotropy is determined in the upper mantle. This anisotropy may be consequence of former mantle anisotropies parallel to the Andes Cordillera rotated during the development of the northern branch of the Scotia Arc. However, the most suitable interpretation suggests that this remarkable anisotropy may be related to the eastwards mantle flow across the Drake Passage during the development of the Scotia Arc.
Magnetic Anomalies in Ona Basin: Early Seafloor Spreading in Drake Passage

Jesus Galindo-Zaldivar\textsuperscript{1} (jgalindo@ugr.es), Anatoly Schreyder\textsuperscript{2}, Fernando Bohoyo\textsuperscript{3}, Yasmina M. Martos\textsuperscript{4}, Andres Maldonado\textsuperscript{5}

\textsuperscript{1}IACT (CSIC-UGR), Dpto. Geodinamica, Universidad de Granada, Granada, Spain, \textsuperscript{2}Russian Academy of Sciences/P.P. Shirshov Institute of Oceanology/, Moscow, Russian Federation, \textsuperscript{3}Instituto Geológico y Minero de España, Madrid, Spain, \textsuperscript{4}NASA Goddard Space Flight Center, Planetary Magnetospheres Laboratory, Greenbelt, United States, \textsuperscript{5}IACT (CSIC- Universidad de Granada), Granada, Spain

Opening of the Drake Passage and Scotia Sea since the Eocene/Early Oligocene constitutes one of the most relevant tectonic events that determined the instauration of the Antarctic Circumpolar Current. Ona Basin, in the southwestern Scotia Sea, included two sectors of NW-SE linear magnetic anomalies that evidence the early stages of oceanic spreading. The western sector, near the corner of Shackleton Fracture Zone, included 3 sequences of N120\degree E trending linear anomalies characterized by amplitudes from 80 to 170 nT and 15-30 km wavelengths. They are interrupted by two orthogonal fractures zones. The best fitting of measured and theoretical profiles suggest a correspondence with A9-A16. Spreading process started near the time of chron C16n.1r (35.892-36.051 my) and ceased in time of chron C9r (27.439-27.859 my). Average spreading velocity is about 0.8 cm/ yr. Moreover, in the eastern Ona Basin, bounded by the Terror Rise, N130\degree E linear magnetic anomalies of 50-100 nT amplitudes and 20-50 km wavelength, affected by one transform fault, are possible related to anomalies A18-A20. Spreading process started near the time of chron C20n (42.301-43.432 my) and ceased in time of chron C18n.1r (39.627-39.698 my). Average spreading velocity is no more than 1.7 cm/ yr. These sets of anomalies are oblique to more recent NE-SW linear anomalies related to the younger spreading of the West Scotia Ridge.
The Characteristic of Geophysical Fields around the Prydz Bay, Antarctica

Liu Chenguang¹, Zheng Yanpeng¹, Gao Jinyao² (jygao@mail.hz.zj.cn)
¹The First Institute of Oceanography, SOA, Qingdao, China, ²The Second Institute of Oceanography, SOA, Hangzhou, China

During 2011~2017, geophysical survey was carried out around Prydz Bay under the project of Chinese National Antarctica Research Expedition. More than 30000km marine gravity data, as well as magnetic data, has been collected by R/V XUELONG. In addition, 5 sites of OBS data has been obtained. The characteristic of gravity and magnetic fields, the thickness and anisotropy of crust can be discussed.
Seafloor Spreading Process in the Cosmonauts Sea, off East Antarctica

Tomoko Hanyu\(^1\) (hanyuu.tomoko@nipr.ac.jp), Yoshifumi Nogi\(^{1,2}\), Masakazu Fujii\(^{1,2}\)
\(^1\)Graduate University for Advanced Studies, Department of Polar Science, Tokyo, Japan, \(^2\)National Institute of Polar Research, Geoscience Group, Tokyo, Japan

The Cosmonauts Sea in the western Enderby Basin, off East Antarctica, had been formed as a result of opening between Antarctica and Sri Lanka/India/Madagascar. The seafloor spreading history of this region is still poorly understood because of sparse marine geophysical data. No obvious magnetic anomaly lineations are observed in a Japanese/German aero geophysical survey of the N-S observation lines, and this area is considered to be created by seafloor spreading during the Cretaceous Normal Superchron. We carried out systematic vector geomagnetic survey including the SE-NW oriented four track lines in the Cosmonauts Sea using the Japanese icebreaker Shirase during the 54th Japanese Antarctic Research Expedition (JARE). We analyzed these data combined with previous data obtained in other JARE cruises.

The isochrons M10N-M3n with the almost NW-SE spreading direction were newly identified with several small segments in the south of the Cosmonauts Sea. The wide-spreading continental ocean transition zone was inferred by the magnetic boundary strikes, as well as satellite gravity data. The transition of seafloor spreading direction was observed at 65°S seafloor, which likely formed during chron M3n-M0r. It suggests that NNE-SSW oriented seafloor spreading started since the chron M0 in the north of the Cosmonauts Sea. We will show clear magnetic anomalies related seafloor spreading in the Cosmonaut Sea and present initial breakup process between Sri Lanka/India and Antarctica.
EN-5 - Big data, small data, your data. What does good data management mean to you?

What Polar Data Do you Need, and how Would you Like to Access and Use Them?

Julie Friddell¹, Gabrielle Alix¹ (gabrielle.alix@uwaterloo.ca), David Friddell¹, Chantel Ridsdale¹, Kishor Sudarshanakumar¹

¹Polar Data Catalogue, University of Waterloo, Canadian Cryospheric Information Network, Dept. of Geography and Environmental Management, Waterloo, Canada

Using examples from Canada’s polar research and data community and the Polar Data Catalogue, this presentation will highlight a selection of users’ evolving expectations regarding polar data and some of the challenges to making curated data collections truly accessible and usable. We will describe issues with providing efficient access to datasets resulting from disparate collection and recording methods, designing a friendly user interface for both novice and advanced users, providing streamlined access to complex datasets containing Terabytes of files, protecting sensitive data, and other examples. We will provide an opportunity for direct feedback from the audience on functions and interfaces which serve the needs of the polar research community and other targeted users.

The Polar Data Catalogue (PDC, https://polardata.ca) is one of Canada’s primary online sources for data and information about the Arctic and Antarctica. With over 2,500 metadata descriptions of projects and datasets and almost 3 million data files, the PDC contains data on physical, social, and health science and other research in Canada and globally, including significant collections from the ArcticNet Network of Centres of Excellence, the International Polar Year, satellite imagery from the RADARSAT-1 and RADARSAT-2 missions, and hundreds of metadata from the Circumpolar Biodiversity Monitoring Programme. The PDC is a member of the World Data System and is Canada’s National Antarctic Data Centre.
Mapping Information Landscape in the Context of Disaster Diplomacy in the Arctic

Yekaterina Kontar¹² (yekaterina.kontar@tufts.edu), Peter Pulsifer³, Paul Berkman¹²
¹Tufts University, The Fletcher School of Law and Diplomacy, Medford, United States, ²Tufts University, Science Diplomacy Center, Medford, United States, ³National Snow and Ice Data Center (NSIDC), Boulder, United States

Disaster resilience is a common interest and goal throughout the Arctic region. Building resilience foremost requires a thorough understanding of the physical and social processes behind the key components of disasters - hazards, risks, and vulnerability. This requires collaborations among disaster experts, including practitioners, natural and social scientists, and local knowledge holders. Expert collaborations across the Arctic nations significantly expand the data and knowledge pools. Disaster diplomacy encourages and facilitates such collaborations. To inform decision-making, produced data needs to be readily available to the policymakers in a useable to them format. By developing a disaster-relevant information e-cosystem model we were able to map relevant information flow and identify gaps in it. The ecosystem metaphor allowed us to identify key data sources (e.g. scientific projects and data centers) and information users (e.g. policymakers, emergency managers, and communities at risk) in the field of Arctic disasters, and map the flow of information between them. The corpus analyzed as a foundation for the model included assessments and reports published by the working groups of the Arctic Council - an intergovernmental forum that promotes cooperation among the Arctic States and indigenous communities on issues of sustainable development. Lessons learned from this analysis will be beneficial to other pan-Arctic collaborations that depended on data sharing.
Data Management for Model Output: What Are the Issues?

Stuart Corney¹, Jess Melbourne-Thomas¹², Rowan Trebilco¹ (rowan.trebilco@utas.edu.au), Michael Sumner¹², Andrew Constable¹²

¹Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia, ²Australian Antarctic Division, Hobart, Australia

Procedures around data deposition and access for observational data that relate to marine and Antarctic environments are now fairly well established. However, despite an increasing expectation that model output will be generally available as part of publication of scientific research, the corresponding procedures relating to model output are yet to be clearly defined. Data repositories allow for permanent storage and curation of data/model output while also encouraging increased re-use by the general community. This is beneficial for observations, which are bound to a fixed time and place, but how well does this system work for model output?

In this presentation, we will discuss a number of scenarios involving the cataloguing of model output. Specific issues raised include

- Ensuring model currency: what happens to my output when I update my model?
- Does model output have a half-life?
- My model is global, but my study is regional. Should model output outside of the original study region be archived?
- Models are a representation of a system, based on certain assumptions, defined to answer specific questions. What are my responsibilities to ensure future users understand these restrictions upon the output?
- Model output or modelling environment? When should I archive just the output, and when is a code repository or virtual machine the better choice?
Developing an Environmental Data Portal: Characteristics and Design Principles

Ionut Iosifescu Enescu¹ (ionut.iostescu@wsl.ch), Gian-Kasper Plattner¹, Lucia Espona Pernas¹, Michael Lehning²,³, Konrad Steffen¹,³,⁴

¹Swiss Federal Research Institute WSL, Birmensdorf, Switzerland, ²WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland, ³EPFL, Lausanne, Switzerland, ⁴ETH Zurich, Zurich, Switzerland

The Swiss Federal Research Institute WSL is developing EnviDat, an overarching environmental data portal for facilitating the management, search and access to its rich data reservoir. EnviDat is designed to publish, connect and search existing data, while data curation and quality control remain with the experts. The current EnviDat Beta version provides access to several polar data sets such as the high resolution sea ice surface topography from the SIPEX-2 expedition, East Antarctica, 2012 (www.envidat.ch/dataset/10-16904-9). More polar and high-altitude research data will be incorporated into EnviDat, including the Greenland Climate Network (GC-Net).

The EnviDat design principles focus on usability and user-friendliness, with easy search and find, availability of relevant data filters, and ideally one click access to the data source. The portal’s functional requirements include metadata and map search, the publishing of datasets with DOIs, and the provision of a data repository. Non-functional requirements such as reliability, security and maintainability are taken into account through a multi-server architecture. Moreover, the interoperability with the wider data management community is achieved by leveraging community software such as CKAN and by adopting best practices in data sharing.

Based on the above characteristics and design principles, EnviDat represents an important WSL initiative dedicated to addressing the challenges related to data sharing with the community.
Unprecedented changes on climate and environment have been observed in the three poles, including Arctica, Antarctica and the Tibetan plateau (the so-called Third Pole). The three poles are relatively data-scarce regions due to the data accessibility and hard living environment though numerous earth observation data have been collected. And consequences of these changes on global environment and human being remain poorly known.

To address these challenges, there is an urgent need for better data acquisition, integration, curation, and service, and use these data to better support fundamental scientific research and sustainable development for the three poles.

The CASEarth Poles, a project within the framework of “Big Earth Data Science and Engineering” program of Chinese Academy of Sciences, aims to construct a comprehensive big data platform of the three poles. This project will devote to: (1) breaking the bottleneck of polar data integration, curation, and sharing, (2) developing high resolution remote sensing products over the three poles, (3) generating atmospheric reanalysis datasets for polar regions, (4) exploring synchronization, asynchronization, and teleconnection of environmental changes in the three poles, (5) investigating the dynamics of climate, water cycle, and ecosystem, and interactions among multi-spheres in polar regions and their effects globally, (6) supporting the decision-making on sea ice forecast, polar development and governance.
Southern Ocean Data Sharing Tools in a Global Data Management Community

Pip Bricher1 (data@soos.aq), Steve Diggins2, Joana Beja3, Alicia Aleman4, Mathieu Belbeoch5, Taco de Bruin6, Kenneth Casey7, James Cusick8, Bruno Danis9, Florence Fetterer10, Alexander Kozyr11, Wu Lizong12, Benjamin Pfeil13, Roger Proctor14, Petra Ten Hoopen15, Anton P. Van de Putte8

1Southern Ocean Observing System, University of Tasmania, Battery Point, Australia, 2Scripps Institution of Oceanography, San Diego, United States, 3British Oceanographic Data Centre, Liverpool, United Kingdom, 4NASA HQ, Baltimore, United States, 5JCOMMOPS, Brest, France, 6Taco.De.Bruin@nioz.nl, Texel, Netherlands, 7National Centers for Environmental Information, Baltimore, United States, 8Australian Antarctic Division, Kingston, Australia, 9Royal Belgian Institute for Natural Sciences, Brussels, Belgium, 10National Snow and Ice Data Center, Boulder, United States, 11National Centers for Environmental Information, Knoxville, United States, 12Polar Research Institute of China, Hangzhou, China, 13Bjerknes Centre for Climate Research, Bergen, Norway, 14Integrated Marine Observing System, Hobart, Australia, 15British Antarctic Survey, Cambridge, United Kingdom

The Southern Ocean Observing System (SOOS) bridges many divides - among communities, scientific disciplines, National Antarctic Programs, logistics personnel, and scientists. Each of these groups has a history of data sharing through online systems that have been built up to meet their needs through decades of negotiation and effort. Data management for this disparate community must build on the existing data sharing infrastructure and behavioral norms of its constituent groups.

To support the SOOS 20-year vision, the SOOS Data Management Sub-Committee is tasked with developing an integrated data management system to collect the marine observing datasets from around Antarctica, document them, make them discoverable, accessible, and compile them into composite datasets that can be fed into circumpolar models. This is a task that is well beyond the capacity of any small group of data managers to implement and one that can only be fulfilled by working within a global ecosystem of data integration efforts.

In this presentation, we will describe the new tools that SOOS has developed to date and the community relationships through which we hope to accomplish this vision.
Diseases Threatening Polar Seabirds: From Immuno-ecology to Conservation

Amandine Gamble¹ (amandine.gamble@cefe.cnrs.fr), Romain Garnier², Jérémy Tornos¹, Raül Ramos³, Thierry Boulinier¹

¹CEFE, CNRS - Université Montpellier, Montpellier, France, ²University of Cambridge, Department of Veterinary Medicine, Cambridge, United Kingdom, ³Universitat de Barcelona, Departament de Biologia Evolutiva, Barcelona, Spain

Infectious diseases are a relatively neglected but potentially important threat to wild populations, especially in polar areas where global changes may facilitate the introduction of new parasites. In addition, the life histories of seabirds, combining long lifespan and high site fidelity, raises the possibility that their immune system may have evolved special features to protect them against potential recurrent exposure to parasites at the breeding site. This is notably the case for species breeding in dense aggregations which can be subject to recurrent epizootics, as observed in Arctic and Subantarctic populations of seabirds hit by avian cholera. In this context, we combined observational and experimental data to undertake basic immune-ecological investigations that led us to some original findings with potential implications for conservation. Our results, obtained in collaboration with several groups of biologists in Arctic and Subantarctic, particularly highlight the dynamics of Lyme disease *Borrelia* in Arctic and Antarctic seabird colonies and of avian cholera in an albatross colony. They also stress that the persistence of maternally inherited immunity varies between seabird species, being especially long in Procellariiforms. These results thus open some promising venue for the use of vaccination in the wild in some critical situations.
From “-omics” to Behavior of Reproduction in a Top Antarctic Predator

Michelle Shero¹ (mrshero@alaska.edu), Gregg Adams², Robert McCorkell³, Amy Kirkham¹, Kimberly Goetz⁴, Daniel Costa⁵, Jennifer Burns¹

¹University of Alaska Anchorage, Biological Sciences, Anchorage, United States, ²University of Saskatchewan, Western College of Veterinary Medicine, Saskatoon, Canada, ³University of Calgary, Faculty of Veterinary Medicine, Calgary, Canada, ⁴National Institute of Water and Atmospheric Research (NIWA), Wellington, New Zealand, ⁵University of California Santa Cruz, Ecology & Evolutionary Biology, Santa Cruz, United States

From 2010-2017, we used a suite of molecular, physiological, and behavioral tools to study factors influencing reproduction in adult female Weddell seals (Leptonychotes weddellii; n=291) in Erebus Bay, Antarctica. Metabolomics approaches were used to determine biochemical pathways critical to establishing a successful pregnancy, and were paired with early pregnancy diagnosis via ultrasound (embryos ≥3mm diameter). Pregnancy rates were high (82%), yet Weddell seals are known to have low birth rates (65%) relative to other pinnipeds. Energy balance in late gestation is likely important to carrying the embryo to term. Indeed, constructed embryo growth curves revealed that Weddell seals have a protracted placental gestation (~10.5 months), which would spread the energetic costs of pregnancy over a longer timeframe. Remarkably, neither mass nor body condition influenced the probability of embryo loss or pupping. However, increased foraging effort (dive duration, depth, exceeding aerobic capacities) across gestation influenced the probability of pupping the next year. Despite intense foraging, Weddell seals exhibited low rates of energy acquisition, gaining only 15% of the mass and lipid stores typically acquired by other phocid seal species during gestation. In combination, this integrative approach suggests that the Weddell seal’s life history has been shaped by energetic constraints, and may also make this top predator particularly vulnerable to environmental perturbations.
2049
Detecting and Mitigating Health Threats to Muskoxen in a Changing Arctic

Susan Kutz1 (skutz@ucalgary.ca), Sylvia Checkley1, Chimone Dalton1, Tracy Davison2, Juliette DiFrancesco1, Taya Forde3, Craig Gerlach1, Wendy Hutchins1, Pratap Kafle1, Lisa-Marie Leclerc4, Fabien Mavrot1, Matilde Tomaselli1, Frank van der Meer1, Katherine Wynne-Edwards1

1University of Calgary, Calgary, Canada, 2Government of Northwest Territories, Inuvik, Canada, 3University of Glasgow, Glasgow, United Kingdom, 4Government of Nunavut, Kugluktuk, Canada

Rapid climate change in the arctic is posing increasing threats to wildlife health and sustainability, and by extension, the health and socio-economic well-being of northern communities. During the past decade, muskoxen, which are integral to the culture, food system and economy of communities in many parts of the Arctic, are experiencing widespread disease, mortality, and regional population declines. This has resulted in significant concerns about muskox health and sustainability as well as the food safety and security for local people. We are using a combination of scientific, traditional, and local knowledge to evaluate and monitor the health and vulnerability of muskoxen in a rapidly changing Arctic. Specifically, we are
(i) determining the current health status of muskoxen in parts of the Inuvialuit and Kitikmeot regions, Canada,
(ii) investigating the ecology and drivers of three emerging parasitic, bacterial, and viral diseases,
(iii) developing indicators of health to incorporate into muskox monitoring programs.

Our goal is to establish and implement an integrative and responsive muskox health surveillance system that can pro-actively inform wildlife management, public health, and land-use policy. Tools, techniques, and programs developed will lead to improved technical and human resources for health monitoring not only of muskoxen, but other arctic wildlife, and will contribute to conservation and improved food safety and security across the North.
Plasticity of Female Humpback Whale Fertility to Variable Nutritional Condition

Greta Dalle Luche1 (greta.dalleluche@griffithuni.edu.au), Ashley Boggs2, John Kucklick2, Susan Bengtson Nash1

1Griffith University, Environmental Future Research Institute (EFRI), Brisbane, Australia, 2National Institute of Standards and Technology (NIST), Hollings Marine Laboratory, Charleston, United States

The southern hemisphere humpback whale (HW), Megaptera novaenangliae, have evolved to optimise energy intake and expenditure by breeding at equatorial latitudes in winter, and feeding on Antarctic krill in summer. During their migration journey, pregnant HW give birth and nurse a single calf, only relying on their previously accumulated fat. The recording of HW vocalisation in Antarctica, and an observation of a 2.4 male to female gender ratio among migrating individuals has led to the hypothesis that not all females engage in the migration annually. As the mating also takes place during the migration, it is plausible that a number of females would not participate back out of the migration and incorporate one or more years of rest between pregnancies to replenish their energy reserves. Accordingly, the female inter-calving period may vary as a function of summer feeding conditions.

This work combines blubber steroid hormonal profiles with histological measurements of the adipocytes of 36 free-roaming, migrating female HW to test the expectation that the individual's reproductive state and nutritional condition correlate. Reproductive state is assessed by liquid chromatography tandem mass spectrometry (LC-MS/MS) measurement of testosterone, androstenedione and progesterone from remotely collected biopsies. This work contributes new knowledge regarding HW reproductive habits, and provides insight into the resilience of female fertility to years of variable krill availability.
Factors Determining the Gastrointestinal Microbiota in Chinstrap Penguin Chicks

Andres Barbosa1 (barbosa@mncn.csic.es), Vanessa Balague2, Francisco Valera3, Ana Martinez4, Jesus Benzal3, Miguel Motas5, Julia I. Diaz6, Carlos Pedros-Alio7

1Museo Nacional de Ciencias Naturales, CSIC, Ecologia Evolutiva, Madrid, Spain, 2Institut de Ciencies del Mar, CSIC, Barcelona, Spain, 3Estacion Experimental de Zonas Aridas, CSIC, Almeria, Spain, 4Instituto Investigaciones en Materiales, UNAM, Mexico DF, Mexico, 5Facultad de Veterinaria, Universidad de Murcia, Murcia, Spain, 6Centro de Estudios Parasitologicos y de Vectores, CONICET, La Plata, Argentina, 7Centro Nacional de Biotecnología CNB-CSIC, Madrid, Spain

The gastrointestinal microbiota is composed by a complex community which depends of different factors, external/ internal and environmental/genetics. We carried out a cross-fostering experiment in nesting chinstrap penguins. In experimental nests one of the chicks was exchanged at seven days old with a chick from another nest with the same hatching date. In control nests, chicks were briefly removed and put back in the nest again. After twenty days we collected cloacal samples of adults and chicks and carried out sequencing of the V1-V3 region of the 16S rDNA by Illumina. We did not find any effect of chick manipulation in bacteria diversity as no differences were found between experimental and control chicks. We found differences in bacteria diversity between adults and biological chicks but not with adopted chicks. We did not find significant relationships of bacteria diversity between chicks reared in the same nest but from different parents and either between siblings reared in different nests. Moreover, we did not find significant relationships between parents and the biological chicks or the adopted chicks. This suggests that chick bacteria diversity is not dependent of the parents or external factors and should be dependent of chick intrinsic factors.
Range Expansion of Protostrongylid Nematodes in Response to Arctic Warming

Pratap Kafle1 (pkafle@ucalgary.ca), Lisa-Marie Leclerc2, Peter Peller3, Tracy Davison3, Marsha Branigan4, Morgan Anderson5, Shane Black6, Heather Sayine-Crawford7, Stephanie Behrens7, Mike Suitor8, Matilde Tomaselli1, Fabien Mavrot1, Susan Kutz1

1University of Calgary, Calgary, Canada, 2Government of Nunavut, Kugluktuk, Canada, 3Government of Northwest Territories, Yellowknife, Canada, 4Government of Northwest Territories, Inuvik, Canada, 5British Columbia Government, Fish and Wildlife, Prince George, Canada, 6Canada North Outfitting, Edmonton, Canada, 7Government of Northwest Territories, Norman Wells, Canada, 8Government of Yukon, Whitehorse, Canada

Protostrongylids, Umingmakstrongylus pallikuukensis (UP) and Varestrongylus eleguneniensis (VE), are pathogenic parasites of northern ungulates. These parasites are of interest not only because of their possible impacts on their hosts but also because their recent and rapid northern range expansion associated with Arctic warming provides a model system for understanding the impacts of climate change on parasitic nematodes in general. We aimed to

i). determine the diversity and distribution of protostrongylids in muskoxen and caribou in the Canadian Arctic, and

ii). assess climate warming as a potential driver for their range expansion.

We performed widespread fecal surveys across the Canadian Arctic from 2013-2017; conducted lab experiments on the thermal sensitivities of UP and VE, and modelled the suitable habitat for these parasites using the field, laboratory data, with satellite-derived climate data from historical to future period. We found that protostrongylid diversity in muskoxen and caribou varies geographically. On Victoria Island, UP and VE are expanding rapidly northwards, but at differential rates. UP is expanding faster over a broader geographical range. Predictive habitat modelling using the parasite's physiological data and the Arctic climate data shows a significant expansion of suitable habitat for both the lungworms, but greater for UP. Similarly, models predict the possibility of a future invasion of other Arctic islands currently free of lungworms.
Monitoring Genetic Adaptation in Humans Using Ingenuity Pathway Analyses (IPA®)

Alexander Choukèr¹ (achouker@med.uni-muenchen.de), Jean-Noël Billaud², Judith-Irina Buchheim¹, Matthias Feuerecker³, Claudia Strewe³, Roel Quintens³, Marjan Moreels⁴, Igor Mekjavic⁵, Brian Crucian⁶, Clarence Sams⁶, Satish Mehta⁶, Sarah Baatout⁴, Gustav Schelling⁷

Adaptation to changing environments has been critical to survive. A hallmark of adaptive responses to environmental pressure is genetic regulation. Antarctica is providing a unique, space-analogue environment to investigate such adaption. The CHOICE study took place in 2 overwintering crews at the Antarctic station Concordia (3200m) and was complemented by a simulated microgravity study in Slovenia. Here a similar sized group was exposed for 21d to 3 conditions of hypoxia and bedrest (PlanHab). Transcriptomics were performed in blood (Affymetrix Human Gene2.0ST) and analyzed through “Array Studio” (OmicSoft,NC,USA) and IPA. Comparisons of the earlier time point (3-4 wks upon arrival) to baseline revealed in both Concordia seasons prominent changes of ~790-850 genes (FC2,FDR< 0.01). The exposition to a comparable condition in an experimental setup in PlanHab under hypoxia resulted in 360 gene alterations, while combination of hypoxia+immobilization showed a much higher number of significant gene changes (~2500). Between both Concordia seasons and the PlanHab hypoxic ambulatory condition 1072 or 1182 common genes were detected. Several top canonical pathways were identified by IPA® and included immune and metabolic related pathways.

Grants & support from ESA ELIPS 3/4 programs, NASA HRP, IPEV, PNRA, AWI, BelSPO, DLR and the European Union Programme FP7 and all the wintering over Crews and volunteers (PlanHab) who supported with outstanding professionalism.
According to the literature, sleep disturbances are worse in the Antarctic winter, the period of isolation and constant darkness (latitude dependent). This is confirmed by results on much larger samples from Arctic regions. However, there is still no consensus on the causal mechanisms, and there is a lack of investigations during the period of constant illumination.

The current project investigated sleep and its circadian regulation at the height of summer and at the height of winter in two winterover crews. To disentangle the effect of time on station and the effect of seasonality, 1 crew had the summer measurements during their second summer on station, whereas the other was measured during the first summer on station.

The results show the same sleep disturbances for both summer and winter when it was measured after 6 months on site. When summer measurements were recorded after 1 month on site, the results paint a slightly different picture: sleep onset latency is similarly disturbed, but the amount of slow wave sleep and sleep efficiency are less affected. A melatonin phase delay was present at all seasons in both groups. These results underscore that there is more to sleep in Antarctica than a disturbed photoperiodicity: the duration of time-on-station has a major effect on the psychophysiological adaptation. Overall, the present results show the need for a specific support to personnel from both summer and winter campaigns in terms of sleep and fatigue management.
Antarctica is an isolated, confined and extreme environment. Australia has conducted expeditions to Antarctica since 1911, and the Australian Antarctic Division (AAD) has maintained a permanent presence in Australia’s Antarctic Territory since 1948, with three continental stations and one subantarctic station. Medical support for expeditions was initially informed with access to paper based medical logs and research reports. In 1986, the AAD developed a unique and innovative electronic health register, now called the Australian Antarctic Health Register (AAHR), to capture longitudinal epidemiology including expeditioner medical history, medical fitness, all health events and treatment, and importantly, person-years of exposure to the extreme expedition environments. This unique evidence base informs Australia’s Antarctic expedition medical and safety policy development. It is integral to medical screening, research and support. Online access from Antarctic stations via satellite enabled confidential data entry utilising ICD9 and specific Antarctic coding. In 2009, the AAHR was integrated with a program wide electronic health record for all clinical and telemedicine support. This paper highlights 30 years of experience with the AAHR and the importance of epidemiology and electronic health records in ensuring the safety and wellbeing of those travelling and living in polar and extreme environments such as Antarctica, the Arctic and those contemplating long term space missions.
POWER - Physiological Adaptations in Women during a North Pole Exploration

Susan Gallon¹ (susan.gallon@googlemail.com), Jessica Devitt², Caroline Gilbert³, Andrew Lange², Alexandre Zahariev⁴, Sophie Bourgeon⁵, Chantal Simon⁶, Audrey Bergouignan²⁴

¹University of Glasgow, Glasgow, United Kingdom, ²University of Colorado, Aurora, United States, ³Ecole Nationale Veterinaire d'Alfort, Maison-Alfort, France, ⁴CNRS, Strasbourg, France, ⁵Arctic University of Norway, Tromso, Norway, ⁶University of Lyon, Lyon, France

The earth's Polar Regions offer a unique set of challenges and hazards including extreme temperatures, blizzards, difficult and changing terrain due to the shifting icepack, and disrupted circadian patterns due to the extended hours of daylight. Due to the geography and remoteness of the Arctic, deep access is restricted to walking or cross-country skiing. These modes of locomotion impose a very high energy expenditure which, coupled with the extreme conditions, pose a challenge to health. The extent to which this extreme environment impacts the human body is poorly understood. Few men have been studied during Arctic explorations but no data exist for women.

The objective of this research project was to take advantage of an all-female polar expedition to examine the metabolic and physiological adaptations to extreme conditions in women skiing to the North Pole (http://www.euroarabianexpedition.com/, April 2018). Specifically, we examined changes in

1) energy needs (free-living total energy expenditure, metabolic rates and body composition),
2) biological rhythms (pattern of physical activity, sleep, body temperature and melanocortin) and
3) physiological stress (saliva cortisol).

This study shows how collaboration between scientists and explorers provides an exceptional opportunity to better understand the physiological flexibility of humans when facing extreme environmental conditions. Energetics data will be analyzed prior to the congress.
Antarctic Research Enabling Space Exploration

Marc Shepanek¹ (marc.a.shepanek@nasa.gov)
²NASA HQ, Office of the Chief Health and Medical Officer, Washington, United States

This presentation will address some of the most currently pressing research questions, countermeasures and training that make Antarctica an excellent space mission analog.
One of the biggest challenges facing the Antarctic station is medical evacuation (Medevac) in case of unpredictable emergency. Since its establishment in 1988, Korea Antarctic King Sejong Station (62°13′S, 58°47′W) is operated by winter-over team consisting of about 17 people each year. In case of Medevac, it is transferred initially to Chilean Frei base in King George Island using a helicopter or Zodiac, and subsequently transported to the flight to Punta Arenas.

In this study, we collected 22 Medevac cases (24 people) in the past 30 years (1988-2017). It is compared with other previous studies, and also seasonal difference to Antarctic winter and summer. Orthopedic problems due to trauma had the highest proportion of the entire Medevac cases, else there were distress and frostbite, burns, tooth problems, head trauma, gastritis, tuberculosis, eye problem, decompression sickness, and malignancy work-up, etc.

Since the Medevac system in Antarctica is directly related to the member’s safety issue, it is essential to prepare for specified emergencies. It could be done by case-specific scenario, guidelines, and regular training considered each Medevac steps: first aid, waiting Medevac, rapid transfer, proper treatment. Additionally, it needs to be considered along with the efforts of such pre-screening, safety education to prevent these Medevac situations in advance.

(This article is revised and updated version of the 2016 COMNAP symposium proceeding.)
Since the 1990s, satellites have shown accelerating ice loss in the glaciers draining central West Antarctica into the Amundsen Sea. The rate of ice loss now accounts for about 10 percent of global sea-level rise. Pine Island Glacier, which has the highest rate of ice loss, was the focus of the UK-NERC iSTAR Programme and US-NSF funded projects during the past decade. Recent studies indicate that the greatest uncertainty and risk for future rapid sea-level rise now arises from Thwaites Glacier. Rapid changes are already underway and there is concern that ice sheet loss from the Thwaites Glacier basin will become irreversible, if it is not already.

The need to characterize the potential range and uncertainty in Antarctic contributions to sea-level rise on decadal to multi-century timescales was underscored by the SCAR in its "Horizon Scan 2020", and by U.S. National Academy of Sciences, Engineering, and Medicine. Building on this priority, and recognizing the high logistic and scientific demands call for an international endeavour, the US-NSF and the UK-NERC have begun a joint initiative focusing on Thwaites Glacier and the adjacent Amundsen Sea, involving ~30 UK and US institutes, and international partners. The program will improve understanding of the stability of marine ice sheets, the processes of thinning, retreat, and acceleration, and the role of oceans in driving change. It will require shipborne, aircraft, and over-snow research in the austral summers of 2018-2021.
A New Heat Flux Model Incorporating Variable Crustal Radiogenic Heat Production

Alex Burton-Johnson¹ (alerto@bas.ac.uk), Jacqueline Halpin², Joanne Whittaker², Felicity Graham², Sally Watson²

¹British Antarctic Survey, Geology & Geophysics Team, Cambridge, United Kingdom, ²Institute for Marine and Antarctic Studies, University of Tasmania, Hobart, Australia

We present findings recently published in GRL (Burton-Johnson et al., 2017) on the variability of Antarctic sub-glacial heat flux and the impact from upper crustal geology. Our new method reveals that the upper crust contributes up to 70% of the Antarctic Peninsula’s subglacial heat flux, and that heat flux values are more variable at smaller spatial resolutions than geophysical methods can resolve. Results indicate a higher heat flux on the east and south of the Peninsula (mean 81 mWm⁻²) where silicic rocks predominate, than on the west and north (mean 67 mWm⁻²) where volcanic arc and quartzose sediments are dominant. Whilst the data supports the contribution of HPE-enriched granitic rocks to high heat flux values, sedimentary rocks can be comparable dependent on their provenance and petrography. Models of subglacial heat flux must utilize a heterogeneous upper crust with variable radioactive heat production if they are to accurately predict basal conditions of the ice sheet. Our new methodology and dataset facilitate improved numerical model simulations of ice sheet dynamics.

The most significant challenge faced remains accurate determination of crustal structure, particularly the depths of the HPE-enriched sedimentary basins and the sub-glacial geology away from exposed outcrops. Continuing research (particularly detailed geophysical interpretation) will better constrain these unknowns and the effect of upper crustal geology on the Antarctic ice sheet.
Combining Upper Crust and Lithosphere Contributions to Heat Flow Models

Anya Reading1,2 (anya.reading@utas.edu.au), Tobias Staal2,3, Jacqueline Halpin2, Joanne Whittaker2

1University of Tasmania, Mathematics and Physics, Hobart, Australia, 2University of Tasmania / Institute for Marine and Antarctic Studies, Hobart, Australia, 3University of Tasmania, Earth Sciences, Hobart, Australia

Geothermal heat supplied to the base of Antarctic ice sheets, and the spatial variation of supplied heat, is an important input model parameter in ice sheet models. Continental models of heat flow (usually referred to in the cryosphere research community as heat flux density, abbreviated to heat flux) may be generated using seismic wavespeed tomography maps or by inference from other geophysical observables. Upper crustal models, however, are generated directly from measuring the heat production of dominant or particularly radiogenic lithologies.

In this contribution, we combine upper crust and lithosphere contributions to heat flow models with a focus on East Antarctica, including the continental interior which is covered by ice of several kilometres thickness. We review alternative approaches to combining low resolution information on the deeper lithosphere with broad spatial coverage, and high resolution information with very limited spatial coverage relating to the upper crustal. Providing effective estimates of the heat supplied by the upper crust is an important research goal due to the significance of small pockets of elevated heat flow on ice sheet models. Our model for East Antarctica represents a step towards future probabilistic approaches to solid Earth constraints for ice sheet models.
The Sensitivity of GIA in West Antarctica to a Laterally Varying Earth Structure

Grace Nield¹, Pippa Whitehouse¹ (pippa.whitehouse@durham.ac.uk), Wouter van der Wal², Bas Blank², Andrew Lloyd³, Douglas Wiens³, JP O'Donnell⁴, Graham Stuart⁴, Alex Brisbourne⁵

¹Durham University, Department of Geography, Durham, United Kingdom, ²Delft University of Technology, Faculty of Aerospace Engineering, Delft, Netherlands, ³Washington University in St Louis, Department of Earth and Planetary Sciences, St. Louis, United States, ⁴University of Leeds, School of Earth and Environment, Leeds, United Kingdom, ⁵British Antarctic Survey, Cambridge, United Kingdom

The one-dimensional Earth structure adopted in many glacial isostatic adjustment (GIA) models leads to bias in model predictions in regions where rheological parameters differ significantly from the 1D structure used. The advancement of 3D GIA modelling techniques in recent years has led to improvements in the representation of the Earth through the incorporation of laterally varying structure. This study investigates the influence of 3D Earth structure on deformation rates in West Antarctica using a finite element GIA model with power-law rheology, where the effective mantle viscosity depends on stress. We use a high resolution model of seismic velocity to infer temperatures and derive creep parameters from a flow law for the crust and upper mantle with the aim of determining a data-driven model of Earth rheology across Antarctica. We investigate the range of plausible mantle viscosities this model predicts, given uncertainties in the input parameters to the flow law. Furthermore, we consider the differences in model-predicted vertical deformation rates when compared to an equivalent 1D Earth structure.
ANET (Antarctic Network) GPS observations from the Polar Earth Observing Network (POLENET) record solid earth deformation in response to ice mass change. In the Transantarctic Mountains (TAM) region, observed horizontal motions are towards modelled West Antarctic centers of ice mass loss, opposite to the radially outward pattern expected. We investigate alternative ice history and earth structure inputs to GIA models in an attempt to reproduce observed motions in the region. The W12 ice history model is altered to include unloading in the Wilkes Subglacial Basin based on glaciological records indicating LGM ice thicknesses greater than present. These scenarios, along with the unmodified W12 ice history, are coupled with 60 radially varying (1D) earth model combinations. Additionally, the influence of laterally heterogeneous earth structure is investigated by coupling loading scenarios with earth models that permit two different viscosity profiles on either side of a longitudinal boundary bisecting East and West Antarctica. For both the 1D and laterally heterogeneous case, resulting model-predicted motions fit ANET GPS-derived crustal motions in the northern and central TAM region for a suite of earth model combinations. Further south, observed and predicted motions do not agree. Best fitting ice history and earth models are presented, including preferred upper mantle viscosity values.
A New Global GPS Dataset for Testing and Improving Modelled GIA Uplift Rates

Maike Schumacher¹ (maike.schumacher@bristol.ac.uk), Matt King², Jonathan Rougier¹, Zhe Sha¹, Shfaqat Abbas Khan³, Jonathan Bamber¹

¹University of Bristol, Bristol, United Kingdom, ²University of Tasmania, Hobart, Australia, ³Technical University of Denmark, Lyngby, Denmark

Permanent GPS stations provide a globally distributed record of long-term signatures of glacial isostatic adjustment (GIA). In this study, we use about 4000 GPS vertical velocities as an observational estimate of global GIA uplift rates, after correcting for major elastic deformation effects. A novel fully automatic strategy is developed to post-process the GPS time series and to correct for non-GIA artifacts. Before estimating vertical velocities and uncertainties, we detected outliers and jumps, and corrected for atmospheric mass loading displacements. We corrected the resulting velocities for the elastic response of the solid Earth to global changes in ice sheets and glaciers, as well as for changes in the Earth’s rotational pole relative to the 20th Century average. We applied a spatial median filter to remove sites reflecting local effects and to arrive at the ~4000 GPS site velocities.

The novel global GPS dataset shows a clean GIA signal at all post-processed stations and is therefore suitable to investigate the behaviour of global GIA forward models. The dataset is compared with 13 global GIA solutions considering differences in reference frame origins. Furthermore, we use the novel dataset to update global forward model solutions within a Bayesian Hierarchical Modelling framework to identify statistically significant deviations between the observations and the models, which may be due to either uncertain mantle rheology and/or ice loading history or GPS errors.
Interdisciplinary collaboration is crucial to addressing threats to the Antarctic region, including global warming, growing tourist numbers and marine harvesting. Currently, creative artists and non-scientific researchers can visit Antarctic bases primarily through national residency programs. Such residencies have long existed, but began to be consolidated into formal state-sponsored schemes in the late twentieth century. The structure and format of residency programs vary considerably with national context, with each emphasizing a different (and often uneasy) combination of artistic merit, promotion, communication, education and public accessibility. Given the financial investment that many states make in these residencies, it is worth critically evaluating their purpose and effectiveness. In preparation for a larger research project, this paper explores ways in which such an evaluation might be undertaken. We briefly compare several residency programs, before posing a series of questions. How does access to Antarctica impact on creative artists and the scientists they work alongside? What innovations arise from the residencies? What can we learn from other residency models, such as those in scientific institutions or wilderness environments? What do several decades of residencies teach us about the most productive options for the future? We conclude by outlining some methods we plan to use to address these questions and expected benefits for key stakeholders.
Feminist Institutional Research: Challenges, Opportunities for Antarctic Science

Morgan Seag¹ (mcs89@cam.ac.uk)
University of Cambridge, Scott Polar Research Institute, Cambridge, United Kingdom

Scholars in Antarctic humanities and social sciences are increasingly turning to gendered histories. Thanks to scholarship in a range of disciplines, it is well understood that Antarctic activity has always been deeply gendered (e.g. Glasberg, Lewander, Dodds). Still, much remains to be done. In particular, we have a limited understanding of the processes through which women gained access to Antarctic field opportunities after being categorically excluded through much of the twentieth century, and we insufficiently understand how national contexts contributed to sometimes dramatic variation in women’s access to the continent.

Drawing on archival work and interviews dealing with the British Antarctic Survey and the US Antarctic Program, as well as existing literature on several other national Antarctic programs, this paper examines the potential of a feminist institutional framework to address current gaps. It asks: how can the tools of feminist institutionalism help us unpack the historical exclusion of women from Antarctica and the factors that contributed to progress? What trends, connections, and contingencies are revealed? What weaknesses are identified, and what lessons can be learned? It is argued that this approach offers valuable insights into several dimensions of Antarctic activity, from scientific and sociocultural to geopolitical. Inspired by Traweek and others, this paper issues a call for international discourse on Antarctica’s gendered institutional histories.
Collaborators, Competitors or Window Shoppers
Jihoon Jeong¹ (jj@kopri.re.kr), Sunhwi Kim¹, Chaerin Jung¹, Hyoung Chul Shin¹
¹Korea Polar Research Institute (KOPRI), International Cooperation Team, Incheon, Korea, Republic of

Collaborators, competitors or window shoppers: perception of Asian Arctic observers determined by media coverage and public commentaries
The emergence of Asian actors in the Arctic affairs is attracting attention from many stakeholders in the Arctic, ever since the 2013 Kiruna Ministerial Meeting.
As most of the region in the Arctic Circle is under sovereignty or sovereign right of the eight Arctic states, non-Arctic players generally look for invitations from the Arctic, which in turn renders their overall perception by the Arctic community a matter of significance.

This study aims to provide empirical answers to the following questions:
(a) What activities of Asian observer states, and at what time draw the attention of the eight Arctic states and become featured in Arctic media and commented by key Arctic figures?
(b) What is the attitude toward the activity in each case - positive, negative, or neutral?
(c) Can the background of the respective attitudes be determined?
From selected Arctic media, we collected and analyzed articles that cover Arctic activities of these Asian Arctic observers, since May 2013. The articles were classified by issue areas (i.e. research/education; environmental conservation; regional development; shipping/routes; resources; and strategy/military), and then sorted by the nature of the stances expressed therein. The perception conveyed by these articles did not always correspond with the public statements of the observers in question.
Most analyses of Antarctic politics and geopolitics so far have taken a descriptive approach and presented matter-of-factly what actors there are, what goals they have, and what tensions and challenges this will bring to the Antarctic Treaty System. In this presentation, I suggest that such a descriptive approach should be complemented by a normative one, where assessments are made concerning—among other topics—the status of territorial claims and the external legitimacy of the Antarctic Treaty System. Starting from the assumption that politics is not just a matter of force and rhetoric, but also a matter of following certain basic moral principles, such a normative assessment is urgently needed in a time where global pressure over living and non-living natural resources in Antarctica will keep mounting. Its practical purpose, ultimately, should be to foster peaceful knowledge-based management and policy-making in the White Continent.
Antarctic stations have for decades been used as research analogues of spacecraft, especially space stations such as Skylab, Mir, and the International Space Station. The two environments share isolation, confinement, novelty, discomfort, danger, and remoteness. They are attractive analogues because research in space is expensive, complex, and limited in research time, facilities, and subjects. It is time to review this practice. Analogues should not merely look similar, they should have similar effects. Is this true of Antarctica and space? Data, some of them unpublished, from multi-year studies conducted in the two environments are reviewed to compare the stressful and adverse (pathogenic) and healthful, positive (salutogenic) effects of the two environments on human physiology and psychology in order to evaluate this question.
Arctic Horizons and IASSA: The State and the Future of Arctic Social Sciences

Andrey Petrov¹ (andrey.petrov@uni.edu)
¹University of Northern Iowa/IASSA, Cedar Falls, United States

This presentation will offer an overview of the Arctic Horizons report that outlines major milestones, trends and priorities in Arctic social sciences research. The report resulted from a series of workshops with primarily US researchers devoted to identifying strengths, weaknesses, emerging science questions and funding priorities for social sciences in the Arctic. These findings are placed in the broader international context from the positions of the International Arctic Social Sciences Association (IASSA).
Towards Cross-weaving of Knowledge for Better Decisions

Finn Danielsen¹, Pâviâra K Jakobsen², Nette Levermann³, Bjarne Lyberth⁴, Michael Køie Poulsen¹, Hajo Eicken⁵, Martin Enghoff⁵, Peter Pulsifer⁶ (peter.pulsifer@colorado.edu), Julia Collins⁶, Betsy Sheffield⁶

¹Nordic Foundation for Development and Ecology, Copenhagen, Denmark, ²Qaasuisup Municipality, Aasiaat Area Office, Aasiaat, Greenland, ³Greenland Ministry of Fisheries and Hunting, Nuuk, Greenland, ⁴Greenland Association of Fishermen and Hunters (KNAPK), Nuuk, Greenland, ⁵University of Alaska Fairbanks, International Arctic Research Center, Fairbanks, United States, ⁶Exchange for Local Observations and Knowledge of the Arctic, National Snow and Ice Data Center, University of Colorado at Boulder, Boulder, United States

Arctic people observe the environment all year round. Their knowledge is critical for effective resource management. Yet, while approaches to data collection with community members have been well described, means of disseminating and using local knowledge for decision-making have received less attention. Here, we discuss lessons learned and tools developed from Greenland. Our case is the Piniakkanik Sumiiffinni Nalunaarsuineq (PISUNA) approach in Greenland. Here, in communities where there is interest, the village residents establish a Natural Resource Council comprising hunters and fishers. They decide which species and resource uses should be observed. Together, they compile data on species and resource uses during their hunting and fishing activities. Every three months, data are summarised and analysed, and possible management interventions discussed. The proposed management interventions and supporting data are forwarded to the government. The Council uses matrices that encourage self-interpretation and validation and, at the same time, they promote discussion of resource management actions. With 2-3 keystrokes, decision-makers can access trend-information and management proposals at PISUNA-net, a searchable icon-based database developed with SIZO-net and ELOKA projects. This approach combines local knowledge with digital technology, providing an opportunity for the community members’ insights and knowledge to be used and their voices heard.
Community-based Monitoring Networks, Data Sharing, and Earth Observation

Noor Johnson1,2 (noor.johnson@colorado.edu), Maryann Fidel3, Lisbeth Iversen4, Rodion Sulyandziga5, Hajo Eicken6, Martin Enghoff7, Olivia Lee8, Peter Pulsifer1, Ania Albin7, Michael Køie Poulsen7, Colleen Strawhacker1, Finn Danielsen7

1University of Colorado Boulder, National Snow and Ice Data Center, Boulder, United States, 2Tufts University, Fletcher School of Law and Diplomacy, Medford, United States, 3Yukon River Inter-Tribal Watershed Council, Anchorage, United States, 4Nansen Environmental and Remote Sensing Center, Bergen, Norway, 5Center for Support of Indigenous Peoples of the North, Moscow, Russian Federation, 6University of Alaska Fairbanks, International Arctic Research Center, Fairbanks, United States, 7Nordic Foundation for Development and Ecology, Copenhagen, Denmark

Community-based monitoring and observing programs exist around the Arctic, drawing on both Indigenous methods of observation, protocols developed by scientists, and combinations of the two. These programs use a variety of data collection methods, ranging from interviews to field diaries to handheld computers and digital devices. In this paper, we examine challenges and opportunities related to data collection, compilation, and dissemination for community-based monitoring programs. Community-based monitoring offers unique, in situ observational data that can contribute to management of natural resources as well to large scale observing systems. Management of CBM data requires an understanding of the context in which community members engage in both formal and informal observing, with implications for design of infrastructures and networks for data sharing. We draw on information gathered through workshops with community-based monitoring practitioners held in Alaska, Canada, and Russia, organized under the INTAROS project, and a student field trip to Svalbard, organized by INTAROS and REGIMES. Practitioners gathered at the workshops identified good practices and specific needs for establishing and sustaining CBM programs and connecting them to natural resource management and decision-making. Participants also discussed CBM in relation to broader themes such as access to resources, health of subsistence species, and unusual events.
The Earth Radiation Budget Explorer (EAGER) Mission Concept

Benjamin Walter¹ (benjamin.walter@pmodwrc.ch), Margit Haberreiter¹, Wolfgang Finsterle¹, Werner Schmutz¹
¹Physikalisch-Meteorologisches Observatorium Davos, World Radiation Center, Davos Dorf, Switzerland

It is widely accepted that a significant net-influx of radiative energy of about 1 Wm⁻² to the Earth’s atmosphere is mainly responsible for global warming. However, instruments and methods used to determine the global radiative energy budget at the top of the atmosphere (TOA) are so far not able to accurately resolve this small difference between the incoming and outgoing radiation. The relevant radiative components include the Total Solar Irradiance (TSI), the Spectral Solar Irradiance (SSI), the Reflected Solar Radiation (RSR) and the Earth’s Infrared Emission (EIE).

The Earth Radiation Budget Explorer (EAGER) mission concept planned by PMOD/WRC together with the University of Leipzig, the Fraunhofer Institute for Physical Measurement Techniques and the Royal Observatory of Belgium aims for providing direct measurements of all four components required for detecting the energy budget imbalance with unprecedented accuracy. We present the instrumental approach and technical challenges of the EAGER mission concept consisting of two Sun and four Earth oriented instruments on an Airbus satellite platform: i) A Digital Absolute Radiometer (DARA) for measuring TSI, ii) an Extreme-Ultraviolet and Infrared (EUV/IR) Spectrometer (SoIACER) for measuring SSI, iii) three Bolometric Oscillation Sensors (BOS) for measuring RSR and EIE, and iv) a DARA Albedo Earth Sensor (DARA-AES) for periodically recalibrating the BOS instruments.
An International Observing System for the Southern Ocean

Louise Newman1 (louise.newman@utas.edu.au), Andrew Constable2, Sebastiaan Swart3, Oscar Schofield4, Mike Williams5, Phillippa Bricher6

1Southern Ocean Observing System, Institute for Marine and Antarctic Studies, Hobart, Australia, 2Australian Antarctic Division, Hobart, Australia, 3University of Gothenburg, Gothenburg, Sweden, 4Rutgers University, New Jersey, United States, 5National Institute for Water and Atmospheric Research, Wellington, New Zealand, 6Southern Ocean Observing System, Hobart, Australia

The Southern Ocean and its related atmo-, cryo-, geo- and bio-sphere, has a profound influence on the global Earth system. Although geographically remote, it directly impacts global societies through, for example, its role in maintaining Earth’s heat and carbon budgets and storage, provision of food, and in providing intrinsic value for conservation and tourism. Moreover, the ocean-ice-atmosphere interactions will have far-reaching consequences for the globe through sea-level rise. Yet, the Southern Ocean remains one of the most under-observed regions in the world. The IPCC has identified uncertainties in estimations of future state of Southern Ocean processes, and highlighted that a sustained system for observing trends in physics, chemistry and biology is urgent for this region, to reduce those uncertainties. The Southern Ocean Observing System (SOOS) developed over the last decade to fill this urgent need. SOOS has established regional and capability working groups to coordinate the contributions of Antarctic nations in delivering a system for observing essential variables, and to provide data streams to the scientific community, stakeholders and policy-makers. SOOS also provides a hub for accessing data repositories, linking data from satellites, remote in-situ observations, and in-field activities. In this paper, we outline the vision for SOOS and, in particular, highlight new products that facilitate fieldwork planning and coordination, and data discovery and sharing.
ICEBERG: Imagery Cyberinfrastructure and Extensible Building Blocks to Enhance Research in the Geosciences

Satellite imagery is rapidly transforming the way we see the planet, including our ability to study the most remote parts of the Arctic and Antarctic. Satellite imagery can help us map networks of rivers, study changes in the flow and thickness of glaciers, identify rock and soil types, and even find animals like penguins and seals. Because the availability of imagery in polar areas has increased rapidly over the last decade, we are now faced with a challenge: How do we scale-up the scientific discoveries that have been enabled by satellite imagery to larger spatial scales? Moving from small pilot-studies to pan-Arctic or pan-Antarctic analyses of geological and biological processes requires new infrastructure to link scientists, satellite imagery, and high-performance computers. This new imagery-computing superhighway will make it easier for scientists to study processes at much larger spatial scales than has been previously possible. Our project, called ICEBERG — Imagery Cyberinfrastructure and Extensible Building-Blocks to Enhance Research in the Geosciences, aims to build the cyberinfrastructure required to make the most of satellite imagery for geosciences, starting with researcher working in polar areas, where much of this science is already underway, and then branching out to the entire EarthCube community.

ICEBERG is supported by the NSF EarthCube program.
Continuous collection of environmental data about the Arctic ocean, involving algorithms and models for the analysis of its characteristics is essential not only for operational monitoring and enforcing economic activities, but also to explore different-scale natural processes in the atmosphere and ocean, their dynamics.

The presentation discusses the establishment of a comprehensive geographic information system based on open source satellite data, combining the processes of assessment of ice conditions and primary productivity of the ocean. The core algorithms are developed and implemented methods for automated classification of types of sea ice, ice drift fields retrieving, ice deformations retrieving, iceberg detection and calculations of various characteristics of biological productivity.

Collecting and processing of data consolidated in an integrated information system that is accessed via standard protocols with two types of interfaces - web portal NIERSC Data Center and desktop application NIERSC QGIS ToolBox implemented as an extension to the open source desktop GIS QGIS. Deployment of desktop solution is automated with the virtual machines hypervisor Oracle VirtualBox and Vagrant software with storing the source codes of the algorithms on GitHub.

Development of data processing methods and access interfaces allows to explore natural environment of the Arctic ocean more deeply with every step.
Temporal Trends of PCBs and OCPs in Landlocked Char from High Arctic Lakes

Ana Cabrerizo1 (anacabrerizopastor@hotmail.com), Derek Muir1, Günter Köck2, Debbie Iqaluk3, Xiaowa Wang3, Scott Lamoureux4, Melissa Lafraeniere4

1Environment & Climate Change Canada, Burlington, Canada, 2Institute for Interdisciplinary Mountain Studies, Innsbruck, Austria, 3Resolute Bay, Resolute, Canada, 4Queen’s University, Kingston, Canada

Temporal trends and climate related parameters affecting the fate of legacy persistent organic pollutants (POPs) such as polychlorinated biphenyls (PCBs), organochlorine pesticides (HCHs, DDTs and HCB) and toxaphene were examined in landlocked Arctic char from six lakes in the Canadian Arctic located on Cornwallis Island (Resolute, Char, Amituk Lakes), Ellesmere Island (Lake Hazen) and two paired lakes in Melville Island (West and East Lakes). Research performed over the past 10 years in the study area has revealed ongoing permafrost disturbances, which are of significant magnitude and importance on the West Lake watershed and lake (Melville Island). Adult char were collected in late July from almost every year from 2001 to 2016, by gill netting or by jigging through the ice at a rate of 7 to 25 adult fish per lake and year. All fish were dissected in situ and subsamples of muscle+skin, liver, otoliths and GI tract were kept frozen for transport and storage in an ultra clean freezer (-30°C). In total, more than 500 samples from muscle+skin arctic char were collected and analyzed for POPs in this study with the aim of i) examining the trends of legacy POPs such as PCBs and OCPs (DDTs, HCHs and HCB) and toxaphene, ii) study which parameters are affecting the occurrence of POPs in Arctic char and iii) investigate whether or not climatic parameters and climatic oscillation patterns may affect the temporal trends of POPs in Arctic Char.
Emerging and Legacy POPs in Norwegian Marine Sediments: The MAREANO Program

Stepan Boitsov¹ (stepan@imr.no), Jarle Klungsøyr¹, Henning K.B. Jensen²

¹Institute of Marine Research, Bergen, Norway, ²Geological Survey of Norway, Trondheim, Norway

The Norwegian national program of seabed mapping, MAREANO, has been carried out on a yearly basis for over a decade in remote open-sea areas of the Norwegian Arctic. Several groups of organic contaminants in surface and subsurface sediments from shelf areas of the Barents and the Norwegian Seas have been mapped. The hydrocarbons are the most abundant among all the studied types of contaminants due to natural presence in the marine environment. Analyses of 48 separate PAH compounds in dated sediment cores, together with grain size and total organic carbon contents, allow to distinguish the natural background from anthropogenic inputs and discuss possible sources. While pyrogenic PAHs dominate the PAH composition of most samples, petrogenic and biogenic PAHs are sometimes also found in significant amounts. The geographical distribution of manmade legacy POPs (PCBs, five types of chlorinated pesticides, PBDEs) in surface sediments shows some variations at low levels throughout the area. The first results of analyses of several groups of emerging contaminants (PFAS, PFR, siloxanes), as well as alkylphenols, alkylphenol ethoxylates and bisphenol A, indicate trace amounts of some of these compounds in surface sediments. A pilot study of microplastics in a small selection of samples from the same areas have revealed the presence of different quantities of several types of plastics in the µm range in all the analysed samples. However, several methodological challenges remain.
Anthropogenic Effects on the Marine Environment at Palmer Station, Antarctica

Terence Palmer¹ (terry.palmer@tamucc.edu), Stephen Sweet², Andrew Klein³, Larry Hyde¹, Paul Montagna¹, Jose Sericano², Terry Wade²

¹Texas A&M University-Corpus Christi, Harte Research Institute, Corpus Christi, United States, ²Texas A&M University, Geochemical and Environmental Research Group, College Station, United States, ³Texas A&M University, Department of Geography, College Station, United States

Palmer Station is a small US research base (15-40 people) north of the Antarctic Circle (64.8°S). In 1989, the Argentine supply vessel Bahia Paraiso ran aground and eventually sunk, leaking an estimated half a million liters of diesel and other hydrocarbons. Subsequent impact monitoring from 1989 to 1992 determined that some marine sediments were contaminated, along with bioaccumulation in, and mortality of, intertidal limpets (Nacella concinna). However, an assessment of local anthropogenic effects on the marine environment had not been conducted since 1992. In 2014 and 2015, marine sediments were collected to quantify the extent and effects of any potential contamination on deep (18 to 24 m), soft-sediment benthic macrofauna from both the Bahia Paraiso, and from Palmer Station itself. Intertidal and subtidal limpet tissues were also sampled to determine any potential contamination effects in shallow areas (< 10 m) where hard substrate dominates. Preliminary results show that Polycyclic Aromatic Hydrocarbon (PAH) concentrations in the sediment have decreased since 1991, however high concentrations exist at three sites within the vicinity of Palmer Station. PAH concentrations in limpet tissues have also decreased over time, however concentrations are still high in limpet tissues at the Bahia Paraiso and at some sites close to Palmer Station. The status of human impacts on the marine benthos, and comparisons with the 1989 to 1992 assessments will be presented.
First Detection of SCCPs in Humpback Whales Foraging in Antarctic Waters

Valeria Casà¹² (valeria.casa@griffithuni.edu.au), Louise van Mourik³, Liesbeth Weijs⁴, Susan Bengtson Nash⁵
¹Environmental Futures Research Institute, Nathan, Australia, ²Griffith University, Nathan, Australia, ³VU University Amsterdam, Amsterdam, Netherlands, ⁴Griffith University, Gold Coast, Australia

Chlorinated paraffins are industrial mixtures of polychlorinated-n-alkanes. Their synthesis started in the 1900s when they were used in the preparation of an antiseptic solution during World War I. They can be released through production, storage, transportation, usage and disposal of, plastics, adhesives, rubber, sealants, liquor leathering and metal cutting fluids. Short chain chlorinated paraffins (SCCPs; C₁₀₋₁₃) are of particular interest because they have been detected in remote environments, such as the poles of the earth, demonstrating their capacity for long range transport. Further, their persistence, capacity for bioaccumulation in lipids and long-range transport, led to their inclusion in the persistent organic pollutants (POPs) list, under the Stockholm Convention, in May 2017. Here we report for the first time, the detection of SCCPs in the blubber of humpback whales (n=10), belonging to the southern hemisphere E1 population known to feed on Antarctic krill (Euphausia superba) in Antarctic waters. The blubber samples were collected from humpback whales stranded along Australian coasts between 2008-2012 and approximately 2g of blubber from each specimen was dedicated to the analysis. As long-lived cetaceans with a large proportion of body lipid mass, humpback whales represent suitable bioindicators of Antarctic lipophilic chemical pollution. The study serves as a further proof of the ubiquity and bioaccumulation potential of these newly listed POPs.
Persistent Pollutants in Arctic and Antarctic Krill and in Commercial Krill Oil

Simonetta Corsolini¹ (simonetta.corsolini@unisi.it), Nicole Camicetti², Tania Martellini², Alessandra Cincinelli²

¹University of Siena, Department of Physics, Earth and Environmental Sciences, Siena, Italy, ²University of Florence, Department of Chemistry 'Ugo Schiff', Florence, Italy

Krill are considered key-species of marine ecosystems of the Polar Regions, being main food source for fish, marine mammals and birds in the Southern Ocean and in Arctic seawaters. Through ingestion, persistent organic pollutants accumulated in their body could be transferred to their predators due to biomagnification process and may cause effects in the entire trophic web. We studied krill from the Arctic and Antarctic seawaters in order to assess the toxic risk for their predators. Recently, the krill oil has been used in commercial preparation of pills for supplying unsaturated fatty acids, hence including humans in the list of krill predators. In order to assess the contaminant level and toxic risk for predators, the presence of some persistent organic pollutants was determined by gas chromatography-mass spectrometry in Antarctic and Arctic krill samples and commercial pills. The sum of 4 congeners of mono- and 8 congeners of non-ortho polychlorinated biphenyls was < 0.001-0.471 and < 0.001-0.499 ng/g wet wt in the Antarctic and Arctic krill, respectively. HCHs and DDTs were more abundant in the Arctic krill (0.856±0.315 ng/g wet wt) while the sum of 23 congeners of polybrominated diphenyl ether predominated in the Antarctic krill (0.121±0.074 ng/g wet wt), with BDE47 making up most of the residue. The same contaminants were detected in the krill oil pills; the assessed TDI was below the limit suggested by the World Health Organization.
Persistent organic pollutant (POP) exposure in Adelie penguins (*Pygoscelis adeliae*) may reflect local or regional conditions better than other seabird groups as they are highly constrained within their foraging habitat and remain south of 60°S during winter. While POP contamination within Antarctica is largely caused by long-range atmospheric transport, Antarctic research bases have been shown to be local sources of emerging POPs such as polybrominated diphenyl ethers (PBDEs). In addition, Antarctic soil concentrations near Adelie penguin colonies have shown elevated concentrations of legacy POPs such as organochlorine pesticides (OCPs) and polychlorinated biphenyls (PCBs), suggesting guano and bird remains may contribute substantially to local contamination levels. This study aims to evaluate Adelie penguin colonies as indicators of local contamination of POPs within east Antarctica. Soil samples (n=68) were collected from Adelie colonies within close proximity to Australian research stations Mawson and Davis as well as further afield during the 2016/17 austral summer. Samples are being analysed for OCPs, PCBs, PBDEs and novel flame retardants using selective pressurised liquid extraction (S-PLE) and gas chromatography coupled to tandem mass spectrometry (GC-MS/MS). Results will provide baseline data for regional POP contamination with Adelie species local to east Antarctica, as well as provide an assessment of potential station-derived impacts.
Understanding Diversity in CMIP5 Projections of Winds over the Southern Ocean

Tom Bracegirdle¹ (tjbra@bas.ac.uk), Patrick Hyder², Caroline Holmes¹
¹British Antarctic Survey, Cambridge, United Kingdom, ²Met Office Hadley Centre, Exeter, United Kingdom

The CMIP5 climate models simulate a robust poleward shift and strengthening of the main eddy-driven belt of Southern Hemisphere (SH) mid-latitude near-surface westerly winds ('westerly jet' or 'jet') as part of the climate change response to increasing greenhouse gases. Such changes have wide-reaching implications both regionally and globally relating to impacts on, for example, uptake of heat and CO₂ in the Southern Ocean and ice-ocean interactions around Antarctica. However, there is a large inter-model spread in the magnitude of jet responses.

The focus of this presentation will on linkages between diversity in simulated CMIP5 sea ice area (SIA), Antarctic amplification and diversity in projected 21st century changes in the westerly jet. Broadly it is found that model diversity in projected 21st century jet strengthening is much more highly correlated with sea ice area (SIA) (and associated Antarctic amplification) than diversity in jet shift. Specifically, CMIP5 models with larger simulated present-day SIA broadly exhibit more sea-ice retreat and less jet strengthening in future projections. To help disentangle cause and effect in the coupled model analysis, output from uncoupled atmosphere-only fixed sea-surface experiments from CMIP5 was also evaluated. This analysis points to a coupled link between simulated present-day jet strength biases and projected future jet strengthening.
The energy budget of Arctic land surfaces is expected to change significantly under future climate warming. All components of the energy budget might undergo shifts under increasing air temperature and precipitation. Examples include changes of irradiance due to alterations in cloud cover; of albedo as a response to changing snow cover, water surface extent, plant composition and structure; and of ground heat fluxes in response to changing thermal conductivity related to increasing or decreasing soil moisture. However, predictions of most of these changes are still highly uncertain, as well as their combined effect onto the energy budget.

Based on our recent observational and modelling studies of land surface energy budget components in the northeastern Siberian Arctic tundra and recent literature, I will synthesize the status and needs to improve the predictability of land surface energy fluxes in the Arctic. Discussed aspects include observations, experiments, and modelling from local to regional scale. A special emphasis will be on how we can predict the effects of vegetation change on shortwave energy fluxes through experimental evidence, linking plant traits to vegetation-light interaction, from leaf to landscape scale.
We investigate the lead/lag linkages between summertime Arctic sea ice extent (SIE) and high-latitude climate. Arctic SIE anomalies exhibit notable persistence from midsummer (~July) through autumn (~October). The persistence of summertime Arctic SIE anomalies extends to Arctic temperature, geopotential height, and mid-tropospheric zonal flow. Hence, summertime SIE anomalies are significantly linked to Arctic climate variability up to three months in advance. The inferred skill that derives from summertime SIE is robust over the Arctic basin, but does not appear to extend to midlatitudes. It is theorized that the lagged relationships between summertime SIE and autumn Arctic climate derive from a combination of

1) the persistence of SIE anomalies from summer to autumn and

2) the anomalous surface fluxes of heat and moisture that accompany the persistent SIE anomalies.
Arctic sea ice has undergone a substantial decline since the beginning of satellite observations (Stroeve et al. 2014), a negative trend that is modulated by internal variability on decadal time scales, which complicates near-term predictions of Arctic climate (Swart et al. 2015). We focus here on the modulation of Arctic sea ice response to CO2 by Atlantic Multidecadal Variability (AMV) using the following sensitivity experiments done with the CNRM-CM5 climate model:

1-Control (CTL): Twin ensemble experiments (13 members of 30 years) started from a strong (AMV+) and weak (AMV-) AMV state, respectively, with fixed external forcing.

2-Abrupt CO2: Same as CTL except that CO2 is instantaneously doubled at the beginning of the simulation and then hold fixed.

3-Transient CO2: Same as CTL except that CO2 is increased by 2% per year.

We present climate differences in terms of air temperature, surface heat fluxes, winds and sea ice in the AMV+ and AMV- ensembles and analyze the variability of oceanic heat transport through the main Arctic gateways. Previous studies suggested an increased ocean heat transport into the Arctic in response to climate change because of an enhanced heat flux into the Barents Sea (Koenigk et al. 2013). We show that such transport can be modulated by the AMV in agreement with previous studies (Zhang 2015, Arthun and Eldevik 2016). We highlight the importance of better understanding ocean decadal variability for improved predictions of Arctic climate.
Sub-seasonal Predictability of Cold Air Outbreaks

Mikhail Dobrynin¹ (mikhail.dobrynin@uni-hamburg.de), Erik Kolstad², Daniela Domeisen³, Johanna Baehr¹

¹Institute of Oceanography, Universität Hamburg, CEN - Center for Earth System Research and Sustainability, Hamburg, Germany, ²Uni Research Climate, Bjerknes Centre for Climate Research, Bergen, Norway, ³ETH Zürich, Zürich, Switzerland

Rapid propagation of cold polar air masses into middle or lower latitudes known as cold air outbreaks (CAOs) leads to the formation of extreme negative anomalies of air temperature over large areas. The most persistent CAOs may have a period of a few weeks, which is in the sub-seasonal forecasting range. Here, we investigate the potential of a seasonal prediction system to provide a skillful prediction of long-term CAOs on sub-seasonal scales. We use the seasonal prediction system based on the mixed resolution CMIP5 version of the Max Planck Institute for Meteorology Earth System Model (MPI-ESM-MR). In our analysis of 30-members ensemble hindcasts we focus on strong and most persistent CAOs in the period from 1982 to 2017. Prediction skill of sub-seasonal CAOs as well as background parameters such as surface and 850 hPa air temperature will be presented.
