M dwarfs account for 75% of stars in the Milky Way. However, their properties are not well understood and significant discrepancies exist between model predictions and observations. Low mass stars in detached eclipsing binaries are the most valuable objects to study because their radius, mass, and temperature can be measured. The vast majority of systems that have been characterized to date have short orbital periods (< 10 days), yielding a strong coupling between both stars. Sampling a larger parameter space is mandatory to explore the observed discrepancies. The four month continuous night during the Antarctic winter combined with excellent weather conditions is favourable to the detection of variable objects including with long periods. We observed a field centred on the celestial South Pole during four winters with the ASTEP South instrument, a 10 cm refractor in a thermalised box installed at Dome C, Antarctica, and we detected a 76 day period G-M eclipsing binary, among other objects. In this talk, we present this discovery, the follow-up observations of this object, and we investigate the properties of the M dwarf. At such a long orbital period, both stars are largely decoupled making this system a unique benchmark for the study of low mass stars. We also present some results about the characterization of Dome C for photometry in the visible.
Pulsations and Planetary Transit Events of Beta Pictoris as Observed by ASTEP

Djamel Mékarnia¹ (mekarnia@oca.eu), Tristan Guillot¹, Lyu Abe¹, Karim Agabi¹, Eric Chapellier¹, François-Xavier Schmider¹, Konstanze Zwintz², Anne-Marie Lagrange³, Lionel Bigot¹, Nicolas Crouzet¹, Jason Wang⁵, Kevin Stevenson⁶, Paul Kalas⁵, Yuri De Pra⁷

We present results of high-precision photometric observations of Beta Pictoris achieved during the 2017 and 2018 Antarctic polar campaigns, using the ASTEP-400 telescope installed at Dome C, in Antarctica. These observations, only focused on Beta Pictoris, enabled us to characterize the delta scuti pulsations of the star, by detecting 31 pulsation frequencies among which 28 are new, and to investigate the transit of the Hill sphere of its planet Beta Pictoris b.

Furthermore, because of its location in Antarctica, ASTEP is ideally suited to monitor stars with declination below -30°. In this talk, we will also present ASTEP+, the proposed ASTEP successor, designed to make the instrument fully robotic and able to get higher accuracy photometry, by minimising any turbulence along the optical path. ASTEP+, will be operational in 2019. It will observe stars with exoplanets detected in radial velocimetry to check for possible planetary transits, confirmed transiting planetary systems to characterize them, and generally any target of opportunity that is of high scientific interest. ASTEP+ will also follow up the southern hemisphere planet candidates to be discovered by NASA/TESS space mission.
Exoplanets in the Antarctic Sky

Hui Zhang¹ (huizhang@nju.edu.cn)
¹Nanjing University, Astronomy and Space Science, Nanjing, China

While the space based exoplanet survey projects (e.g. Kepler) have achieved great success, there is still valuable exoplanetary science that can be done from the ground. This is especially important at some unique sites. Dome A, the highest point of the Antarctic plateau, is one of these sites. In 2008, China established a scientific site at Dome A. Now, in a significant collaboration with Australian astronomers, a large survey project has been ongoing there for several years. This is the Antarctic Survey Telescope (AST3) project, consisting of three 0.5m telescopes located at Dome A. The exoplanet searching program is one of the two major scientific aims of AST3. I will briefly outline this project and introduce the progress of the exoplanet survey in details. It will cover the exoplanet scientific goals, instruments, designs of survey strategy, data reduction pipeline and exoplanet candidates we found within TESS's Southern Continuous Viewing Zone.
Optical Observations of LIGO Source GW 170817 by the ASTs at Dome A, Antarctica

Lei Hu1,2,3, Xuefeng Wu1,2,3, Igor Andreoni4,5, Michael C. B. Ashley6, Jeff Cooke4, Xiangqun Cui2,7, Fujia Du7, Zigao Dai8, Bozhong Gu7, Yi Hu7,9, Haiping Lu7, Xiaoyan Li7, Zhengyang Li7, Ensi Liang8, Liangduan Liu8, Bin Ma9, Zhaohui Shang7,8,10, Tianrui Sun1,2,11, Nicholas B. Suntzeff12, Charling Tao13,14, Syed A. Uddin1,2, Lifan Wang1,2,12, Xiaofeng Wang14, Haikun Wen7, Di Xiao8, Jin Xu7, Shihai Yang9, Xiangyan Yuan7, Peng Jiang15

The LIGO detection of gravitational waves (GW) from merging black holes in 2015 marked the beginning of a new era in observational astronomy. The detection of an electromagnetic signal from a GW source is the critical next step to explore in detail the physics involved. The Antarctic Survey Telescopes (AST3), deployed at the Chinese Antarctic Kunlun Station, is uniquely situated for rapid response time-domain astronomy with its continuous night-time coverage during the winter. We report optical observations of the GW source (GW 170817) in the nearby galaxy NGC 4993 using AST3. The data show a rapidly fading transient at around 1 day after the GW trigger, with the i-band magnitude declining from 17.23±0.13 magnitude to 17.72±0.09 in ∼1.8 hour. The brightness and time evolution of the optical transient associated with GW 170817 are broadly consistent with the predictions of models involving merging binary neutron stars. We infer from our data that the merging process ejected about ∼10⁻² solar mass of radioactive material at a speed of up to 30% the speed of light.
Measuring Atmospheric Turbulence at Dome A, Antarctica with AST3

Bin Ma1 (mabin22@gmail.com), Zhaohui Shang1,2, Yi Hu1, Michael Ashley3, Lifan Wang4,5
1National Astronomical Observatories, CAS, Beijing, China, 2Tianjin Normal University, Tianjin, China, 3University of New South Wales, Sydney, Australia, 4Purple Mountain Observatory, Nanjing, China, 5Texas A&M University, College Station, United States

Dome A, Antarctica is expected to have excellent seeing, however, there has not been direct night seeing measurement yet, because DIMM is hard to be operated at Dome A automatically. Alternatively, we have attempted to measure seeing with the second Antarctic Survey Telescope (AST3-2). During CCD frame transfer, a bright star generates a visible trail along the readout direction, whose random motions can be utilized to derive seeing. When AST3-2 was tested in China, we compared this method with DIMM and found they agreed moderately. However, this method is biased by telescope vibration. Our new method utilizes the differential motion between a pair of stars. Benefiting from its wide field-of-view and adequately large aperture, AST3-2 is able to capture multi stars even in a 10 ms exposure. Since the two light beams (i.e. air beams)from the two stars to telescope have increasing distances with height, unlike DIMM, these image motions do not correspond to seeing directly, but instead reflect $C_n^2$ profile. In 2017, we have selected optimized fields with many bright stars, and taken continuous short exposures from 5 ms to 100 ms. There are a dozen of stars with separations from 0.1 deg to 2 deg. The rms of the differential motions has a typical values of ~ 0.1" at the separation of 0.1 deg and it increases with separation linearly in most cases. We infer the turbulence properties from this and show that Dome A is a superb site.
1939
Meteorological Data from KLAWS-2G for Site Testing at Dome A, Antarctica

Yi Hu¹ (huyi.naoc@gmail.com), Zhaohui Shang¹², Bin Ma¹, Keliang Hu¹, Michael Ashley³
¹National Astronomical Observatories, CAS, Beijing, China, ²Tianjin Normal University, Tianjin, China, ³University of New South Wales, Sydney, Australia

We built the second generation Kunlun Automated Weather Station for monitoring astronomical site at Dome A as well as for operation support of AST3 telescope. KLAWS-2G has 11 temperature sensors and 7 anemometers in different elevations, 1 humidity sensor and 1 barometer, which are mounted on a 15-meter-tall mast. It was installed by the traverse team to Dome A in early 2015 during the 31st CHINARE. From then on, it survived the extremely cold polar winter and continuously worked for more than one and half years. KLAWS-2G has been maintained by the traverse team of the 33rd CHINARE, and now the sensors below 4m are still working properly. By analyzing the data from KLAWS-2G, we find that a strong and lasting long time temperature inversion and stable atmosphere existed at all heights for most of the time in 2015 and 2016, confirming our finding for 2011 data from KL-AWS (Hu et al. 2014). The monthly wind speeds are 3-5 m/s. Strong temperature inversion and moderate wind speed suggest that Dome A should have a very shallow boundary layer above which we could obtain supreme free atmosphere seeing. All the data from KLAWS-2G can be viewed in real-time on http://aag.bao.ac.cn/klaws/.
Southern Ocean Air-sea Fluxes: An Overview and Contrasts with the Arctic

Simon Josey\(^1\) (simon.josey@noc.ac.uk)
\(^1\)National Oceanography Centre Southampton, Southampton, United Kingdom

The Southern Ocean is a key component of the global climate system: insulating the Antarctic polar region, transferring climate signals and forming the southern component of the global overturning circulation. However, the air-sea fluxes that drive these processes are severely under-observed due to the harsh and remote location. This paucity of reference observations has resulted in large uncertainties in ship-based, numerical weather prediction, satellite and derived flux products. Here, recent and ongoing analyses of Southern Ocean observations from air-sea flux moorings, research ships, atmospheric reanalyses and high resolution coupled climate models will be reviewed. The moorings provide the first accurate near-annual quantifications of the cycle of net air-sea heat exchange and wind stress from Southern Ocean locations. They reveal a strong degree of variability in the net heat flux and are key reference points for addressing the high level of uncertainty that currently exists in Southern Ocean air-sea flux datasets. The reanalysis and coupled model output enables these results to be put in a wider context and the dependence of the air-sea exchanges on atmospheric modes of variability to be explored. Finally, Southern Ocean air-sea interaction will be contrasted with the regime that prevails in the Arctic Ocean with a focus on differences between the dominant terms in the surface heat budget and potential common causes for extreme heat loss events.
There are very few ocean observations during autumn-winter south of the Antarctic ice edge, particularly as far south as the coastal polynyas. In the Ross Sea alone, we know of only three prior autumn-winter U.S. oceanographic expeditions. In 2017 the PIPERS (Polynyas, Ice Production and seasonal Evolution in the Ross Sea) project conducted an oceanographic expedition to the southwestern Ross Sea aboard the RVIB Palmer during April-June. Its main objective was to assess the local/large-scale controls on sea ice production, water mass transformation, and carbon/trace metal inventories during an autumn-winter transition. In contrast to the strong positive sea ice trends observed over 1979-2015, the PIPERS ocean observations were acquired prior to, and during, very anomalous air-sea-ice conditions in the Ross Sea. These hydrographic observations extended from north of the ice edge, to the advancing ice edge, and along south/north transects to/from the coastal polynyas under an anomalously thin ice cover. Extensive observations were collected in Terra Nova Bay before/after several strong katabatic wind events, as well as in front of the Ross Ice Shelf under milder katabatic conditions. These ocean observations (water mass types, mixed layer evolution, heat/salt inventories) will be discussed within the context of the anomalous air-sea-ice conditions that occurred prior to and during PIPERS, as well as to the few autumn-winter ocean observations available for the Ross Sea.
Ocean Forcing of Pine Island Glacier Melt Rate on Weekly to Monthly Time Scales

Peter Davis¹ (petvis@bas.ac.uk), Adrian Jenkins¹, Keith Nicholls¹, Paul Brennan², Povl Abrahamsen¹, Karen Heywood¹, Pierre Dutrieux⁴, Sang Hoon Lee³, Tae Wan Kim⁵

¹British Antarctic Survey, Cambridge, United Kingdom, ²University College London, London, United Kingdom, ³University of East Anglia, Norwich, United Kingdom, ⁴Lamont-Doherty Earth Observatory Columbia University, New York, United States, ⁵Korea Polar Research Institute, Incheon, Korea, Republic of

Ocean-driven basal melting of Amundsen Sea ice shelves has forced significant acceleration, thinning, and grounding line retreat on many of West Antarctica’s largest outlet glaciers. Here, we present a year-long (2014) time series of basal melt rate at daily resolution from a single location on Pine Island Ice Shelf, and determine the drivers behind the observed variability. Dynamical adjustment of the thermocline to local wind forcing is proposed as the dominant control on basal melting at weekly to monthly time scales, and the temporal variability in the basal melt rate appears to be representative of variability in the basal melt rate over a much wider geographical area. In other years the impact of local wind forcing on thermocline height variability is more limited, highlighting the various time scales of, and the intricate interplay between, the different processes that ultimately set the basal melt rate beneath Pine Island Ice Shelf.
Using Noble Gases to Show Upper Ocean Glacial Meltwater in the Amundsen Sea

Louise Biddle1,2 (louise.biddle@marine.gu.se), Brice Loose3, Karen Heywood2
1University of Gothenburg, Department for Marine Science, Göteborg, Sweden, 2University of East Anglia, Centre for Ocean and Atmospheric Sciences, Norwich, United Kingdom, 3University of Rhode Island, Graduate School of Oceanography, Narragansett, United States

Pine Island Ice Shelf, in the Amundsen Sea, is a region of high ocean-driven basal melting. Tracing the glacial meltwater it produces can help identify the regions most affected by the increased input of this freshwater. Here, optimum multi-parameter analysis is used to deduce glacial meltwater content from independent water mass tracers (hydrographic observations, noble gases and oxygen isotopes), collected during a ship-based campaign in the eastern Amundsen Sea in February-March 2014. Noble gases (neon, argon, krypton and xenon) are used to trace the glacial meltwater, and the results are compared to the standard hydrographic meltwater signature. Differences between the water mass analyses of up to 4 per mil glacial meltwater content are observed, and associated with the erosion of the hydrographic Winter Water properties by the meltwater. The noble gases are used to improve the hydrographic method, by simulating a 'pure' Winter Water endpoint. Remaining differences between analyses can be used to show upper ocean processes such as mixing and biological activity. The corrected glacial meltwater content values show a persistent signature in the upper 400 m of the water column across all of the sample locations (up to 500 km from Pine Island Ice Shelf), with increased concentration towards the west along the coastline.
Convection in the Southern Ocean - What Controls it?

Erik Behrens¹ (erik.behrens@niwa.co.nz), Graham Rickard¹
¹National Institute for Water and Atmospheric Research, Wellington, New Zealand

Open ocean convection ("convection") in the Southern Ocean is rare phenomena. Despite its re-occurrence in the last years it was not present for roughly 40 years. However, coupled and forced simulations show an occurrence of these events in the Southern Ocean on various time and spatial scales with drastic implications for sea ice and heat content. We present results of an extensive sensitivity study of non-eddy resolving and eddy permitting global forced simulations. The sensitivity studies consider changes in the surface freshwater forcing, heat content management of Circumpolar Deep Water, vertical mixing and surface heat flux variations, as well as the parameterisation of mesoscale eddies. Results show that freshwater forcing affects directly surface stratification and thus the occurrence and intensity of convection. It will be demonstrated that brine rejection as a consequence of sea ice growth and thus stratification during winter season is a potential critical trigger for convection. Furthermore, we will show that increased vertical mixing leads to postponed onset of deep convection but not to a reduction as other studies have suggested. Mesoscale eddies reduce convection, since they tend increase the surface stratification.
Preconditioning of the Weddell Sea Polynya by the Ocean Mesoscale and Overflows

Carolina O. Dufour¹ (carolina.dufour@mcgill.ca), Adele K. Morrison², Stephen M. Griffies³, Ivy Frenger⁴, Hannah Zanowski⁵, Michael Winton¹

¹McGill University, Atmospheric and Oceanic Science, Montreal, Canada, ²Australian National University, Research School for Earth Sciences, Canberra, Australia, ³NOAA/Geophysical Fluid Dynamics Laboratory, Princeton, United States, ⁴GEOMAR Helmholtz Centre for Ocean Research Kiel, Kiel, Germany, ⁵University of Washington, Joint Institute for the Study of the Atmosphere and Ocean, Seattle, United States

The Weddell Sea polynya is a large opening in the open-ocean sea ice cover associated with intense deep convection in the ocean. A necessary condition to form and maintain a polynya is the presence of a strong subsurface heat reservoir. This study investigates the processes that control the stratification and hence the buildup of the subsurface heat reservoir in the Weddell Sea. To do so, a climate model run for 200 years under preindustrial forcing with two eddying resolutions in the ocean (0.25° CM2.5 and 0.10° CM2.6) is investigated. Over the course of the simulation, CM2.6 develops two polynyas in the Weddell Sea, while CM2.5 exhibits quasi-continuous deep convection but no polynyas, exemplifying that deep convection is not a sufficient condition for a polynya to occur. CM2.5 features a weaker subsurface heat reservoir than CM2.6 owing to weak stratification associated with episodes of gravitational instability and enhanced vertical mixing of heat, resulting in an erosion of the reservoir. In contrast, in CM2.6, the water column is more stably stratified, allowing the subsurface heat reservoir to build up. The enhanced stratification in CM2.6 arises from its refined horizontal grid spacing and resolution of topography, which allows, in particular, a better representation of the restratifying effect by transient mesoscale eddies and of the overflows of dense waters along the continental slope.
Some Like it Hot: Metagenomics of an Isolated Antarctic Geothermal Refugium

Stephen Craig Cary¹,² (caryc@waikato.ac.nz), Craig Herbold¹,³, Charles Lee¹,³, Chelsea Vickers¹, Ian McDonald¹
¹University of Waikato, International Centre for Terrestrial Antarctic Research, Hamilton, New Zealand,
²University of Delaware, College of Earth, Ocean, and Environment, Lewes, United States, ³University of Vienna, Department of Microbiology and Ecosystem Science, Vienna, Austria

Geothermal systems in Antarctica support a diverse microbiota and may have served as essential refugia for terrestrial organisms during periodic glacial maxima. As the most remote geothermal environments on the planet, they provide a rare opportunity to address questions around microbial biogeography and the interactions between globally distributed and endemic microbes. Despite their biological importance, these extremely remote geothermal locations remain vastly understudied. Tramway Ridge, an Antarctic specially protected geothermal area (ASPA 175 - elevation 3340 m), located near the summit of Mount Erebus, is home to a unique and poorly understood community of micro-organisms. Here we provide the first metagenomic characterization of high-temperature fumarolic sediments, and the first from terrestrial Antarctica. We recovered 17 nearly complete genomes, representing 11 prokaryotic phyla/divisions to infer their role in the environment. Our results demonstrate that the subsurface of Tramway Ridge on Mount Erebus is dominated by novel, possibly endemic deep-branching members of several bacterial phyla, and a single deep branching relative of the Thaumarchaeota. Based on its phylogenetic position and novel functional attributes we propose Candidatus Austellarchaeum erebusii to help infer the defining characteristics of the earliest Thaumarchaeota.
Dynamics of Microbial Community Succession in Polar Deglaciated Forefields

Asuncion de los Rios1 (arios@mncn.csic.es), Isaac Garrido-Benavent2, Carmen Ascaso2, Rüdiger Ortiz-Alvarez3, Starri Heiðmarsson4, Francisco Navarro5, Ricardo Rodríguez5, Sergio Pérez-Ortega1,6
1Museo Nacional de Ciencias Naturales, CSIC, Madrid, Spain, 2Museo Nacional de Ciencias Naturales, CSIC, Biogeoquímica y Ecología Microbiana, Madrid, Spain, 3Centro de Estudios Avanzados de Blanes/ CSIC, Blanes, Spain, 4Icelandic Institute of Natural History, Akureyri, Iceland, 5E.T.S. de Ingenieros de Telecomunicación/UPM, Madrid, Spain, 6Real Jardin Botánico, Madrid, Spain

Melting glaciers in polar regions are indicators of global warming. A key consequence of the gradual ice retreat is that new terrestrial habitats are created as recently exposed soils and rocks are susceptible to biological colonization. Microorganisms are the first colonizers and subsequently vascular plants and cryptogams establish. Thus, glacier forefields offer a type of natural experiment in which temporal colonization dynamics can be explored.

In this study, chronosequences at Breiðamerkurjökull (Iceland) and Hurd (Livingston Island, Antarctica) glaciers were used as a comparative framework to examine microbial forefield colonization dynamics in both polar regions. By high-throughput amplicon sequencing of fungal and bacterial communities combined with scanning electron microscopy, we identified microbial colonizers at different successional stages and assessed the specific colonization features of polar deglaciated areas. Microbial community structure in recently uncovered soils and rocks (close to the glacier front) differed considerably from the components found in later successional stages with cryptogam covers. Similar succession patterns were detected for soil microbial communities along both glacier forefields. However, different colonization strategies were shown by lithobiontic communities in each polar region, as the extent of colonization was determined both by exposure time and by the textural features of the rocks.
Cyanobacterial Diversity from Pole to Pole: Metagenome of Arctic and Antarctic

Nur Fadzliana Abdul Rahman¹, Wan Maznah Wan Omar² (wmaznah@usm.my), Peter Convey³
¹Universiti Sains Malaysia, Penang, Malaysia, ²Universiti Sains Malaysia, School of Biological Sciences, Penang, Malaysia, ³British Antarctic Survey, Cambridge CB OET, Malaysia

Cyanobacteria are the most ancient and widespread group of photosynthetic prokaryotes, which had a major role in the evolution of the plant kingdom and Earth’s atmosphere. They are primary producers in a wide variety of habitats, and are able to thrive in harsh environments. In this study, metagenomic approach was used to determine the diversity of cyanobacteria in soil samples collected from selected areas of Antarctica (Browning Peninsula, Dee Island, Greenwich Island and Reeve Hills) and Arctic (Spitsbergen, Kvartsitsletta and Baranowski Polar Station). DNA was extracted using Mo-Bio Powersoil DNA kit and the genomic DNA was sequenced using Illumina, MiSeq with targeted V3 and V4 regions. The reads were then processed using Qiime with at least 97% similarity. East Antarctica (Browning Peninsular and Reeve Hills) recorded nine species of cyanobacteria and west Antarctica (Dee Island and Greenwich Island) recorded seven species. The Arctic recorded the least numbers of species; five in the east sampling localities (Kvartsitsletta and Polar Station Baranowski). *Nostoc* sp., *Leptolyngbya* sp. and *Pseudanabaena* sp. were dominant in all Arctic and Antarctic samples. The cyanobacterial diversity in Antarctica was higher than the Arctic. Thus, metagenomic is important as a reliable tool to study the cyanobacteria diversity in soils.

**Keywords:** Cyanobacteria, Antarctic, Arctic, poles, sequencing, metagenomics.
On the Antarctic continent, cyanobacterial mats are widespread in the lacustrine biotopes and they often dominate the phototrophic biomass. Their diversity and biogeography are poorly understood because most studies cover a limited geographic area or are based only on morphotypes. Therefore, cyanobacteria are not fully taken into account in the biological datasets used to delineate conservation biogeographic regions (ACBRs). Recently, we have shown by 454 pyrosequencing of cyanobacteria-specific 16S rRNA amplicons that their distribution across the lacustrine ecosystems could be explained by ecological parameters (e.g. salinity and dissolved organic carbon). In order to further test this hypothesis, we significantly increased the spatial coverage of our samples. Here, we describe the results of 16S rRNA amplicons Illumina sequencing of 98 cyanobacterial mat samples from 10 ACBRs. From the 16012393 raw reads, 713 OTUs were obtained by bioinformatics analysis. Preliminary results show that both ecological parameters and latitude could explain the patterns of cyanobacterial communities. Indeed, nonmetric multidimensional scaling shows that sub-Antarctic samples (Macquarie and Marion Islands) group with North-East Antarctic Peninsula samples, whereas more continental samples (e.g. East Antarctica, South Victoria Land) group together. These findings can form the basis for a better understanding and a more adequate conservation of lacustrine ecosystems in Antarctica.
Did Antarctic Lichens Originate in, or Arrive to, Antarctica?

Isaac Garrido-Benavent¹ (igbenavent@mncn.csic.es), Sergio Pérez-Ortega², Asunción de los Ríos¹
¹National Museum of Natural Sciences-CSIC, Biogeochemistry and Microbial Ecology, Madrid, Spain, ²Royal Botanical Garden-CSIC, Mycology, Madrid, Spain

Lichens represent a paradigm of mutualism between two or more phylogenetically unrelated organisms involving an heterotrophic fungus, also called the mycobiont, and a population of at least one photosynthetic partner, either a green alga or cyanobacterium. About 500 lichens (ca. 2.5% of all known species worldwide) occur in Antarctica and reach as far as 84º S. They constitute the most conspicuous component of terrestrial macrobiota. Biogeographic evidence shows that about 38% of the current lichen diversity is shared with the Arctic and Sub-Arctic regions (bipolar distribution). Long-distance dispersion has been commonly invoked to explain this disjunct distribution pattern, but it is still unknown whether those species originated in or arrived to Antarctica. Similarly, the proportion of endemic Antarctic lichens is considerable (ca. 33%); several authors have suggested that these lichens have an ancient origin which pre-dates the last glaciations, implicating that these species may have taken refuge in ice-free areas. So far however, no studies have formally tested hypotheses modelling allele evolution in space and time in bipolar and endemic Antarctic species. Herein, through phylogeography analyses (including genetic clustering, divergence time estimation and gene flow inference), we provide evidence for the colonization of Antarctica in the Pleistocene by some bipolar species, and point to endemics as long-term inhabitants of this continent.
Microbial Biogeography in Arctic Soils

Lucie Malard¹ (lucie.malard@northumbria.ac.uk), David Pearce¹
¹Northumbria University, Faculty of Health and Life Sciences, Newcastle upon Tyne, United Kingdom

With a relatively low number of studies investigating microbial diversity in pristine Arctic soils and different analytical approaches used in each, the identification of microbial biogeographical patterns across the region remains difficult. Currently, differences in microbial communities are generally described on small scales, however, whether these are true ecological difference or merely methodological variations remains to be properly investigated. Furthermore, few studies have shown an absence of large-scale variation while other studies suggest regional differences. Using a small scale, mid-scale and pan-Arctic soil sampling design, we aimed to investigate the level of sampling required to understand terrestrial spatial patterns of microbial diversity across the Arctic.

We analysed core physico-chemical properties of sampled soils, used amplicon-sequencing and geostatistics to investigate biodiversity, diversity hotspots and to understand the potential drivers of microbial diversity in Arctic terrestrial ecosystems.

We identified microbial biogeographical patterns on different scales, with distinct Arctic regions harbouring different microbial communities. Alaska and Canada appear to support different communities than the European Arctic and Siberia. Identifying biogeographical patterns is a step towards a better understanding of microbial diversity and its drivers in the Arctic region.
The Soundscape of Western Fram Strait - A Key Habitat for Endemic Arctic Cetaceans

Heidi Ahonen¹ (heidi.ahonen@npolar.no), Kathleen Stafford², Laura de Steur¹, Christian Lydersen¹, Øystein Wiig³, Kit Kovacs¹
¹Norwegian Polar Institute, Fram Centre, Tromsø, Norway, ²University of Washington, Applied Physics Laboratory, Seattle, United States, ³University of Oslo, Natural History Museum, Oslo, Norway

Global warming and concomitant reductions in sea ice will affect the underwater soundscape of the Arctic, with the greatest changes expected to be linked to anthropogenic activities. Ocean noise is a growing conservation concern, but management of underwater noise pollution is constrained by a lack of baseline data. To address this concern, and to document area use by marine mammals, an acoustic recorder has been deployed on an oceanographic mooring in western Fram Strait (78°49N, 4°59W) 2008- present. Analyses show that the mean overall sound level of this area was low to moderate (< 60 dB). The level of anthropogenic activity in the region was low, with few ships traversing the area. However, airgun signals were prevalent throughout most of the year, in all years. During summer/autumn, signals from airgun surveys were detected > 12 h/day. Vocalisations by fin and bowhead whales were the main biotic sounds during autumn-spring. Nearly constant singing by bowhead whales dominated the winter soundscape at frequencies between 100-1000 Hz. Narwhal signals occurred year round, suggesting that this area is also important for this endemic Arctic cetacean. Bearded seal vocalisations were detected March-July, whereas blue whale calls were recorded mainly during summer/autumn. This study outlines the main contributors to the soundscape of western Fram Strait, describes seasonal patterns of both noise and biota and thus provides baseline data from which changing trends can be monitored.
Sea Noise from Southern Australia to Eastern Antarctica

Robert McCauley¹ (r.mcccauley@curtin.edu.au), Curt Jenner², Micheline Jenner², Chritine Erbe¹, Alexander Gavrilov¹

¹Curtin University, Perth, Australia, ²Centre for Whale Research, Fremantle, Australia

In conjunction with the Australian Antarctic Division sea noise data was collected from moorings at 44°S (2006-2007), 54°S (2006-2009) and 65°S (2006-2007) using Curtin’s underwater sound recorders. In January 2014, during a cruise of RV Whale Song south from Hobart, to and along the ice edge (138°6'E to 115°42'E) and returning to Fremantle, Western Australia, 140 sonobuoys were deployed at a ~4 hour interval. Mooring data showed seasonal trends in calls from whales: Antarctic blue; Antarctic minke; fin; Australian pygmy blue (to 54°S only); and the unidentified species producing the so-called ‘spot’ call. Seal calling showed pronounced seasonal patterns with a large variety of signal types. South of the Antarctic convergence sperm whale clicking and seal calling rates increased towards Antarctica. Feeding humpbacks near the ice edge were largely silent except on one occasion an animal approached a wide-band sonobuoy and produced a signal at ~20 kHz. General, nondescript increases in high-frequency sea noise were detected in the presence of large krill aggregations. Vessel noise was comparatively rare along the Antarctic coast. Seismic survey signals from a vessel operating over the western edge of Bass Strait (~ 40°S) in 2006 were detected on the line of stationary recorders to 65°S, although only when the vessel was operating over the shelf slope and at low levels. This presentation will discuss major trends in sea noise south of Australia and down to the Antarctic coast.
Estimating the Distribution of Vocalizing Whales from Ambient Sound Spectra

Sebastian Menze (sebastian.menze@imr.no)
Institute of Marine Research, Bergen, Norway

Marine mammal vocalizations are transient sounds, but the combined sound energy of a population continuously repeating a vocalization, adds up to a quasi-continuous chorus. These choruses are frequently observed as peaks in ambient sound spectra throughout the world's oceans. Here I present an approach to estimate the distribution of vocalizing marine mammals from averaged ambient sound spectra. This is an extremely under-determined inverse problem. The method is based on inverse theory and uses simulated annealing to find the most likely distribution of sound sources (vocalizing animals) on a geodesic grid. This includes calculating a transmission loss matrix connecting all grid nodes and recorders, using an arbitrary sound propagation model. Two models were successfully implemented: geometrical spreading and the ray trace model BELLHOP.

The inversion method was tested under different simulated scenarios for vocalizing fin whales in the North Atlantic (ambient sound peak at 20 Hz). The accuracy of the inversion mainly depends on the number and distribution of recorders. For the Norwegian Sea, simulations indicate that fin whale chorus inversion is possible using as few as 12 recorders between Iceland and Svalbard. Further development and application of the proposed method could admit automatic year-round monitoring of marine mammal distribution on a basin-wide scale, using existing mooring and float platforms.
The Canada Basin Acoustic Propagation Experiment (CANAPE) involved measuring underwater acoustic propagation and ambient noise in the Arctic over the course of a year. As a part of this experiment, from October 2016 to October 2017, four vertical hydrophone arrays were deployed north of Barrow, Alaska. The arrays were moored in water depths between 100 and 300 m. Each array recorded at approximately 15% duty cycle at sample rates between 4000 Hz and 64000 Hz, with a 24-bit dynamic range. The data from each recorder were processed to produce 1-minute metrics over the entire duration. The 1-minute metrics were then processed to look for correlations over time, frequency, space, and with environmental factors such as weather and ice cover, including ice keel depth inferred from high-resolution Radarsat images. The recorders were all equipped with Chip-Scale Atomic Clocks (CSAC), enabling each acoustic time series to be precisely time-aligned with the others as well as with supporting oceanographic and remote sensing data. Therefore the changes in soundscape can be compared at a wide range of temporal and spatial scales. We will compare the soundscape temporal and spatial variability over spatial scales of 20-50 km and time scales of seconds up to one year, in the area of the continental shelf break between the Chukchi Sea and the Canada Basin.
Seismic airguns used in scientific surveys in the Southern Ocean produce high-intensity impulsive sounds with most energy concentrated in the low frequency band. This frequency range overlaps with many marine mammal vocalizations, especially the songs and calls of baleen whales. Even at large distances from the source, airgun noise may therefore interfere with marine mammal communication.

In order to assess the masking effect of airgun noise we first studied the propagation of airgun signals in the Southern Ocean. A parabolic equation approximation was used to model sound propagation. The propagation models were verified based on recordings and metadata for two seismic surveys in the Southern Ocean. Numerical predictions are consistent with the measurement results within a few dBs for the sound exposure and energy spectral levels.

Subsequently we studied the ability of a listening animal to detect vocalisations of a conspecific in the absence and presence of propagated airgun noise. The auditory detection process was modelled using a spectrogram correlation.
Marine Soundscape Planning: Seeking Acoustic Niches for Anthropogenic Sound

Ilse Van Opzeeland1,2, Olaf Boebel1 (olaf.boebel@awi.de)
1Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Ocean Acoustics, Bremerhaven, Germany, 2Helmholtz Institute for Functional Marine Biodiversity (HIFMB) at University Oldenburg, Oldenburg, Germany

Both marine mammals and hydroacoustic instruments use underwater sound to communicate, navigate or infer information about the marine environment. Concurrent timing of acoustic activity or the use of similar frequency regimes may result in (potentially mutual) masking of acoustic signals when both sources are within reception range. In analogy to landscape planning, the concept of marine soundscape planning aims to reconcile potentially competing uses of acoustic space by managing the anthropogenic sound sources. We here present a conceptual framework exploring the potential of soundscape planning in reducing (mutual) acoustic interference between hydroacoustic instrumentation and marine mammals. The basis of this framework is formed by the various mechanisms by which acoustic niche formation occurs in species-rich communities that acoustically coexist while maintaining high fidelity (hi-fi) soundscapes, i.e., by acoustically partitioning the environment on the basis of time, space, frequency and signal structure. Hydroacoustic measurements often exhibit certain flexibility in their timing, signal characteristics and even instrument positioning, offering the opportunity to minimize the underwater acoustic imprint. We evaluate how the principle of acoustic niches could contribute to reduce potential (mutual) acoustic interference based on actual acoustic data from three recording locations in polar oceans.
International Ocean Discovery Program (IODP) Expedition 374 was scheduled to collect a latitudinal and depth transect of six drill sites in the eastern Ross Sea in January to March 2018. The expedition will resolve the relationship between climatic/oceanic change and West Antarctic Ice Sheet (WAIS) evolution over the past 20 million years. This location was selected because numerical ice sheet models indicate that it is highly sensitive to changes in ocean heat flux and sea level. The drilling was designed for optimal data-model integration, which will enable an improved understanding of the sensitivity of WAIS mass balance during warmer-than-present climates (e.g., Pliocene and middle Miocene). The objectives were to 1) Evaluate the contribution of WAIS to far-field ice volume and sea level estimates; 2) Reconstruct ice-proximal atmospheric and oceanic temperatures to identify past polar amplification and assess its forcings/feedbacks; 3) Assess the role of oceanic forcing on WAIS stability/instability; 4) Identify the sensitivity of the WAIS to Earth’s orbital configuration under a variety of climate boundary conditions; 5) Reconstruct eastern Ross Sea bathymetry to examine relationships between seafloor geometry, and ice sheet stability/instability. We will present the initial scientific results that resulted from this expedition, with a focus on the paleoenvironmental reconstructions that were obtained from the sedimentological, geochemical and paleontological datasets.
Initial Seismic Stratigraphic Results from IODP Exp. 374 in the Ross Sea

International Ocean Discovery Program Expedition 374 will core several sites in the Ross Sea in January-March 2018. The geological records will recover the distal component of a Neogene latitudinal and depth transect across the continental shelf and rise, with previous ANDRILL and DSDP Leg 28 sites comprising the ice-proximal component. This transect approach will allow for assessment of oceanic drivers of marine ice sheet instabilities. The existing reflection seismic data suggests that intervals with limited ice cover occurred among episodes of grounded ice that extended to the shelf margin during the Neogene. Following initial shipboard characterization of the cores during the Exp. 374, the correlation between synthetic logs at the new drill sites and the crossing seismic sections will provide crucial information about the age and the environmental conditions during the deposition of glacial and marine strata. Changes in the bathymetry of the continental shelf are important for understanding the dominant West Antarctic Ice Sheet mass balance controls. The stratigraphic information from the Exp. 374 will allow us to date the paleobathymetric maps of the main seismic unconformities and therefore provide a measure of the geomorphological changes under the action of the ice sheet and ocean circulation. The results will be fundamental for numerical ice sheet models aimed to infer the past Antarctic volume fluctuation contribution to Neogene sea-level changes.
Modeling Antarctic Climate and Ice-sheet Variability in the Mid-Miocene

Anna Ruth Halberstadt\textsuperscript{1} (ahalberstadt@umass.edu), Rob DeConto\textsuperscript{1}, Edward Gasson\textsuperscript{2}, Douglas Kowalewski\textsuperscript{3}, Richard Levy\textsuperscript{4}, Timothy Naish\textsuperscript{5}, Hannah Chorley\textsuperscript{5}

\textsuperscript{1}University of Massachusetts-Amherst, Department of Geosciences, Amherst, United States, \textsuperscript{2}University of Sheffield, Department of Geography, Sheffield, United Kingdom, \textsuperscript{3}Worcester State University, Department of Earth Environment and Physics, Worcester, United States, \textsuperscript{4}GNS Science, Department of Paleontology, Lower Hutt, New Zealand, \textsuperscript{5}Victoria University of Wellington, Antarctic Research Centre, Wellington, New Zealand

The mid-Miocene Climatic Optimum (~17-15 Ma) serves as a possible analog for future Antarctic conditions, because atmospheric CO\textsubscript{2} concentrations were similar to those projected for the next few decades. During the mid-Miocene Climatic Transition, the Antarctic Ice Sheet evolved into a continental ice sheet roughly resembling its modern geometry.

Near-shore marine records from the Ross Sea (ANDRILL-2A; Levy et al., 2016) imply highly dynamic AIS behavior in the mid-Miocene. Reconstructed environmental conditions during this time period range from a fully glaciated Ross Sea region to a smaller 'interglacial' ice sheet during warmer conditions with higher CO\textsubscript{2} and orbital forcing sensitivity. These records are seemingly inconsistent with sedimentary and geomorphic studies in the McMurdo Dry Valleys (MDVs) that suggest the East Antarctic Ice Sheet was mostly invariable since the mid-Miocene (Sugden & Denton, 2004).

Here, we use a Regional Climate Model with a range of greenhouse gas concentrations, orbital configurations, ice sheet and shelf geometries, and sea surface conditions to reconcile the apparent dichotomy between marine and terrestrial records during the mid-Miocene. Model results are compared with emerging terrestrial data from the Friis Hills in the MDVs to test the hypothesis that climate in the marginal, continental setting of the MDVs remained relatively cold and insensitive to a highly variable West Antarctic Ice Sheet and marine conditions in the proximal Ross Sea.
Marine sediment records from circum Antarctica show that the ice sheet volume and extent fluctuated substantially through time. The understanding of past Antarctic ice sheet (AIS) dynamics highly depends on the reconstruction of the bedrock and seabed morphologies evolution in time. Paleo-bathymetries based on reflection seismic interpretation combined with sediment cores analysis show that the marine basins of Antarctic continental shelf over-deepened through time. A first step of inner continental deepening below sea level, resulted from the fluctuations of a dynamical and temperate AIS, increasing in volume in response to global cooling prior to mid-Miocene (~15 Ma). A second step occurred between ~15 and 3 Ma, when the AIS, gradually more stable and cold-based (as recorded by decreasing sedimentation rates), fluctuated over the continental margins, thus causing an over-deepening with a pronounced landward slope due to the erosion and sediment transport from the inner shelf to the outer shelf and slope. We investigate the impact of over-deepening on the AIS by means of an ice-sheet model forced by Mid-Miocene and Last glacial cycle warm and cold climates. Idealised bathymetries based on BEDMAP2 are used to test the importance of ice fluxes, ocean water masses and bathymetry in the advances and retreats of the AIS. Results show the increasing influence of ocean on the AIS while the circum Antarctic continental margins gradually over-deepened through time.
Pre-glacial to Glacial Amundsen Sea Shelf from Seismic and Seabed Drill Records

Karsten Gohl1 (karsten.gohl@awi.de), Gabriele Uenzelmann-Neben1, Robert Larter2, Johann Klages3, Claus-Dieter Hillenbrand2, Torsten Bickert1, Steve Bohaty4, Ulrich Salzmann5, Thomas Frederichs3, Catalina Gebhardt1, Katharina Hochmuth1
1Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Dept. of Geosciences, Bremerhaven, Germany, 2British Antarctic Survey, Cambridge, United Kingdom, 3MARUM at University of Bremen, Bremen, Germany, 4University of Southampton, Ocean and Earth Science, Southampton, United Kingdom, 5University of Northumbria, Dept. of Geography and Environmental Sciences, Newcastle, United Kingdom

The sedimentary sequences of the Amundsen Sea Embayment (ASE) shelf contain records that have the potential to reveal the environmental and ice sheet evolution from pre-glacial to glacial times for a very dynamic sector of the West Antarctic Ice Sheet (WAIS). The currently observed massive loss of continental ice in this region may be a precursor to a partial or full collapse of the WAIS. Deciphering paleoclimate and paleo-ice sheet records from the shelf sediments is therefore a major scientific objective for studying processes of past warm times that can be considered as analogues to the present and future WAIS behavior. In previous work, the seismic stratigraphic model of the shelf was based solely on long-distance jump correlation with seismic records from the Ross Sea shelf. New MeBo70 seabed drill cores collected in early 2017 from the ASE shelf contain unconsolidated to highly consolidated sediments spanning time periods from the Holocene to Cretaceous. We are now able to correlate the mapped seismic horizons and units with the physical property and age information from the drill cores to obtain new insight into the sedimentary and paleoenvironmental development of the entire shelf. The drill records and seismo-stratigraphic units of the ASE provide new constraints on the timing of the transition from the pre-glacial terrestrial environment of the Cretaceous-Paleocene to marine transgression thereafter, and the first advances of grounded ice across the shelf.
Of notable interest, but poorly understood, is the magnitude and sensitivity of Oligocene and Miocene (35-5 Ma) Antarctic ice sheet change, and the role of warm ice-proximal oceans in past ice sheet behaviour. Oligocene and Miocene sediments were recovered from the Wilkes Land continental Margin. These allowed us to investigate Oligo-Miocene Southern Ocean oceanographic regime and variability therein also in older sedimentary archives. We will present quantitative paleoceanographic reconstructions based on dinoflagellate cyst and biomarker studies on Site U1356 and Site 269. These sites are conveniently situated below the present-day Antarctic divergence, and are today dominated by sea-ice affiliated dinoflagellates. The obliquity-paced glacial-interglacial variability detected in the lithologies allows us to separate our results between glacial and interglacial extremes. In the Oligo-Miocene we document the dominance of dinocysts which now thrive at the subtropical front. Moreover, we note considerable variation in oceanographic regime at the overlying site over glacial/interglacial extremes, arguing for profound oceanographic and SST changes over g-i cycles. Our results argue for a fundamental different and variable oceanographic regime during the Oligo-Miocene compared to today. We argue that much of the Oligo-Miocene benthic foraminiferal δ¹⁸O variability may be explained by Southern Ocean surface ocean change, rather than ice volume change.
Stunning Stress Adaptation of a Black Fungus and Implications for Astrobiology

Claudia Pacelli¹ (pacelli@unitus.it), Laura Selbmann¹, Laura Zucconi¹, Silvano Onofri¹
¹University of Tuscia, Department of Ecological and Biological Sciences (DEB), Viterbo, Italy

The McMurdo Dry Valleys in Antarctica are the coldest hyper-arid desert on Earth characterized by several environmental stressors including low temperatures, freeze-thaw cycles, low water availability, high solar and UV irradiation; they are the best terrestrial analogue for Mars. Suitable niches for microbial colonization exist inside the rocks where some microorganisms can find a refuge. The cryptoendolithic endemic black fungus Cryomyces antarcticus demonstrated huge ability to withstand stresses beyond the conditions, already prohibitive, of its natural environment.

Here, we review the ability of C. antarcticus, to resist temperature cycles (-20°C/+20°C), high temperature (+90°C), high saline concentration (up to 25% NaCl), high UV exposure (up to 5x10⁵ kJ/m²), ionizing radiation (Co⁶⁰, up to 55.81 kGy) and α particles (He²⁺, up to 1000 Gy). The fungus survived and recovered the metabolic activity even after 1.5 years of real space exposure (10⁻⁴Pa vacuum, -20°C/+47°C, 439 MJ/m² UV irradiation) and simulated Martian conditions (-25°C, Mars-like CO₂ atmosphere, 980Pa). For this remarkable resistance, this fungus is nowadays considered the best eukaryotic model for astrobiological researches.

The outcomes of these studies outstretched the concept of limits for microbial life and are giving clues for defining the boundaries for habitable environments on Earth, discovering life in environments previously considered sterile, and assessing the habitability of Mars or other planets.
New Finding of *Marinilactobacillus* sp in the Subglacial Antarctic Lake Vostok

Sergey Bulat¹ (bulat@omrb.pnpi.spb.ru), Maxim Doronin¹, Elizabeth Rudaya¹, Dominique Marie²

¹Petersburg Nuclear Physics Institute of NRC ‘Kurchatov Institute, St Petersburg, Russian Federation, ²Station Biologique de Roscoff, Roscoff Cedex, France

The objective was to search for microbial life in the subglacial Antarctic Lake Vostok by analyzing the uppermost water layer entered the borehole and got frozen within following three lake unsealing (05.02.2012; 25.01.2015; 03.02.2015). The borehole-frozen water samples proved to be generally contaminated with the drill fluid. The cell concentrations varied from 167 (drillbit frozen water) until 5.5 - 38 cells per ml (clearer borehole-frozen samples). The sequencing of 16S rRNA genes came up with total 62 bacterial phylotypes. Of them only 3 phylotypes successfully passed all contamination criteria. Two phylotypes both detected after the 1st lake unsealing were reported before (Bulat, 2016) - hitherto-unknown and phylogenetically unclassified phylotype w123-10 showing less than 86% similarity with known taxa and likely belonging to *Parcubacteria* Candatus *Adlerbacteria* featured by unusual biology and 3429v3-4 showing 93.5% similarity with *Herminiimonas glaciei* of Oxalobacteraceae (Beta-Proteobacteria) - water-inhabited ultramicrobacterium isolated from deep Greenland ice core. The new finding just came from the samples after the 3rd lake unsealing. The phylotype discovered (3698v46-27) showed the conspecificity with several species of *Marinilactobacillus* of Carnobacteriaceae (Firmicutes) featured by very similar 16S rRNA genes (e.g. *M. piezotolerans* from Nankai Trough). Thus, 3 discovered bacterial phylotypes may represent ingenious life forms from the subglacial Lake Vostok.
Arctic Phytoplankton Can Compensate for the Effects of Multiple Stressors

Clara Jule Marie Hoppe¹ (clara.hoppe@awi.de), Klara Wolf¹, Nina Schuback², Philippe D. Tortell³, Björn Rost¹
¹Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, ²Curtin University, Perth, Australia, ³University of British Columbia, Vancouver, Canada

Arctic phytoplankton are exposed to particularly fast rates of environmental change caused by anthropogenic CO₂ emissions. In experiments with natural phytoplankton assemblages from different regions of the Arctic, we found primary production and species composition to be largely insensitive to ocean acidification, warming and changes in irradiances. These results are in contrast to those of similar studies from the Southern Ocean. Our Arctic results imply a high capacity to compensate for environmental change, which can be understood in light of the environmental history of organisms thriving in highly variable environmental conditions. Based on subsequent laboratory experiments and field observations, we could identify the underlying compensatory mechanisms such as physiological plasticity of organisms, intraspecific diversity of populations and functional redundancy of species.
More widespread phytoplankton blooms predicted as the Arctic warms will impact the amount of algal metabolites released in the system which may in turn be a good source of energy, C, N and S to marine bacteria. Here, we assessed the metabolic potential of surface bacterial communities to use one-carbon and methylated algae metabolites in the Baffin Bay during the GreenEdge cruise in summer 2016. The bacterial response to a pulse of metabolites was also determined during 9-d enrichment experiments at sea-ice and open water stations. Bacterial community composition and activity show that despite the capacity to use these compounds in situ, bacteria did not appear to respond to the specific enrichments, suggesting that the summer Arctic bacterioplankton is dominated by generalist taxa adapted to an already rich environment. These results, complemented by quantification of functional genes of interest and single cell activity, will help understand whether the Arctic bacterioplankton is well adapted to use and cleave some of the algae metabolites (such as methanol, methylamines and DMSP) which may influence the fluxes of trace gases to the atmosphere. This is of particular importance as the sea-ice coverage declines increasing the area of potential sea to air exchange and the effect of biological emissions on atmospheric chemistry and radiative budget.
Antarctic Subglacial Environments and the Extremophiles That They Host

Jill Mikucki¹ (jmikucki@utk.edu), Richard Campen¹, Bruce Boles¹, Ellen Taylor¹, Aaron Perry¹, Samantha Vancleave¹, Peter Lee²
¹University of Tennessee, Knoxville, United States, ²College of Charleston, Hollings Marine Laboratory, Charleston, United States

We now know that groundwater, saturated sediments and hundreds of subglacial lakes exist below the Antarctic Ice Sheet. While few have been sampled, subglacial environments are proving to be diverse microbial habitats. Because the overlying glacial ice can be 100s-1000s of meters thick, direct access is logistically challenging and sample acquisition is rare. Two recent drilling expeditions have enabled detailed study of the subglacial biomes below the Whillans Ice Stream (WIS) along the Siple Coast and the Taylor Glacier in the McMurdo Dry Valleys. Below the WIS, Subglacial Lake Whillans, a shallow fresh water lake, drains along the ice sheet base and into the Ross Sea at its grounding zone. Below Taylor Glacier an iron-rich brine episodically emerges at Blood Falls. These ecosystems exhibit measureable microbial metabolic activity and appear to persist independent of photosynthetically derived carbon inputs. Molecular data and biogeochemical measurements indicate these systems are chemically and phylogenetically distinct, however both are chemoautotrophic with energy derived in part by cycling inorganic iron and sulfur compounds. Physiological and genomic characterization of microbial isolates obtained show adaptation to their local environment includes genes for growth at low temperatures and high salt concentrations. Collectively these data suggest that despite extended isolation in icy darkness, microbial life persists and possibly thrives below the Antarctic Ice Sheet.
Cold adapted microorganisms have evolved a large repertoire of adaptation strategies: the biosynthesis of lipids and enzymes with a sufficient physical flexibility to contrast cellular membrane rigidity, and the production of anti-freeze proteins and carbohydrate-based extracellular polymeric substances (EPS), which serve as cryo- and osmo-protectants.  

Colwellia psychrerythraea 34H is an obligate psychrophilic γ-proteobacterium, isolated both from subzero Arctic sediments and Antarctic sea ice. It is considered a model to study adaptive strategies to subzero lifestyle. In the last years, our team has been involved in an in-depth study of the structure of carbohydrate molecules from this model organism and of its role in sea-ice lifestyle. C.psychrerythraea 34H grown at 4°C produces a rough-LPS. In addition, three different exopolysaccharides, a capsule and two totally released polysaccharides, displaying IRI activity, have been found. In this communication, the structural characterization of glycoconjugates molecules produced by Colwellia grown at -2°C, 8°C, and 15°C, is described. This study allowed us to establish how the carbohydrates polymers are involved in Colwellia cold-adaptation.

Improved subarctic and Arctic SWE Retrieval using Passive Microwave over Canada

Alain Royer1 (alain.royer@usherbrooke.ca), Fanny Larue1, Céline Vargel1, Alexandre Roy1, Alexandre Langlois1, Vincent Vionnet2,3, Ghislain Picard4, Emmanuel Cosme4

1University of Sherbrooke, CARTEL, Sherbrooke, Canada, 2University of Saskatchewan, Saskatoon, Canada, 3Environment and Climate Change Canada, Meteorological Research Division, Dorval, Canada, 4Université Grenoble-Alpes, IGE, Grenoble, France

Over northern snow-dominated basins, the snow water equivalent (SWE) is of primary interest for monitoring the global warming impacts. SWE retrievals from satellite microwave (MW) observations, the only type of data sensible to snow volume, are still not well resolved. On the other hand, the use of snowpack models is challenging due to the large uncertainties in meteorological input forcings and the snow model parameterization. This presentation shows improvements for SWE prediction by assimilating satellite brightness temperatures (TB) in a detailed multilayer snowpack model (SURFEX/Crocus) without any ground-based observations and driven by forcing data generated by the 10 km - Canadian GEM model. While the results appear in agreement with continuous in-situ SWE observations for subarctic snow covers over North-Eastern Canada, with 16 to 30% bias accuracy, the simulations are poor for arctic snow (in-situ database at the Cambridge Bay, Nu). We discuss the sources of the main uncertainties, including a bad stratification of the arctic snowpack density and microstructure simulated by the snow model. The presence of ice crusts within the snowpack also generates significant variations in TB that have to be corrected. The snow radiative transfer model SMRT, used in this study, need to be scaled in order to reduce the RMSE between simulated and observed TB. Preliminary results of these improvements, specific for this type of arctic snow, are presented.
A New Dual-frequency Ku-band Radar Mission Concept for Cryosphere Applications

Chris Derksen\(^1\) (chris.derksen@canada.ca), Joshua King\(^1\), Camille Garnaud\(^2\), Stephane Belair\(^2\), Melanie Lapointe\(^3\), Yves Crevier\(^3\), Ralph Girard\(^3\), Juha Lemmetyinen\(^4\), Geoff Burbidge\(^5\), Jose Marquez\(^5\), Duncan Bourne\(^5\)

\(^{1}\)Environment and Climate Change Canada, Toronto, Canada, \(^{2}\)Environment and Climate Change Canada, Montreal, Canada, \(^{3}\)Canadian Space Agency, Longueuil, Canada, \(^{4}\)Finnish Meteorological Institute, Helsinki, Finland, \(^{5}\)Airbus, Portsmouth, United Kingdom

Moderate resolution (~1 km) terrestrial snow water equivalent (SWE) measured across the Northern Hemisphere at a revisit of 1 to 5 days is a priority observational gap which limits operational environmental monitoring, services, and prediction. To address this need, Environment and Climate Change Canada, the Canadian Space Agency, industrial partners at Airbus, and international scientific collaborators are developing a new dual frequency (Ku-band: 13.5 and 17.2 GHz) radar mission concept. Following technical trade-off studies, a concept capable of providing 250m spatial resolution measurements across a 500 km swath was identified. Orbital analysis defined a dawn/dusk orbit flying at a fixed offset of 3.5 hours ahead of Met-Op Second Generation (Sat. B). This orbit will provide synergistic active and passive measurements through complete swath overlap with the multi-frequency Microwave Imager (MWI). This presentation will provide an overview of the technical mission concept, and how it addresses measurement requirements for the primary mission objective of terrestrial snow, and secondary objectives related to sea ice, land ice, and ocean vector winds. Modeling activities to
(1) identify the current state of backscatter modeling capabilities for layered snowpacks at Ku-band,
(2) develop and validate SWE retrieval algorithms, and
(3) determine the potential impact of radar backscatter measurements on radiance-based land surface data assimilation will also be presented.
Monitoring of sea ice processes, i.e. ice edge variations and motion, is important for practical tasks such as ice navigation and for scientific studies. High-resolution data from C-band SAR have been used as the main data source for analysis of the sea ice regime in the Kara Sea to study details of ice distribution as well as changing of the ice conditions and sea ice types. The aims of our study is to develop recommendations for the planning of ship routes around the habitats, migration of the endangered species of fauna objects, taking into account long-term trends, seasonal and interannual variations of the ice conditions in the Kara Sea. To accomplish this goal, an automated classification algorithm based on the support vector machine (SVM) approach for Sentinel-1 Extra Wide (EW) swath dual-polarization mode data (HH + HV), was applied. Several technical issues for Sentinel-1 Extra Wide (EW) data were solved in the pre-processing stage including thermal noise reduction in HV-polarization and correction of angular backscatter dependency in HH-polarization. Texture features were explored and used in addition to supervised image classification. Algorithm was trained to classify types of underlying surface in the Kara Sea region: first-year ice thin, first-year ice medium, young ice, water and nilas. The automated classification is included in the ice conditions monitoring system developed at NIERSC for solving practical problems.
Spatial and Temporal Variability at the Toolik Lake Vegetation Grid (Alaska)

Birgit Heim\textsuperscript{1} (birgit.heim@awi.de), Alison Beamish\textsuperscript{1}, D. A. Walker\textsuperscript{2}, Howard E. Epstein\textsuperscript{3}, Ulrike Herzschuh\textsuperscript{1}, Torsten Sachs\textsuperscript{4}, Sabine Chabrillat\textsuperscript{4}, Maximilian Brell\textsuperscript{4}, Sebastian Roessler\textsuperscript{5}, Marcel Buchhorn\textsuperscript{6}  
\textsuperscript{1}Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research AWI, Polar Terrestrial Ecosystems, Potsdam, Germany, \textsuperscript{2}University of Alaska Fairbanks, International Arctic Research Center, Institute of Arctic Biology, Fairbanks, United States, \textsuperscript{3}University of Virginia, Charlottesville, United States, \textsuperscript{4}Deutsches GeoForschungsZentrum GFZ, Potsdam, Germany, \textsuperscript{5}FIELAX, Bremerhaven, Germany, \textsuperscript{6}VITO, Flemish Institute for Technological Research, Mol, Belgium

Ground data for the validation of satellite-derived terrestrial Essential Climate Variables (ECVs) at high latitudes are sparse. Also for regional model evaluation of terrestrial variables we lack accurate ranges of terrestrial ground data and face the problem of a large mismatch in scale. Within the German research programs Regional Climate Change (REKLIM) and the Environmental Mapping and Analysis Program (EnMAP), we conducted a study on ground data representativeness for vegetation-related variables within a monitoring grid at the Toolik Lake LTE Research station in Alaska. The grid covers an area of ~ 1 km\textsuperscript{2} containing Eight five grid points spaced 100 meters apart. Moist acidic tussock tundra is the most dominant vegetation type. Permanent 1 m\textsuperscript{2} plots were also established to be representative of the individual gridpoints. During summer 2016, we conducted field spectrometry at selected plots during early, peak and late summer. We experimentally investigate more spatially extensive Elementary Sampling Units (ESUs) for the spatial representativeness of the permanent 1 m\textsuperscript{2} plots and to map ESUs for various tundra types. We will present the first data analyses and maps of biophysically-focused ESUs for evaluation of the use of remote sensing data to estimate these ecosystem properties.
Hybrid Sentinel-1 / Radarsat Backscatter Time Series of Arctic Canada

David Small¹ (david.small@geo.uzh.ch), Christoph Rohner¹, Marius Vögtli¹, Nuno Miranda², Stephen Howell³, Yves Crevier⁴
¹University of Zurich, Dept. of Geography, Zurich, Switzerland, ²European Space Agency ESRIN, Frascati, Italy, ³Environment & Climate Change Canada, Toronto, Canada, ⁴Canadian Space Agency, St. Hubert, Canada

The Sentinel-1 satellites (S-1A/S-1B) currently provide approximately 1-2 day close-to-seamless revisit over Ellesmere Island in the Canadian Arctic. The impressive temporal resolution achieved using these two satellites can be further improved by integrating observations from other C-band satellites such as Radarsat-2 and, in the near future, data from the Radarsat Constellation Mission. We employ radiometric terrain flattening and local resolution weighting to generate normalised gamma nought backscatter over wide regions, not restricted to a single sensor or track’s swath width limitations. Ascending and descending passes are integrated into composite backscatter maps. These can be used to generate terrestrial snow/ice-melt and sea-ice-melt products with sufficient temporal resolution to delimit short-lived melting periods.

We illustrate the temporal resolution of wide-area composites time-series achieved by using the Sentinel-1 or Radarsat-2 in isolation. We then compare those results with what can be achieved with hybrid backscatter maps that accept observations from both missions. These tests have been undertaken within the framework of the World Meteorological Organisation’s Polar Space Task Group (PSTG) and SAR Coordination Working Group (SARCWG). We describe coordinating actions that can and have been taken by the space agencies to help ensure generation of properly calibrated “hybrid” backscatter composite values that derive from multiple sensors.
Retrieval of Ice Thickness on Large Northern Lakes from Jason-2 Data

Claude Duguay¹ (crduguay@uwaterloo.ca), Elena Zakharova², Alexei Kouraev², Homa Kheyrollah Pour¹, Marie Hoekstra¹

¹University of Waterloo, Waterloo, Canada, ²Université de Toulouse, LEGOS, Toulouse, France

Lake ice grows steadily between the end of the freeze-up and onset of the break-up periods as a result of the thermodynamics of freezing water as well as dynamic ice motion on the surface. The value of passive microwave and radar altimeter data from satellite altimetry missions has been shown for the determination of ice dates (freeze-up and break-up) and only very recently been evaluated for the estimation of ice thickness. Data acquired from current satellite missions (e.g. Jason-2/3, Sentinel-3) provide an opportunity for investigation of the development of lake ice thickness retrieval algorithms.

The objective of this study is to investigate the potential of radar altimeter and passive microwave radiometer data from the Jason-2 satellite mission for the estimation of ice thickness on large northern lakes. Backscatter and brightness temperature (Tb) measurements from its nadir-pointing radar altimeter (13.575/5.3 GHz) and passive microwave radiometer (18.7 and 34 GHz) are compared against ice thickness estimates obtained with a thermodynamic lake ice model and in situ measurements collected on three lakes in northern Canada over the course of eight ice seasons (2008-2009 to 2015-2016). The temporal evolution of backscatter and Tb is then explored to estimate ice thickness. Results show that both passive microwave and radar altimeter data acquired in the 5-19 GHz frequency range allow for the retrieval of ice thickness on the lakes investigated with a 10-20 cm accuracy.
Since the International Polar Year 2007-2008, polar education, outreach and communication (EOC) has matured significantly. This is illustrated by a shift from ‘pop outreach’ aimed at the general public, to ‘informing decision-making’ targeted at key stakeholders. However, a significant number of scientist communicators still lack the support, training and professional recognition required for effective and thoughtfully designed EOC activities.

Using a mixed-methods approach, including data from interviews and four different surveys, we explore the field of polar EOC over the past ten years. We draw on four polar outreach case studies — an expedition, a documentary, a festival, and an education event — that the authors have been associated with. We supplement this data with a survey of 170 scientist communicators from 22 countries, which shows that while 90% of respondents engage in EOC activities, only 38% have training in science communication and only 10% incorporate formal or external evaluation.

Building on these data, we highlight the current barriers and opportunities associated with the evaluation and reporting of EOC activities. We also present a new framework for engagement design that encourages reflexive practice and mechanisms for development, delivery and evaluation of EOC activities based on explicit and articulated objectives. Through more thoughtful approach to science communication, we hope to increase the value, impact and reach of such activities.
The Arctic is changing rapidly with new business opportunities and environmental threats, calling for enhanced knowledge, efficient education and innovative educational support programmes not least in the fields of STEM. EU H2020 EDU-ARCTIC is a multilingual Pan-European science communication and educational support initiative available for all secondary schools, using Arctic research as a vehicle to encourage pupils aged 13 to 20 to pursue education in science, technology, engineering and mathematics.

Objectives:
- Encourage interest in science, technology, engineering and mathematics (STEM) education to secondary school students
- Provide an innovative and supportive educational program, accessible to schools, educators and students across Europe and beyond
- Establish strong links between the research and education communities by connecting schools to scientists at Arctic research stations and research institutes throughout Europe.

The project uses a mix of different innovative tools and methodologies for science communication supporting STEM education, including virtual lessons with scientists dealing with polar research, environmental monitoring program, teacher trainings and workshops, online Polarpedia, interactive portal explaining scientific terminology through text, images, maps, videos and multimedia tools.

Edu-Arctic has a strong webportal at edu-arctic.eu and uses actively and innovatively Social media outreach and communication tools to reach the widest audience.
Major Lessons from Teaching Young Children Complex, Abstract Polar Concepts

Alexander Thornton¹ (alexander.e.thornton@gmail.com), Gary Wesche²

¹University of Alaska Fairbanks, Fairbanks, United States, ²Polar Educators International, Kansas City, United States

If researchers want to shift public perceptions about complex, abstract concepts—such as impacts of climate change on polar ecosystems—we need to educate young children. Many kids form negative opinions about Science, Technology, Engineering, & Mathematics (STEM) fields by the time they are seven-years-old; after this age, educators must combat previously ingrained attitudes towards STEM to teach new ideas. However, young children are not developmentally mature enough to understand complex, abstract concepts until reaching adolescence after 10-years-old. This mismatch in educational development may seem unfortunate, but is not insurmountable using the right engagement techniques to facilitate a child’s exploration of the polar world. Promoting development of cognitive and emotional intelligence at an early age combats poor polar literacy and mistrust of scientists, opening the door for informed, public conversation on highly-politicized issues like climate change. This presentation highlights experiences teaching complex, abstract polar concepts to elementary school children in Fairbanks, Alaska, USA. We reflect upon methodology and major lessons learned to provide suggestions for scientists interested in communicating broader impacts of their research with children. We will also introduce plans to develop a working group for educators and researchers to collaborate on a resource bank for polar curriculum meeting educational standards in multiple countries.
Teenager and School Teacher Program for the Polar Education and Outreach

Ji Young Lee¹ {jylee@kopri.re.kr}, Hana Cho¹, Mingu Kang¹, Hye Lim Jun¹, Hyoung Chul Shin¹
¹Korea Polar Research Institute, Incheon, Korea, Republic of

A teenager program of Korea Polar Research Institute (KOPRI) has been running for over 10 years, allowing selected individuals sent to visit the polar research infrastructure, usually our Arctic summer research station, and to join the efforts of field scientists. A nation-wide call is made before essay writings and interviews that help us to admit the best prepared and most willing students. Alumni are later invited to remain connected in order to make the most use of collective experiences gained. In some years, this program opted to take some variations to engage school teachers and artists. KOPRI also delivers customized education program, particularly to high school science teachers as a community service, namely the Polar Academy. This also led to our efforts to develop learning materials for students. Utmost challenge is to continue to engage these participants and have them connected and networked. Furthermore, KOPRI makes efforts to actively communicate via new social media; KOPRI vividly portrays activities like this program and others, for example, conducted by field researchers through its coverage of the scientific achievements from the research stations. For example, it creates and distributes contents such as interesting and informative news posts and events to many followers. KOPRI also organizes various events such as ‘feel the polar world yourself’ exhibitions or photo exhibitions in subway stations, to provide the urban audience with polar experiences.
A Decade of USA-Mexico Virtual K-12 Participation in Antarctic Expeditions

Ana Lucia Weissling¹ (ana.lucia.weissling@gmail.com), Julissa Jimenez², Stephen Ackley³, Blake Weissling³
¹University of Texas at San Antonio, Bilingual and Bicultural Studies, San Antonio, United States, ²Grupo Escolar Simon Bolivar, Briones Campus, Xalapa, Mexico, ³University of Texas at San Antonio, Geological Sciences, San Antonio, United States

This session presents an innovative outreach initiative for the education and motivation of young learners on themes related to polar regions and science. Two binational groups of elementary students worked alongside polar scientists in an ongoing collaboration as virtual researchers. A decade of polar research in three Antarctic expeditions, and a teacher-scientist partnership, served as a basis for an interdisciplinary primary and secondary academic model. The project began with a 2nd/3rd grade bilingual class in Texas, transforming the classroom into a virtual icebreaker during the 2007 SIMBA expedition, and afterwards in an Antarctic thematic-unit to develop science knowledge and literacy skills. Many of the same children followed the 2010 Oden and 2017 PIPERS expeditions through digital technology, in classrooms in Texas and Mexico. With guidance by their teachers and support from the scientists, the students have served as ambassadors of polar knowledge and research creating research exhibits, presentations, science fairs, and conferences in their schools and communities, including presenting at the 2012 TABE (Texas Association for Bilingual Education) Conference where students demonstrated their acquired scientific polar knowledge in two languages. Through this session we hope to inform and illuminate an amazing 10 year outreach effort in polar science and education across two languages and cultures, and to promote this model in other schools and programs.
A Global Snapshot on the Thermal State of Permafrost and Active Layer Thickness

Boris Biskaborn¹ (boris.biskaborn@awi.de), Vladimir E. Romanovsky², Sharon S. Smith³, Dmitry Streletskiy⁴, Jeannette Noetzli⁵, Goncalo Vieira⁶, Philippe Schoeneich⁷, Jean-Pierre F. Lanckman⁸, Hugues Lantuit¹
¹AWI, Potsdam, Germany, ²Geophysical Institute, University of Alaska, Fairbanks, United States, ³Geological Survey of Canada, Ottawa, Canada, ⁴George Washington University, Washington, United States, ⁵WSL Institute for Snow and and Avalanche Research SLF, Davos, Switzerland, ⁶CEG/IGOT - Universidade de Lisboa, Lisboa, Portugal, ⁷Institut de Géographie Alpine, Université de Grenoble Alpes, Grenoble, France, ⁸Arctic Portal, Akureyri, Iceland

The Global Terrestrial Network for Permafrost (GTN-P) is part of GTOS of the Global Climate Observing System, a joint undertaking of the WMO, IOC, UNESCO, UNEP and ICSU. GTN-P was established in 1999 by the International Permafrost Association with the goal of systematic and long-term documentation of the distribution, variability and trends of permafrost based on a global network of field measurements. GTN-P developed a Data Management System (gtnpdatabase.org) for the collection, processing (incl. standardization) and dissemination of permafrost data and metadata. Recent data of ground temperature and active layer thickness are being compiled for a new global snapshot of the current permafrost state. Results indicate that permafrost temperature is generally following the trends in air temperature and increasing, especially in the Arctic areas where permafrost is relatively cold. In the Sub-Arctic, where permafrost temperatures are relatively high, the warming trend is less pronounced and at many locations current permafrost temperature is similar to that of the IPY snapshot. In alpine permafrost areas, most measurement sites significant warming. Active layer thickness exhibits large interannual variability, mainly due to variations in snow-cover, but has generally increased since the IPY, especially in the European Arctic sector. In several sites at northwest Antarctic Peninsula, active layer thickness has been stable or even decreased.
Strategies and Data of Long-term Permafrost Monitoring in the Swiss Alps

Jeannette Noetzli¹ (jeannette.noetzli@slf.ch), Benno Staub²
¹WSL Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland; ²University of Fribourg, Department of Geosciences, Geography, Fribourg, Switzerland

The Swiss permafrost monitoring network PERMOS documents the state and changes of permafrost in the Swiss Alps based on ground temperatures measured in boreholes and near the surface, changes in ice content, and rock glacier creep velocities. The core task of long-term monitoring, and at the same time the biggest challenge, is to deliver reliable, robust and comparable measurements from key sites over decades. This requires coherent strategies that are repeatedly evaluated and adapted to new findings from research. The PERMOS Scientific Committee re-evaluated the PERMOS observation strategy in 2017 and we present the main outcomes. They mainly concern further improvement and definition of standard procedures for site maintenance as well as data processing and documentation because PERMOS evolved from individual research activities. The site maintenance in rough conditions is demanding and problems such as shearing of the boreholes and blocked chains can threaten the continuation of the time series. Renovation or re-drilling, for example, require careful planning to achieve overlap of the different systems and to consider experiences and standards. A second major task is a robust data management system with standardized processing and quality control of new and existing data as well as easy access. Finally, the results and assessments should be reported timely and in an understandable and useful way to researchers, authorities and the public.
The Circumpolar Active Layer Monitoring (CALM) program, established in the early 1990s, is designed to observe temporal and spatial variability of the active layer, near-surface permafrost parameters, and their response to changes and variations in climatic conditions. CALM is an integral part of the Global Terrestrial Network for Permafrost (GTN-P). The CALM network incorporates sites distributed throughout the Arctic. The majority of the sites are in Arctic and Subarctic lowlands. At approximately 90 sites, direct active-layer measurements are conducted on standard rectangular grids ranging from 10 x 10 m to 1 x 1 km. The locations of grids were selected to represent generalized surface and subsurface conditions characteristic of broad regions. Vast majority of CALM sites have continuous active-layer records longer than five years and more than 40 have twenty-year records or longer. Auxiliary information includes air temperature, soil moisture, soil temperature at different depth, snow cover, soil composition, and landscape characterization. Several sites have records of frost heave and thaw subsidence. CALM is the world’s primary source of information about the active layer. The data is assimilated and distributed though CALM (www.gwu.edu/~calm) and GTN-P (gtnpdatabase.org) online databases. This presentation summarizes results and accomplishments of the CALM program and project future directions.
The Thermal State and Distribution of Rock Wall Permafrost in Norway

Florence Magnin¹, Bernd Etzelmuller¹, Paula Hilger², Sebastian Westermann¹, Cristian Lussana³, Ketil Isaksen³ (ketil.isaksen@met.no), Reginald Hermanns²
¹University of Oslo, Department of Geosciences, Oslo, Norway, ²Geological Survey of Norway, Geohazard and Earth Observation Group, Trondheim, Norway, ³Norwegian Meteorological Institute, Oslo, Norway

Climatically driven permafrost degradation may be a serious threat to human activities and lives in Norway in areas where steep rock slopes are located above houses, infrastructures and large water bodies. The CryoWALL project (2015-2019) aims at studying rock wall permafrost in some of the most hazardous rockslide areas in Norway. In 2015 and 2016, 20 Rock Surface Temperature (RST) loggers were installed at 10 cm depth in 7 selected sites along a latitudinal transect from 60°50'N to 69°46'N. Twelve of these loggers are located north of the polar circle. In 2016 and 2017, 20 more loggers were installed at the surface of the coastal cliffs, canyons and alpine rock walls in the Ny-Ålesund area (78°55’N) in Svalbard.

The RST time series are used for (a) characterizing the thermal state and distribution of rock wall permafrost (RWP) across Norway and in Svalbard, (b) running steady-state and transient numerical models of RWP at selected sites, and to (c) calibrate a general linear regression model that will be used to (d) predict the spatial distribution of RWP at the national scale. The preliminary analysis shows that the mean RST differs by 3°C between N and S faces in Southern Norway. In Northern Norway the midnight sun and polar night effects, induce similar RST in both aspects during December, January, May and June and with a difference in RST of 1.5°C on annual scale. This first data set is shown to be of high relevance for predictive modelling.
Recent observations of soil surfaces, streams, and glaciers in the McMurdo Dry Valleys of Antarctica (MDV) show extensive evidence of subsidence, channel migration, and surface roughing. To evaluate the spatial distribution and magnitude of change we compared elevations from two airborne LiDAR campaigns, one collected in the summer of 2001-02 and 2014-15. During this period the intensity of solar radiation increased significantly, indicated by long-term meteorological measurements and supported by long-term ecological responses. Results show subsidence is strongly associated with the presence of massive ground ice and with proximity to surface or shallow subsurface (active layer) water. Subsidence occurs across soil types and landforms in both low-lying, low-slope terrain with impeded drainage and high on steep valley walls. These observations, supported by modeling of heat transfer in the soils, highlights the importance of insolation-driven thermokarst warming and thawing in the MDV. The regional melt pattern shows a transfer of water storage from the local cryosphere (glaciers, permafrost) to the hydrosphere (closed basin lakes and ponds). We interpret this pattern as reflective of a transition process to Arctic and alpine-style, hydrologically mediated ground- and surface-ice loss. Although this may be only an episode within current climate variability, it is suggestive of the processes to be expected when the region warms as predicted by climate models.
Estimating Shrub Height as Indicator for Snow Height and Permafrost Modelling

Annett Bartsch1 (anntett.bartsch@zamg.ac.at), Barbara Widhalm1, Marina Leibman2, Ksenia Ermokhina2, Yuri Dvornikov2, Artem Khomutov2, Timo Kumpula3
1Zentralanstalt für Meteorologie und Geodynamik ZAMG, Vienna, Austria, 2Earth Cryosphere Institute, Russian Academy of Sciences, Tyumen, Russian Federation, 3University of Eastern Finland, Joensuu, Finland

Land cover has strong implications for the small-scale distribution of snow cover. Specifically shrub height is required in order to identify areas with trapping of snow and subsequent impact on ground thermal conditions. Current global and circumpolar maps lack thematic detail and/or spatial resolution to appropriately represent shrubs, their types and height. The recently launched Sentinel-2 satellite optical data suitable for land cover monitoring with 10 m spatial resolution. We have selected a transect spanning from the northern tip of the Yamal peninsula (continuous permafrost) to the south into the tundra-taiga transition zone (with discontinuous permafrost) in order to test these data for shrub height retrieval. The region represents not only a gradient in vegetation zones but also sites with high heterogeneity of shrubs. Especially central Yamal is characterized by shrubs of up to 1.5 m height within continuous permafrost. Several studies over a CALM site and additional transects have exemplified the role of the shrubs for active layer thickness in relation to snow using in situ measurements as well as Synthetic Aperture Radar data from satellites in this region. Shrub height measurements have been collected between 2014 and 2017. All available cloud-free images of summer 2016 and 2017 have been combined and seven indices derived. An R² of 0.72 could be obtained. The index can be potentially applied over the entire Arctic to derive maps of shrub height.
A late fall ENSO teleconnection with the midlatitudes involving the so-called tropical Northern Hemisphere pattern has previously been reported. Recently this teleconnection pathway has been hypothesized to extend eastward to the European sector with impacts on late fall continental temperature and precipitation. Given the likely mechanisms of such a teleconnection it is reasonable to propose that there are effects that extend into higher latitudes and the Barents-Kara region, in particular. This study investigates potential links between strong ENSO events and conditions in the Barents-Kara region. Lagged composites show that robust late fall ENSO-European teleconnections extend northward to include tropospheric atmospheric circulation, moisture transport and surface turbulent fluxes over this important and rapidly changing region. Responses linked to El-Niño and La-Niña are generally of opposite sense but are asymmetric suggesting nonlinear relationships. Analyses examining Rossby wave source, eddy heat fluxes, sea ice, and the role of internal variability are also presented, providing further support for a strong link between tropical variability and Arctic climate from early - late fall. Given that fall conditions in the Barents-Kara region are often assigned a driving role in proposed Arctic-midlatitude teleconnection pathways it is important to investigate the degree to which tropical, and other sources of, variability can modulate said pathways.
The El Niño Southern Oscillation teleconnection (ENSO) to the northern extratropics includes a robust response in the Pacific-North America sector, and less robust responses in the Arctic and Euro-Atlantic sector. Recently, Deser et al. (2017) showed that uncertainty in the response arises mainly from atmospheric internal variability rather than from the diversity of El Niño/La Niña events. This presents a challenge in assessing how teleconnections to high latitudes will change under global warming.

We investigate the high latitude atmospheric response to two El Niño and two La Niña events in multi-model large ensembles (at least 100 members per model) for the present climate and in a 2ºC warmer world (relative to pre-industrial climate). The sea surface temperatures (SSTs) are prescribed such that the events themselves are identical in the two periods, but they occur within different background flows.

The multi-model ensemble mean response is stronger in the 2ºC world than for the present climate. This response can be linked to changes in the mean wave-guide for the high latitude teleconnection patterns. We also examine the spread in the responses and the changes in surface impacts associated with end members of the ensemble. The model uncertainty is assessed by looking at model biases in the wave-guide and in poleward propagating Rossby waves excited by tropical sources.
Spring Dust Weather in North China Linked to Sea Ice in the Barents Sea

Ke Fan1 (fanke@mail.iap.ac.cn)
1Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing, China

The link between winter sea ice cover in the Barents Sea (SICBS) and the frequency of spring dust weather over North China (DWFNC) is investigated. It is found that year-to-year variability of SICBS and DWFNC are strongly correlated for the period 1996-2014, whereas the correlation between SICBS and DWFNC is not statistically significant for the periods 1980-1995. During 1996-2014, low winter SICBS is associated with decreased snow cover over western Siberia (SCWS) in both winter and spring, which is also supported by a strengthening relationship between winter SICBS and spring SCWS since the mid-1990s. This leads to changes in atmospheric circulation and climate conditions that are favorable for increased frequency of dust weather events over North China. Our further analysis suggests that the interannual variability of the standard deviation of SICBS has intensified and the center of actions has moved eastward to the north Barents Sea and Kara Sea since the mid-1990s. Such change may easily induce stronger and southward stationary Rossby wave, influencing the dust-related atmospheric circulation (strengthened East Asian subtropical jet, increased cyclogenesis, and larger atmospheric thermal instability). Thus interannual variation of winter SICBS plays an increasingly important role in dust-related climate conditions over North China, which might serve as a new precursor for the prediction of spring dust activity in North China.
Polar sea ice is a dominant component of the climate system and its variability can cause great impact on global climate. In the recent past, Arctic witnessed many years of rapid sea ice loss. The reason for such a decrease has been attributed to both natural and anthropogenic drivers, though uncertainty remains. The aim of the present study is to understand whether there exists any relation between Indian Summer (June-September (JJAS)) Monsoon (ISM) and September Arctic sea ice retreat. The motivation behind the study is the findings from the analysis of 48 years of Hadley Centre sea ice and APHRODITE precipitation data, which indicated that during most of the strong (weak) ISM years, the Arctic sea ice increased (decreased) particularly over the Chukchi and Beaufort Sea during September. Further analysis with atmospheric parameters (height anomalies and wind divergence) from NCEP/NCAR reanalysis data showed that strong (weak) ISM is accompanied by positive (negative) phase of Summer North Atlantic Oscillation (SNAO) due to the contribution from strong/weak ISM, causing strong convergence/divergence over the upper/lower levels of the Mediterranean-Sahara region through monsoon-desert mechanism. This has great impact on the summer Azores high and SNAO which affects the Arctic circulation and sea ice. The link is supported by correlation with ISM index and sea level pressure. Thus, a tropical-polar teleconnection mechanism between ISM and Arctic sea ice is proposed.
Elucidating the Effects of Arctic Sea Ice Loss on Northern Hemisphere Climate

James Screen¹ (j.screen@exeter.ac.uk), Clara Deser², Doug Smith³, Xiangdong Zhang⁴, Russell Blackport¹, Paul Kushner⁵, Thomas Oudar⁶, Kelly McCusker⁶, Lantao Sun⁷

¹University of Exeter, Exeter, United Kingdom, ²National Center for Atmospheric Research (NCAR), Boulder, United States, ³Met Office, Exeter, United Kingdom, ⁴University of Alaska Fairbanks, Fairbanks, United States, ⁵University of Toronto, Toronto, Canada, ⁶University of Washington, Seattle, United States, ⁷Cooperative Institute for Research in Environmental Sciences, Boulder, United States

The decline of Arctic sea ice is an integral part of anthropogenic climate change. Sea ice loss is already having a significant impact on Arctic communities and ecosystems. Meanwhile, there is also intensive scientific interest in considering its role as a cause of climate changes outside the Arctic. Evidence is mounting that Arctic sea ice loss can affect weather and climate throughout the Northern Hemisphere.

To fully capture the remote impacts of Arctic sea ice loss, models that simulate interactions among the ocean, sea ice, land and atmosphere are required. A synthesis of six such experiments with different models shows consistent hemispheric-wide atmospheric warming, strongest in the mid-to-high latitude lower troposphere and tropical upper troposphere; an intensification of the wintertime Aleutian Low and Siberian High; and a weakening and southward shift of the midlatitude westerly winds in winter. Fuller diagnosis of the tropical upper tropospheric warming response to Arctic sea ice loss suggests a critical role for ocean heat transport changes. Freshening of the subpolar Arctic due to sea ice melt reduces the strength of the Atlantic Meridional Overturning Circulation (AMOC) and associated northward ocean heat transport, causing a build-up of heat in the tropical oceans. The resulting increase in tropical sea surface temperature enhances atmospheric deep convection and associated latent heat release, leading to tropical upper tropospheric warming.
Changes in Climate Trends in the Antarctic Peninsula Region

Gennadi Milinevsky1,2 (genmilinevsky@gmail.com), Oleksandr Evtushevsky1, Volodymyr Kravchenko1, Asen Grytsai1
1Taras Shevchenko National University of Kyiv, Kyiv, Ukraine, 2Jilin University, International Center for Future Science, Changchun, China

The largest climate warming in the Southern Hemisphere since the middle of the last century is observed in the Antarctic Peninsula in the winter months. Decadal variability of the winter temperature on the regional scale has been analyzed by SCAR READER datasets from the four stations in the Antarctic Peninsula region. Wavelet transform and Fourier analysis reveal both interannual (3-8 years) and decadal (10-20 years) temperature oscillations. Running correlation shows decadal variability in the Antarctic Peninsula winter temperature coupling with the central tropical Pacific. This variability is associated with intensity and persistency of the meridional wavetrain of stationary planetary waves, along which tropical disturbances propagate poleward reaching the Antarctic Peninsula. The period of the most significant tropical effects is 1980s-1990s, when the most rapid winter warming at Faraday/Vernadsky station was observed. One of the components of the winter temperature change on the Antarctic Peninsula is a 16-year periodicity with the amplitude of about 1°C, which also contributes to regional climate change. Absence of 21st century warming on Antarctic Peninsula discussed in the recent works can be partly caused by minimum in this periodicity.
AC-1a - Polar and high altitude atmosphere: clouds, aerosols, climate and interactions

Effect of Arctic Sea Ice on Aerosols in Eastern Lapland, Finland

Ella-Maria Duplissy¹ (ella-maria.duplissy@helsinki.fi), Simo Hakala¹, Victoria Sinclair¹, Riikka Väänänen¹, Veli-Matti Kerminen¹, Tuukka Petäjä¹, Markku Kulmala¹
¹University of Helsinki, Helsinki, Finland

Changes in sea ice are likely to affect the aerosols in the continental Arctic. We calculated linear regressions to median aerosol concentrations and mode peak diameters at SMEAR I in eastern Lapland, Finland, as a function of time over sea ice (TOSI), time over open sea (TOOS) and time over land (TOL). We divided the data into summer (Jun-Sep) and winter (Oct-May) as well as NAO and AO positive and negative phases.

During summer, the total aerosol number, Aitken mode and accumulation mode concentrations were decreasing with increasing time the air mass spent over the sea ice by -8.9, -5.3 and -1.6 cm⁻³ h⁻¹, respectively. The Aitken mode diameter was decreasing -0.3 nm h⁻¹ and the accumulation mode diameter -0.5 nm h⁻¹. Accumulation mode concentration and diameter increased by +0.8 cm⁻³ h⁻¹ and +0.3 nm h⁻¹, respectively, as a function of TOOS. During winter there was a decrease in total, nucleation mode and Aitken mode concentrations (-1.3, -0.3, -0.6 cm⁻³ h⁻¹, respectively) as a function of TOSI. Accumulation mode concentration and diameter were decreasing by -0.4 cm⁻³ h⁻¹ and -0.2 nm h⁻¹ as a function of TOOS.

We conclude, that Arctic sea ice has strong impact on the aerosol concentrations in eastern Lapland, and the changes in the sea ice extent and time that the air parcel spends over sea ice can have an influence on the aerosol-cloud interactions in the continental Arctic. The concentrations of potential CCN have contrasting trends with decreasing sea ice during summer and winter.
Enabling Atmospheric Process Research at MOSAiC

Matthew Shupe1,2 (matthew.shupe@noaa.gov), Markus Rex3
1University of Colorado Boulder, CIRES, Boulder, United States, 2NOAA Earth System Research Laboratory, Boulder, United States, 3Alfred Wegener Institute, Potsdam, Germany

The Arctic is undergoing substantial change, embodied by diminished sea-ice cover, which is opening the region to enhanced human activities requiring an improved ability to model the system on many temporal and spatial scales. Atmospheric processes pose some of the greatest challenges to modelling the Arctic due to a dearth of detailed observations and the overall complexity of atmospheric processes and their interactions. Specific challenges involve clouds, aerosols, precipitation processes, the boundary layer, and the roles these play in the surface energy budget. The Multi-disciplinary drifting Observatory for the Study of Arctic Climate (MOSAiC) will provide a unique opportunity to examine atmospheric processes and their role in the coupled Arctic system in great detail over a full year. Atmospheric measurements will target science themes including: (1) Sea-ice surface energy budget; (2) cloud and precipitation properties; (3) aerosol concentration and composition; and (4) the stable and unstable atmospheric boundary layer. These measurements will enable a process-level understanding of the Arctic system and specifically coupled processes involving the atmosphere. They will also provide the basis for evaluating and improving process models and process representations in larger-scale models. This presentation will introduce the MOSAiC atmosphere measurements and explore specific scientific process-based analyses that they will enable.

On behalf of the MOSAiC Atmosphere Team International Consortium
Aerosol Variability Linked to Clouds and Precipitation in the Sor Rondane Area

Alexander Mangold1 (alexander.mangold@meteo.be), Quentin Laffineur1, Andy Delcloo1, Christian Hermans2, Francois Hendrick2, Alexandra Gossart3, Niels Souverijns3, Paul Herenz4, Heike Wex4, Hugo De Backer1, Nicole Van Lipzig3

1Royal Meteorological Institute of Belgium, Brussels, Belgium, 2Royal Belgian Institute for Space Aeronomy, Brussels, Belgium, 3Katholieke Universiteit Leuven, Heverlee-Leuven, Belgium, 4Leibniz Institute for Tropospheric Research, Leipzig, Germany

Since 2010, continuous measurements of the aerosol number size distribution and total number, and of the aerosol absorption and total scattering coefficient within the boundary-layer have been realised at the Belgian research station Princess Elisabeth, in the Sør Rondane Mountains, East Antarctica (72° S, 23° E, 1390 m asl). In addition, an automatic weather station, a ceilometer (cloud base height and type) and a micro-rain radar (precipitation observation) have been installed for continuous operation. In December 2015, a MAX-DOAS instrument has been installed for the retrieval of the vertical profile of the aerosol extinction coefficient. Backtrajectory calculations for air mass origin complemented the dataset.

The aerosol total number concentration $N_{\text{total}}$ showed a clear seasonal cycle with some hundreds of particles/cm$^3$ during summer and some tens of particles/cm$^3$ during winter. Frequently, $N_{\text{total}}$ increased distinctly during short periods (hours to one/two days; up to some thousands of particles/cm$^3$), with particles smaller than 90 nm responsible for the increase. Three types of such events could statistically be distinguished and each of it with distinct meteorological, cloud and precipitation conditions. Clear changes of the spectral dependency of the absorption coefficient could also be linked to distinct meteorological conditions. The atmospheric stability parameter, MAX-DOAS and radio sounding observations help to link boundary-layer observations and higher levels.
The Effect of Cloud Microphysics on the Surface Energy Balance of Larsen C

Ella Gilbert\textsuperscript{1,2} (ellgil82@bas.ac.uk), Andrew Orr\textsuperscript{1}, Tom Lachlan-Cope\textsuperscript{1}, John C King\textsuperscript{1}, Ian A Renfrew\textsuperscript{2}

\textsuperscript{1}British Antarctic Survey, Cambridge, United Kingdom, \textsuperscript{2}University of East Anglia, Norwich, United Kingdom

Clouds are a poorly constrained component of the Antarctic climate system, yet their importance is huge. Antarctic clouds have a significant impact on the surface energy balance (SEB) of ice shelves, with consequent effects on melt rates. Cloud microphysics greatly influence cloud radiative properties and therefore the SEB, but there is a paucity of data due to the difficulty of making microphysical measurements in Antarctica. However, ice shelves around the peninsula are undergoing considerable change: the most recent example of this is the Larsen C ice shelf. Larsen C’s stability may be diminishing following prolonged melting and surface lowering, as well as the loss of \textasciitilde{}12% of its volume in a single calving event in July 2017. Understanding the drivers of change hinges on the development of atmospheric models that skilfully represent key (micro)physical processes, and which more accurately predict surface melting and ice shelf collapse for future climate change scenarios. In this work, we examine aircraft-based microphysical observations from campaigns over the Antarctic Peninsula. Specific case studies are identified and compared with model simulations using the Met Office Unified Model at 1.5 km grid spacing. We present preliminary findings and initial analysis, as well as directions for future work. Our process-based approach could contribute to an improved understanding of Antarctic clouds and reduced uncertainty in estimates of polar change.
Impact of Meteorology on Aerosols and Clouds in the Antarctic Peninsula

Eija Asmi¹,² (eija.asmi@fmi.fi), Kimmo Neitola¹,³, Edith Rodriguez¹, Aki Virkkula¹, Kimmo Teinilä¹, Ewan O’Connor¹, Maria Elena Barlasina², Gustavo Copes², Germán Pérez Fogwill², Miguel Mei², Ricardo Sánchez²

Atmospheric aerosol particles are an integral part of the climate, having effects on water-, carbon-, and nutrient cycles, the amount of solar radiation entering the surface and changing the amount of cloudiness and rain, as well as the properties of clouds. To understand the inter-annual characteristics of the aerosols in Antarctic Peninsula and their interaction with the Antarctic clouds and climate, we have studied aerosol particle physical and chemical properties in the Peninsula continuously since year 2013. Furthermore, we have studied the low-level clouds and fog, along with the aerosol profiles using a Vaisala ceilometer, operating since year 2016. These measurements are run in Argentinean station Marambio. Our long-term analysis of aerosol optical properties and chemistry have shown clear patterns with 1) more chemically rich aerosol in summer with the origin in the Southern Ocean, 2) higher average aerosol scattering during winter as a result of stronger storms, resulting in dispersion of marine and soil particles in wind-driven processes, and 3) importance of primary aerosol sources, especially in winter. Currently, we are analyzing the presence of fog and low-level clouds using the ceilometer data. Our observations indicate several fog episodes during the Antarctic summer season. During these episodes, the scattering parameters present variability, suggesting an impact of aerosol cloud processing. How systematic these changes are, and is yet to be confirmed.
Aerosol and CCN Properties and Sources in East Antarctica during Austral Summer

Paul Herenz¹, Heike Wex¹, Alexander Mangold², Quentin Laffineur⁷, Irina V. Gorodestkaya³,⁴, Zoë L. Fleming⁵, Marios Panagi⁵, Frank Stratmann¹ (frank.stratmann@tropos.de)
¹Leibniz Institute for Tropospheric Research, Leipzig, Germany, ²Royal Meteorological Institute of Belgium, Brussels, Belgium, ³University of Aveiro Campus Universitário de Santiago, Centre for Environmental and Marine Sciences Department of Physics, Aveiro, Portugal, ⁴KU Leuven, Department of Earth and Environmental Sciences, Leuven, Belgium, ⁵University of Leicester, National Centre for Atmospheric Science, Department of Chemistry, Leicester, United Kingdom

Aerosol measurements were carried out in the framework of the BACCHUS-project (project number: 603445) at the Princess Elisabeth Antarctica Research Station during three Antarctic summers (Dec. 2013 - Feb. 2016). The total particle number concentration (N_{CN}) and the Cloud Condensation Nuclei number concentration (N_{CCN}, @ supersaturations (SS) between 0.1 and 0.7%) were determined using a Condensation Particle Counter and a CCN counter, respectively. Particle number size distributions were measured between 90nm and 7µm using an Optical Particle Counter. By applying the κ-Köhler-Theory (Petters and Kreidenweis, 2007) we determined a median hygroscopicity parameter κ of 1 (@ SS=0.1%). To investigate the influence of the air mass origin on N_{CN} and N_{CCN} we applied the dispersion model NAME and the Potential Source Contribution Function. In both methods we looked at the air mass history of the past 10 days. The NAME dispersion footprints were analysed for the proportional temporal stay in the surface layer (0-100m) over different categorized areas (continental, ocean and a reactive zone, including chlorophyll, penguin and sea ice zones). We found an Antarctic background of 200 to 400 #/cm³ for N_{CN}. Only the occurrence of none continental air masses lead to an enhanced N_{CN}. In terms of N_{CCN} this correlation is less clear, which might be attributable to sinks due to cloud processes. N_{CCN} covers a range between less than 10 at SS=0.1% and several hundreds #/cm³ for larger SS.
Climate change resulting from greenhouse gases and/or ozone depletion is presenting in a myriad of ways in Antarctica, the subantarctic and the Southern Ocean. Effects including localised warming, cooling, altered precipitation patterns, increased wind speeds, shifts in location of low pressure systems and extreme events are being documented. Associated changes in species and ecosystems are now emerging including localised species and ecosystem collapse, colonisation of new ground, shift in ranges, and species responses with various lag phases. In this talk we will examine the variety of species and ecosystem changes recorded, and demonstrate our development of species and ecosystem impact qualitative models.
Widespread changes in temperature and precipitation have the potential to drive substantial shifts in tundra biodiversity, with important implications for the functioning of these ecosystems. We combine three decades of tundra plant community surveys at nearly 200 Arctic and alpine locations with 75,000 tundra plant trait observations to explore changes in both species and functional diversity in response to recent climate change. We find little evidence of consistent changes in species richness, but substantial community turnover over time in both species and functional composition. Our results suggest that the strongest impacts of near-term climate warming on tundra biodiversity-ecosystem function relationships will occur through changes in composition rather than diversity per se.
Tara Oceans: A Pan-arctic View on Plankton Diversity and Community Structure

Lee Karp-Boss1 (lee.karp-boss@maine.edu), Tara Oceans Consortium1
1University of Maine, School of Marine Sciences, Orono, United States

The Tara Oceans expedition, a global-scale study on the diversity and structure of planktonic ecosystems, conducted its circumpolar field campaign in the Arctic Ocean during the summer of 2013 (May-October). Sampling was conducted on board the research schooner ‘Tara’, covering diverse environmental conditions on Arctic shelves. The result is a rich data set that includes DNA and RNA sequences of viruses, prokaryotes and eukaryotes for metabarcode, metagenome and metatranscriptome analyses, particle composition from imaging (phytoplankton, zooplankton and detritus) and 25,000 km of high-resolution inline measurements of physical, chemical and optical properties of surface waters (temperature, salinity, pCO2, pH, Mercury, absorption and scattering), as well as other water column parameters (nutrients, light, DOM, HPLC pigments). We will provide an overview of the sampling program and data sets that are available, and highlight on-going research foci and major results. Particularly, we will show the pan-Arctic distributions and diversity of plankton (unstructured (generalist) vs. localized geographic distributions) as well as cross-comparison of Arctic plankton diversity with results already reported for the global ocean in the special issue of Science dedicated to the Tara Oceans project (22 May 2015). Such direct comparisons are possible thanks to the use of common sampling protocols and analytical pipelines at global scale.
The Way to the Top: The Drivers of Cold-climate Range Shifts in Plants

Jonas Lembrechts¹ (jonas.lembrechts@uantwerpen.be), Jonathan Lenoir², Aníbal Pauchard³, Martin Nuñez⁴, Ann Milbau⁵, Ivan Nijs¹

¹University of Antwerp, Biology, Wilrijk, Belgium, ²Université de Picardie Jules Verne, Amiens, France,

⁵Instituut voor Natuur- en Bosonderzoek, Brussels, Belgium

Until now, non-native plant species were rarely found at high elevations and latitudes. However, partly due to climate warming and increased human presence in these cold environments, both non-native species and upward moving natives are now on the rise. These rapid shifts in distributions in what is often seen as a slow-reacting ecosystem make it timely to undertake a thorough assessment of what drives them, in order to accurately predict their future in a changing world. Here, we show the results from a series of observations and experiments in the subantarctic Andes and subarctic Scandinavian mountains. We assessed the role of human interventions (i.e., disturbance, nutrient increase and propagule input) and climatic factors on shifts in plant species distributions, with our integrative approach allowing us to tease apart the mechanisms. By acknowledging the interactions of the plants with small-scale abiotic (e.g. microclimate, soil properties) and biotic (e.g. mutualism, competition) factors, we found that disturbance plays a defining role along all elevation gradients, a.o. through its effects on soils, biotic interactions, microclimate and seed influx. Undisturbed vegetation, on the other hand, was surprisingly hard to colonise by new-comers. These results -consistent within both our observational and experimental studies - suggest that sub(ant)arctic ecosystems are still relatively resistant to change, unless disrupted by anthropogenic disturbances.
Measurements of the CMB have driven our understanding of the universe and the physics that govern its evolution from quantum fluctuations to its present state. They provide the foundation for the remarkable 6-parameter cosmological model, ΛCDM. Far from being the last word in cosmology, the model raises deep questions: Is Inflation correct? What is its energy scale? What is the dark matter? What is the nature of dark energy? Are there light sterile neutrinos, or other light relics? There remains a great deal more to learn from the CMB, especially from its polarization. South Pole experiments have helped pioneer polarization studies, starting with the DASI detection of E-mode polarization, to the SPT detection of lensing B-mode, to BICEP/KECK’s best limits on the level of B-mode polarization generated by inflationary gravitational waves. This talk will briefly review the current state of the art and then outline the plan for the next generation ground based CMB experiment, CMB-S4, stressing the critical role planned for measurements from the Antarctic.
COSMO (COSmological Monopole Observer) is a spectrometer aimed at detecting spectral distortions in the Cosmic Microwave Background (CMB). The spectrum of the CMB is a precise blackbody (within 100 ppm of the maximum brightness, as measured by the FIRAS experiment on the COBE satellite). According to theory, however, small spectral distortions must be present. Their measurement represents one of the very few ways to investigate the early or very early universe. The main challenge in this measurement is the presence of instrumental, atmospheric and astrophysical foregrounds, which must be minimized or carefully evaluated to estimate the spectral brightness of the CMB with the required accuracy. COSMO is a differential Fourier-transform spectrometer (DFTS) comparing the brightness of the sky above Dome-C to the brightness of a grey-body which, in the spectral range of interest mimics the brightness of the atmosphere. The DFTS is cooled at 4K to reduce its emission, and feeds two arrays of Kinetic Inductance Detectors covering the 1.3mm and 2.0mm atmospheric windows with a spectral resolution of 2 GHz. Accurate atmospheric modelling and template fitting allow to separate CMB spectral distortions from the other brightnesses. In a few months of integration, during the Antarctic winter, we expect to be able to detect a comptonization-like distortion with y at the level of a few ppm. See http://planck.roma1.infn.it/cosmo for info and a full list of collaborators.
SWIPE-LSPE: Cosmic Microwave Background Polarimetry in the Polar Night

Paolo de Bernardis\textsuperscript{1,2} (paolo.debernardis@roma1.infn.it)
\textsuperscript{1}Sapienza Università di Roma, Physics, Roma, Italy, \textsuperscript{2}INFN, Sezione di Roma, Roma, Italy

The Large-Scale Polarization Explorer is a coordinated ground-based and balloon-borne effort to measure Cosmic Microwave Background (CMB) polarization at the largest angular scales, where cosmic inflation left its imprint in the form of a curly pattern (B-modes) of linear polarization. In this scenario, the measurement of B-modes represents a way to study physical phenomena happening a split-second within the big bang, at energies which are not reachable on Earth. The Short Wavelength Instrument on the Polarization Explorer (SWIPE) is in an advanced phase of preparation, to be launched from Svalbard in a long-duration stratospheric flight in the polar-night. The instrument features an array of 330 multi-mode TES bolometers, cooled at 0.3K, and collecting a total of 8800 modes of the CMB. The frequency bands of the detectors have been selected to optimize the sensitivity to CMB signals (with a 33\% wide band at 140 GHz) while removing efficiently the polarized dust foreground (with two 5\% bands at 220 GHz and 240 GHz). The detectors are fed by a 50 cm refractive telescope; polarization modulation is achieved through a magnetically levitating spinning HWP, the first element in the optical chain. In a two-weeks-long flight flown from Longyearbyen in the polar winter SWIPE aims at a sensitivity to the tensor to scalar ratio $r=0.01$, roughly 10 times better than current upper limits. See http://planck.roma1.infn.it/lspe for info and for the full list of LSPE collaborators.
The clear ice below the South Pole has proven to be an excellent medium for neutrino detection. In December 2010 the IceCube collaboration completed the deployment of over 5000 optical sensors at depths between 1450m and 2450m below the South Pole surface. The sensors detect the light which is produced when neutrinos interact in the ice or surrounding bedrock. Soon after completion, the IceCube telescope provided a breakthrough for the astroparticle community, with the first detection of astrophysical neutrinos reported in 2013. In the ensuing years IceCube has provided many more results over its wide physics portfolio. The success of IceCube has motivated plans for the extension of the current instrumentation. In this talk I will provide an overview of the latest results from the IceCube collaboration and the plans for a near-term upgrade to IceCube, and for a next-generation IceCube-Gen2 detector.
The Askaryan Radio Array - Neutrino Astronomy at the South Pole

Albrecht Karle\(^1\) (albrecht.karle@icecube.wisc.edu)
\(^{2}\)University of Wisconsin-Madison, Wisconsin IceCube Particle Astrophysics Center, Madison, United States

The glacial ice at the South Pole offers ideal conditions for the detection of high energy neutrinos. The Askaryan Radio Array seeks to discover extremely high energetic cosmic neutrinos. The goal is to understand the origin of highest energy cosmic rays and there cosmic accelerators. I will report about new developments, new instruments deployed in the 2017/18 field season, current results and the vision for a very large array.
Measurements of Radio Emission of Cosmogenic Neutrinos in the Antarctic Ice

Anna Nelles¹ (anna.nelles@gmail.com), The Arianna Collaboration¹
¹University of California Irvine, Irvine, United States

The most-energetic atomic particles known today, ultra-high energy cosmic rays, are created in yet unknown astrophysical objects. A key ingredient to finding their origin will be the measurement of neutrinos of energies higher than reachable with current detectors. The only feasible way forward is to detect the faint radio emission that is associated with a neutrino interaction. To obtain the necessary sensitivity several tens of cubic kilometers of material will have to act as detector. A detector of this size is also likely to be extremely sensitive to neutrinos from explosive events such as recently observed in gravitational waves. An optimal place for such a detector is the polar ice, which is transparent for the radio emission in the MHz regime. Several pilot-stage experiments run in Antarctica to test the necessary hardware and different detector concepts. Following a number of unexpected observations, also detailed measurements are being performed that aim to study the propagation of radio waves in the ice, including the possibility of horizontal propagation of signals. We will report on the current efforts, focusing on the ARIANNA HRA that has been deployed in Moore’s Bay on the Ross Ice-shelf and the perspectives of radio detection of neutrinos.

Why Is Antarctic Bottom Water Disappearing?

Stephen Rintoul\textsuperscript{1,2,3} (steve.rintoul@csiro.au)
\textsuperscript{1}CSIRO Oceans & Atmosphere, Hobart, Australia, \textsuperscript{2}Antarctic Climate & Ecosystems Cooperative Research Centre, University of Tasmania, Hobart, Australia, \textsuperscript{3}Centre for Southern Hemisphere Ocean Research, Hobart, Australia

Antarctic Bottom Water (AABW) has warmed, freshened and reduced in volume in recent decades. Changes are largest near Antarctica but have spread through much of the abyssal ocean. The magnitude of the changes are sufficient to make a substantial contribution to sea level rise and global energy budgets. However, the causes of the widespread warming and freshening of AABW remain poorly understood because observations are sparse near sources of AABW. The natural experiment resulting from calving of the Mertz Glacier Tongue in 2010 provides insight into polynya dynamics and bottom water change. Changes in the regional icescape after calving reduced the size and activity of the polynya, leading to a sharp reduction in the salinity of dense shelf water formed in winter. This signal propagated to the deep ocean, where a twenty year time series of abyssal water properties confirmed a sharp reduction in the density of AABW. Freshening of the dense shelf water caused warming of the AABW, a result explained by mixing of less dense overflows with ambient waters offshore. Oxygen levels in the AABW remained high, suggesting that the new lighter variety of AABW was still sufficiently dense to reach the sea floor and continued to ventilate the abyssal ocean. The results highlight the sensitivity of AABW formation and ventilation to changes in surface forcing. Early results from a pilot array of deep Argo floats deployed to track change in AABW properties will be presented.
Sources of Southern Ocean Freshening Inferred from Oxygen Isotope Data

F. Alexander Haumann1,2,3 (alexander.haumann@gmail.com), Michael Meredith1, Jorge Sarmiento2, Nicolas Gruber3, Katherine Leonard4,5

1British Antarctic Survey, Cambridge, United Kingdom, 2Princeton University, Princeton, United States, 3ETH Zurich, Zurich, Switzerland, 4University of Colorado Boulder, Boulder, United States, 5EPFL, Lausanne, Switzerland

Long-term hydrographic observations of Southern Ocean waters reveal a substantial freshening signal in Antarctic surface, intermediate, mode and bottom waters over recent decades. These changes have been associated with a redistribution of freshwater by sea ice, an increased glacial meltwater flux from Antarctica, and a potential increase in precipitation or ocean circulation changes. However, large uncertainties in the magnitude and spatial pattern of the surface fluxes confound a quantification of their relative contribution to the observed salinity changes. The stable isotopic composition of the seawater provides an alternative measure of the contribution from these different freshwater sources, since it carries the characteristic imprint of the surfaces processes in the source region. We analyze a newly-compiled dataset of salinity and oxygen isotope samples from the Southern Ocean from the 1970s to the present. In particular, we investigate the hypothesis that sea-ice freshwater fluxes strongly imprint on water masses formed in the seasonal sea-ice zone, and that larger signals of meteoric freshwater can be found in water masses formed over the continental shelf and north of the Subantarctic Front. We discuss decadal changes in these respective contributions, which provide new insights into the driving processes of recent changes in the Southern Ocean properties and structure. These changes critically influence its ability to take up anthropogenic heat and carbon.
Sea Ice Variability and Predictability in the Nansen Basin

Lars Smedsrud¹,² (larsh@gfi.uib.no), Ingrid Onarheim¹, Tor Eldevik¹, Michael Steel³
¹University of Bergen & Bjerknes Centre, Geophysical Institute, Bergen, Norway, ²University Centre in Svalbard, Geophysics, Longyearbyen, Norway, ³University of Washington, Polar Science Center / Applied Physics Laboratory, Seattle, United States

Rapid loss of Arctic sea ice is a clear indicator of climate change. Predicting future change based on mechanistic understanding of air-ice-sea processes would be desirable in many regards, and this study investigates how warm Atlantic water directly influences the Arctic sea ice cover. We particularly assess observed winter sea ice area variability and predictability in the Nansen Basin where the Atlantic water encounters the Arctic sea ice. Observations from the Norwegian Young Sea Ice Cruise in winter and spring 2015 show a well-mixed low salinity surface layer, with its freshwater predominately from sea ice melt moving in tandem with the Atlantic water below. Rooted in observations, we present a conceptual model to assess the sea ice variability and water mass transformation in the Nansen Basin. We find that Atlantic water melts approaching sea ice and thereby transforms into a low salinity surface layer locally. An imbalance between Atlantic heat, heat loss to the atmosphere, and heat needed for sea ice melt causes variations in the sea ice cover. Based on the proposed framework, we show that the variability of winter sea-ice area in the Nansen Basin may be skillfully predicted 1-3 years in advance from observed Atlantic water hydrography upstream. The framework generally captures the observed sea ice variability since the 1970s, and we predict that the winter sea-ice cover in the Nansen Basin will be close to its climatological mean in 2018 and 2019.
Connection of the Sea Ice Drift in the Arctic Ocean with the Synoptic Processes

Aleksandra Mushta\textsuperscript{1} (chipichava@yandex.ru), Vladimir A. Volkov\textsuperscript{1}, Denis M. Demchev\textsuperscript{1}
\textsuperscript{1}Nansen International Environmental and Remote Sensing Center, Applied Meteorological and Oceanographic Research for Industrial Activity, St. Petersburg, Russian Federation

The condition of ice formation and the temporal structure of ice cover variability are not homogeneous in the Arctic ocean and depends on the dynamic processes. Transpolar drift and Beaufort gyre have time cycles with a predominance of different frequencies in the Eurasian and Amerasian parts of the Arctic Basin. The intensity and the position of the Transpolar drift and the center of the Beaufort gyre is changing from year to year, creating the conditions for various ice distribution and ice removal.

Different types of sea ice circulation is formed under the influence of atmospheric pressure and wind fields over the Arctic Ocean. The survey of predominant synoptic types in each year led us to allocation of the types, that can create the conditions for ice accumulation (at an agreeable temperature range), for ice removal and for the sea ice opposition formation.

The authors dissected the long-term changes in the atmospheric circulation and ice drift fields, basing of the satellite data, the ice drift fields calculation (1979-2016) and synoptic types catalogue, and launched the estimation of the relationships between ice drift fields changing and variability of the ice cover fluctuations in the last decades.
Large Eddy Simulations of the Ice Shelf-ocean Boundary Layer

Madelaine G. Rosevear\(^1\) (mmr0@utas.edu.au), Bishakhdatta Gayen\(^2\), Benjamin K. Galton-Fenzi\(^3,4\)
\(^1\)University of Tasmania/Institute for Marine and Antarctic Studies, Battery Point, Australia, \(^2\)Australian National University, Research School of Earth Sciences, Canberra, Australia, \(^3\)Australian Antarctic Division, Hobart, Australia, \(^4\)Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia

The rate of melting at the base of an ice shelf is primarily controlled by oceanic processes that occur on very small scales, namely the diffusive and turbulent fluxes of heat and salt through the viscous and turbulent regions of the ice-ocean boundary layer. These processes are too small in scale to be resolved in the present regional ocean models. Instead, heat and mass transport to the ice-ocean interface is parameterised using bulk transfer coefficients, which determine the interface conditions based on the properties of the ocean interior. Here we investigate the complex, dynamic processes inside the ice-ocean planetary boundary layer beneath an Antarctic ice shelf and estimate basal melt rates using resolved Large Eddy Simulations. Fluxes through the boundary layer are adequately captured, negating the need for parameterisations in the treatment of melting. We force the simulation with oceanic conditions observed in mooring data from beneath the Amery Ice Shelf. The resultant melt rate is consistent with the melt rate measured in situ at the same site. These results can be used to improve the ice-ocean parameterisations in regional ocean models.
Ice Shelf Meltwater Pump Contribution to Vertical Exchange around Antarctica

Michael Dinniman¹ (msd@ccpo.odu.edu), Pierre St-Laurent¹, Kevin Arrigo², Eileen Hofmann¹, John Klinck¹, Robert Sherrell³, Sharon Stammerjohn⁴, Patricia Yager⁵

¹Old Dominion University, CCPO, Norfolk, United States, ²Stanford University, Palo Alto, United States, ³Rutgers University, New Brunswick, United States, ⁴Univ of Colorado, Boulder, United States, ⁵University of Georgia, Athens, United States

Satellite estimates of chlorophyll in Antarctic coastal polynyas are strongly correlated with the basal melt rate of adjacent ice shelves. This has led to speculation that the high productivity of coastal polynyas may be related to the release of the limiting micronutrient iron from melting ice shelves. Strong basal melting of ice shelves can drive a vigorous overturning circulation within an ice shelf cavity ("meltwater pump"). We use a high resolution (1.5 km) ocean/sea-ice/ice shelf model of the Amundsen Sea to examine the effects of this mechanism over the broader Antarctic continental shelf. Four plausible sources of dissolved iron are simulated with independent tracers, assumptions about the end member concentrations, and an idealized summer biological uptake. While direct injection of iron from melting ice shelves is an important contributor to the total dissolved iron supply in the adjacent polynya surface waters, there is an even larger contribution from "deep" sources of iron on the shelf (sediments and Circumpolar Deep Water). The Amundsen Sea is not a strong dense water formation region and sensitivity experiments show that the meltwater pump is far more effective than winter vertical mixing in bringing dissolved iron into the upper water column. The effect of the meltwater pump on vertical mixing is expected to be heterogeneous around Antarctica and experiments examining this were performed with a coarser resolution (5 km), circum-Antarctic model.
A Computational Pipeline for Taxon, Gene and Allelic Analysis of Microbial Omics

Gilda Varliero\(^1\) (gv16363@bristol.ac.uk), Maisie Nash\(^1\), Joshua Blacker\(^2\), Alex Anesio\(^1\), Liane G Benning\(^{2,3,4}\), Gary Barker\(^1\)

\(^1\)University of Bristol, Bristol, United Kingdom, \(^2\)University of Leeds, Leeds, United Kingdom, \(^3\)Helmholtz Centre Potsdam - GFZ German Research Centre for Geosciences, Potsdam, Germany, \(^4\)Free University of Berlin, Berlin, Germany

For environmental studies using high-throughput sequencing technologies, data analysis is now the limiting step in furthering our understanding of structure and function of microbial communities. There are several tools that facilitate the visualisation and analysis of such complex data, such as MEGAN and MG-RAST, but these focus on the taxonomic and high-level (gene ontology) functional annotation of individual shotgun sequences.

We have developed a pipeline to efficiently annotate assembled metagenome contigs using DIAMOND blast, to map raw reads back to their identified gene models and to identify significant differential gene abundance using a flexible General Linear Model. The approach relies on assembling all samples to create a common reference (metagenome or metatranscriptome) on which all DNA/RNA sequences can be mapped and quantified. Users can perform taxon and gene-wise statistical analyses of microbial communities and examine taxon * gene interactions. Differential abundance of functional Single Nucleotide Polymorphisms (SNPs) between sample factor levels is also included: a hitherto unexplored source of variation.

To demonstrate the utility of this approach and how it can be used to analyse complex data, such as microbial communities with geochemical data from different biogeographic regions, we present an analysis of microbial diversity and gene variation in samples from glacial forefield chronosequences collected from Greenland, Svalbard and Sweden.
Keystone Arctic Microbial Genomes Linked to the Dynamics of Phytoplankton Blooms

Marta Royo-Llonch1 (royo@icm.csic.es), Pablo Sánchez1, Carlos Pedrós-Alió2, Tara Oceans Consortium1, Silvia G Acinas1
1Institut de Ciències del Mar ICM-CSIC, Marine Biology and Oceanography, Barcelona, Spain, 2Centro Nacional de Biotecnología CNB-CSIC, Madrid, Spain

Microbial community composition in the north polar waters varies greatly throughout the year. Spring melting of the ice and increase in light disposal spur the bloom of phytoplankton, taking over the functional and phylogenetically diverse bacterioplankton communities of dark and cold winter waters. Mainly heterotrophic and photoheterotrophic bacterial populations feed on the nutrients derived from the phytoplankton bloom during summer. With fall’s shorter light hours and colder seawater temperatures, the bacterial community shifts to those chemolithoautotrophic that will prevail during winter. TaraOceans navigated around the north polar waters extensively sampling the microbial plankton communities during spring, summer and the beginning of fall (May to October 2013). We have generated around 900 microbial metagenomic assembled genomes (or MAGs) from the combination of the 41 sequenced metagenomes, which cover the whole polar circle from spring to the beginning of fall. Together with the physical and chemical information of all stations we are capable of detecting the distribution of the different keystone prokaryotic taxa around the pole and through the seasons at maximum resolution possible, at genome level, with a particular focus on the genomics and metabolic potential of those following the phenology of phytoplankton blooms.
Biodiversity of Endolithic Communities in Battleship Promontory, Antarctica

Claudia Coleine¹ (coleine@unitus.it), Laura Zucconi¹, Jason E. Stajich², Silvano Onofri¹, Laura Selbmann¹
¹University of Tuscia, Department of Ecological and Biological Sciences (DEB), Viterbo, Italy, ²University of California, Department of Microbiology and Plant Pathology and Institute of Integrative Genome Biology, Riverside, United States

The McMurdo Dry Valleys (Southern Victoria Land) constitute the most extensive ice-free area in Antarctica, representing the coldest, driest and windiest desert on Earth; they are considered the closest Martian analogous habitat on Earth, exhibiting extraordinary aridity, low temperatures, wide thermal fluctuations, low nutrient availability, seasonal increased UV radiation, and geographical isolation. In this study, we investigated both bacterial and fungal components of lichen-dominated communities in Battleship Promontory, McMurdo Dry Valleys. Nine rock samples were analyzed with a meta-barcoding approach on Illumina platform coupled, targeting the V4 of 16S and Internal Transcribed Sequence 1 (ITS1) regions for bacteria and fungi respectively. Taxonomic results, alpha-diversity and statistical analysis were performed to investigate microbial diversity and community structure to optimize sampling amplitude for a proper and exhaustive biodiversity description. Preliminary results show a large predominance of phylotypes belonging to the phylum Actinobacteria in bacterial compartment, while Ascomycota, with the classes Lecanoromycetes and Dothideomycetes prevail among fungi. Bacterial richness was higher than fungal richness (517 OTUs and 189 OTUs, respectively); both these microbial components showed a ‘core’ of recurrent species (OTUs present in at least 75% of samples) among all samples.
Environmental changes due to recent glacier retreat phenomenon are expected to challenge the structural and functional variability of ice microbiomes, with different impact on specific glacial habitats. Our comparative study of Antarctic glaciers and Alpine ice cave investigated the bacterial and fungal diversity from glacier transects and subglacial water flows of Barton and Weaver peninsulas from King George Island, and a 13,000-years old ice chronosequence of Scarisoara ice cave. Illumina sequencing of 16S rRNA and ITS2 genes indicated major differences in microbial composition correlated with the habitat type, spatial distribution, geochemistry and age of ice. Glacier ice showed lower diversity relative to subglacial water and cave ice. *Proteobacteria* clearly dominated all Antarctic samples, while the major phylum of cave ice block alternated between *Proteobacteria, Bacteroidetes, Actinobacteria, Firmicutes* and *Cyanobacteria* based on the age, organic content and light exposure of ice layers. Different Beta/ Gamma-*Proteobacteria* ratios were specific for Antarctic ice/water and cave ice of different age. *Acinetobacter* and *Polaromonas* prevailed in all Antarctic samples with a relative abundance depending on sample type and location. Fungal community analyses based on ITS2 sequencing, currently under way, will complete the comparative microbiomes overview of these icy habitats, and their response to environmental variables.

Metabolic and Community Changes Underpinning life Phase Transition of Snow Algae

Matthew Davey¹ (mpd39@cam.ac.uk), Lloyd Peck², Peter Convey², James Blake²,³, Peter Fretwell², Alison Smith³
¹University of Cambridge, Cambridge, United Kingdom, ²British Antarctic Survey, Cambridge, United Kingdom, ³University of Cambridge, Department of Plant Sciences, Cambridge, United Kingdom

Snow algae communities consist mainly of green algal species of the genera Chlamydomonas and Chloromonas. They have a bi-phasic life cycle consisting of an active reproductive motile stage, seen as green patches in the snow, and a dormant encystment phase during which the cells accumulate the red keto-carotenoid astaxanthin, giving rise to red snow patches. We measured the metabolic composition of snow algae in both green and red phases, from samples taken in the field at various locations in Antarctica during the 2014/15 and 2017/18 austral summer seasons. We also determined the community composition of the blooms using 16S and 18S metagenomic sequencing. Our data showed that the metabolic composition of the cells was the same from four geologically distinct but spatially close locations in the vicinity of Ryder Bay (Adelaide Island, 68°S). However, our data also show a high degree of patchiness in the snow melt between the locations where snow algae communities occurred, from mean values of 0.5 g dry algae per L of snow melt at Lagoon Island to 3.25 g dry algae per L of snow melt at Léonie Island. Our metabolite data showed that the snow algae were rich in unsaturated fatty acids and that metabolomic assays could detect detailed changes in lipid, carbohydrate and protein chemistry in the cells during encystment. These Antarctic data are compared to similar community studies carried out in Arctic ecosystems.
The Legal Grounds of Territorial Claims in Antarctica: A Sober Assessment

Alejandra Mancilla1 (alejandra.mancilla@ifikk.uio.no)
1University of Oslo, Philosophy, Oslo, Norway

By virtue of the Antarctic Treaty, the territorial claims made by seven countries over the continent in the previous decades were “frozen”. Putting the question of sovereignty on hold, the Treaty and its related legal instruments came to be considered over the years as a diplomatic success, allowing peaceful cooperation in the continent, built around science and with the protection of the environment at its core. Notwithstanding, the original claimant countries have never surrendered their territorial aspirations, and they have been actively engaged in antarctic matters, signaling their ongoing interest through the establishment of bases, the organization of scientific expeditions, active participation in the ATMs, and so on and so forth. In this presentation, I examine the legal instruments and doctrines upon which these countries grounded their claims, and assess them from a normative perspective. I inquire, that is, into their reasonableness and legitimacy both then and today. Old international treaties, unilateral declarations and later transfers based on them, as well as international law doctrines tailor-made for imperialist powers—like contiguity and continuity—played a key role founding these countries’ aspirations. But do they withhold scrutiny? I suggest that they do not, and that a sober evaluation of them would dramatically reduce their scope. I conclude with some thoughts on how this should lead us to rethink the territorial status of most of the White Continent.
Property Rights: A Solution to the Tragedy of the Commons in Antarctica?

Yelena Yermakova\(^1\) (yy646@cornell.edu)
\(^1\)University of Oslo, Oslo, Norway

Antarctica brings to many minds an image of a peaceful no man’s land: pristine environment and scientific cooperation. However, the reality is that Antarctica is one of the least environmentally protected regions on the planet: only 1.5% of the ice-free habitats on the continent are designated as specially protected areas. Unresolved territorial claims in Antarctica create a jurisdictional vacuum that leads to one of the worst cases of the tragedy of the commons. Climate change and improvements in technology foreshadow future exploration and exploitation of Antarctic resources. To avoid potential conflict there is a need for a normative guidance for management of natural resources on the seventh continent. This paper builds upon Dr. Margaret Moore's work on the theory of territory in unoccupied areas. Dr. Moore suggests that the question of “unclaimed” territory in Antarctica should not be seen as a territorial dispute, but rather a property one. She argues that resources in unoccupied territories have instrumental value and should be regarded as property. This paper discusses some practical implications of applying this property conception to the management of natural resources in Antarctica and whether doing so would strengthen environmental protections. The paper investigates potential roles that stakeholders other than nations, such as the private sector and international organizations, would play in the governance of natural resources in the property-rights scenario.
Protection of Antarctic Historic Sites and Monuments by Domestic Law

Gustavo Ramirez Buchheister1,2 (gusramirezb@gmail.com)
1Universidad de Magallanes, Departamento de Ciencias Jurídicas, Punta Arenas, Chile, 2Philipps-Universität Marburg, Fachbereich Rechtswissenschaften, Marburg, Germany

In February of 2014 a 'historic first' in Antarctic Environmental Protection occurred: two visitors to Antarctica were tried and condemned to pay a fine of ten thousand Euros each, due to the damage caused to an object of protection by the Madrid Protocol: A Historic Site or Monument. This outcome, however, is not product of a direct enforcement of a provision of the Protocol -a non-self-executing agreement-, but rather the implementation of an Antarctic Treaty-Party's domestic law. Article 13 of the Protocol requires Parties to take appropriate measures within their competence to comply with it, including laws and regulations. On the other hand, Annex V regulates Antarctic Specially Protected and Managed Areas, which include Historic Sites and Monuments.

Would the outcome have been similar if the case had been tried by another Party? Is the protection of Historic Sites and Monuments effectively implemented by domestic law? Is there room for improvement? Could ATCM measures or recommendations broaden the protection of these sites?
The Protocol on Environmental Protection to the Antarctic Treaty was signed in 1991 and entered into force in 1998. Its adoption was a reaction to the environmental damage risks of the mineral activities regulated by the Convention on the Regulation of Antarctic Mineral Resource Activities (signed in 1988, not yet in force). But it is also a result of the Antarctic Treaty System long-time evolution. The Protocol is a milestone in this international regime putting the environmental protection as a central aim of it. Since 1991 and more clearly since 1998, important advances in this task have been achieved: the establishment of a group of environmental principles (article 3), the prohibition of mineral resource activities (article 7), the prior assessment of the environmental impacts of major activities (article 8), the establishment of the Committee for Environmental Protection (articles 11 y 12), or the environmental inspections (article 14).

However, there are still several challenges. Some of them are results of the Protocol structure like the activities that are not covered by it or its geographical scope or the number of States for whom it is compulsory. Others come from the new and changing environmental problems that it is necessary to confront. Finally, some come from the implementation of the Protocol itself and how the national domestic law applies its regulations and control its fulfillment.

All this challenges and achievements will be discussed.
How Should We Justify Ecologically Sustainable Resource Rights in Antarctica?

Øyvind Stokke1 (oyvind.stokke@uit.no)

1UiT The Arctic University of Norway, Department of Philosophy, Tromsø, Norway

How should we justify resource rights within a cryosphere that is being transformed as a result of anthropogenic climate change? In light of the increasing environmental pressure on Antarctica in terms of ice-melt, illegal, illegal, unreported and unregulated fishing, as well as tourism, we need to rethink our way of theorising both territory and the legal regimes that govern it. This paper argues that territorial claims in Antarctica have to fulfil certain conditions of environmental responsibility and distributive justice. More specifically we need to

1) question the connection between political self-determination and the claims to huge territories in the Polar regions, and

2) rethink the justification of resource rights under conditions of extreme environmental vulnerability.

The Earth's natural resources and ecosystems are an environmental commons, and hence access to this commons and its services should be shared. However, several of the claimants in Antarctica are taking more than their fair share of these commons, especially in terms of carbon emissions. Consequently, any principle of ecological justice in Antarctica has to include some sort of benefit-sharing mechanism to ensure that any given claimant state realises its desired capabilities with the lowest impact on ecosystems. I end by scrutinising to what extent the justifications in the Antarctic Treaty could ground ecologically sustainable resource rights.
Multiple Evidence for Early Deglacial Ice Mass Loss in East and West Antarctica

Michael E. Weber¹ (mike.weber@uni-bonn.de), Christopher J. Fogwill², Matthew Decesare³, Nicholas R. Golledge⁴, Natalya Gomez⁵, Peter U. Clark⁶

¹University of Bonn, Bonn, Germany, ²Keele University, Staffordshire, United Kingdom, ³Louisiana State University, Baton Rouge, United States, ⁴Victoria University of Wellington, Wellington, New Zealand, ⁵McGill University, Montreal, Canada, ⁶Oregon State University, Corvallis, United States

Based on recent studies conducted on well-dated deep-ocean, near-shelf- and ice-core records from both West and East Antarctica, we show clear evidence for a very dynamic deglacial behavior of the Antarctic Ice Sheet (AIS) with multiple retreat events in sync with global meltwater and climate events, contrary to scenarios developed earlier (e.g., Bentley et al., 2014).

Highly resolved deep-ocean records from Iceberg Alley indicate major AIS discharge events (AID) bracketing Meltwater Pulse 1A (AID6) and 1B (AID2), between ~14.7 - 11.3 ka (Weber et al., 2014). Also, a blue-ice field in the Patriot Hills area indicates marked AIS draw down (in excess of 650 m) and ice mass loss across the Weddell Sea Embayment during the Antarctic Cold Reversal (ACR, 14.7 - 12.7 ka) (Fogwill et al., 2017). Foraminiferal radiocarbon ages from shallow-marine sediment archives in the eastern Ross Sea (DeCesare et al., submitted) directly constrain discrete intervals of WAIS grounding line retreat of 30 km at 14.7 ka (AID6) and 200 km at 11.5 ka (AID2).

The data evidence combined with thermodynamic ice-sheet modeling (Golledge et al., 2014, 2017), confirm that the AIS was highly-dynamic and sensitive to ocean warming and/or sea level forcing that allowed rapid retreat of ice margins into the interior of the ice sheet. Our findings are important in light of current discussions on potential AIS collapse in the near future and its impact on sea-level rise for the coming decades to centuries.
Northern Hemisphere Influence on Antarctic Ice Dynamics during Last Deglaciation

Natalya Gomez1 (natalya.gomez@mcgill.ca), Gabriel Tseng1, Michael Weber2, Peter U. Clark3
1McGill University, Earth and Planetary Sciences, Montreal, Canada, 2University of Cologne, Institute of Geology and Mineralogy, Cologne, Germany, 3Oregon State University, College of Earth, Ocean, and Atmospheric Sciences, Corvallis, United States

Recent work suggests that the Antarctic Ice Sheet was highly dynamic during the Last Deglaciation. Weber et al. (2014)'s analysis of iceberg-rafted debris in ocean sediment cores from Iceberg Alley shows that Antarctic deglaciation was punctuated by a series of rapid ice discharge events (AIDs). An ocean thermal forcing has been proposed, but triggers for these events and their connection to global ice and climate changes are still being explored. There was up to ~130 m global mean sea level equivalent of additional grounded ice cover globally at the Last Glacial Maximum. The majority of this ice was in the Northern Hemisphere (NH), but there remains significant uncertainty in the timing and distribution of global ice cover during the Deglaciation. Rapid pulses of ice loss occurring in the NH that are not fully resolved in the geological record could have raised sea level in Antarctica significantly. We adopt the coupled dynamic ice sheet - global sea level model described in Gomez et al. (2013) to investigate the possibility that the AID events observed in Antarctica could have been triggered or enhanced by pulses of sea-level rise associated with NH ice loss. We present results of simulations of Antarctic ice sheet evolution through the Deglaciation driving by climate changes and a suite of punctuated NH ice histories, and highlight the possibility of inter-hemispheric teleconnection through a sea level feedback on marine ice dynamics.
Here we present iceberg-rafted debris (IRD) provenance records from sediment core PS1571-1 in the NW Weddell Sea, and interpret these records in terms of the geographic sequence of ice sheet retreat in the Weddell Sea embayment during the last three deglaciations. We first characterize the geochemical and geochronological fingerprint of eroded debris from the source areas using: 1. Till in modern moraines at the edges of the Foundation Ice Stream, the Academy Glacier, and the Recovery Glacier; and 2. Subglacial till from cores along the front of the Filchner and Ronne Ice Shelves. Provenance tracers include $^{40}\text{Ar}/^{39}\text{Ar}$ hornblende and biotite thermochronology, U-Pb zircon geochronology, Nd isotopes, and clay mineralogy. Results so far indicate that samples along the front of the ice shelves record the fingerprint that would be expected from tracing ice flow lines back to the upstream bedrock terranes, and that the Ronne (west), Hughes (central), and Filchner (east) sectors have distinguishable provenance source fingerprints. In core PS1571-1, changes in IRD provenance reflect output of debris-laden icebergs during ice sheet retreats from the different sectors of the embayment through each deglaciation. Preliminary indications are that different sectors of the embayment tend to export glacially-eroded debris sequentially, rather than all at the same time, and that MIS-5 has more of a West Antarctic fingerprint than the other deglaciations.
Ross Sea Deglaciation - Environmental Reconstruction from the RICE Ice Core

The Roosevelt Island Climate Evolution (RICE) project recovered a 763.6 m deep ice core to bedrock during 2011-2013 from Roosevelt Island (RI), at the northern edge of the Ross Ice Shelf. The ice at RI is grounded 210 m below sea level and accumulates in situ, with the Ross Ice Shelf flowing around the rise. High resolution radar surveys show well-developed Raymond Arches of isochrones suggesting a stable ice divide. Here, we show isotope and geochemical data spanning the past 30 ka and discuss reconstructions of sea surface and air temperature, sea ice extent, atmospheric circulation patterns, and ice shelf grounding line retreat. An ensemble of sensitivity modelling experiments is used to determine thresholds for the removal of RI ice and correlated grounding line and ice volume changes of the Ross Ice Shelf and the West Antarctic Ice Sheet.

Our data suggest that the onset of the Ross Ice Shelf grounding line retreat during the deglaciation was driven at least in part by the early deglaciation in West Antarctica as recorded in the WAIS Divide ice core, perhaps through a freshwater feedback. The Ross Ice Shelf grounding line started to retreat rapidly with the initiation of an ice shelf cavity. Atmospheric circulation changes precede the onset of the Antarctic Cold Reversal (ACR) by about 200 years. Maximum ACR sea ice extent is reached at the termination of the ACR and is maintained into the early Holocene, a time period of rapid atmospheric warming and circulation changes.
Totten Glacier History in Continental Slope Sediments, East Antarctica

Phil O’Brien1, Leanne Armand2 (leanne.armand@anu.edu.au), Amy Leventer3, Bradley Opdyke2, Alix Post4, Andrea Caburlotto5
1Macquarie University, Dept of Environmental Sciences, North Ryde, Australia, 2Australian National University, Research School of Earth Sciences, Acton, Australia, 3Colgate University, Dept of Geology, Colgate, United States, 4Geoscience Australia, Canberra, Australia, 5Istituto Nazionale di Oceanografia e di Geofisica Sperimentale, Trieste, Italy

Developing an understanding of how the Antarctic Ice Sheet responds to climate change will require data from the continent’s major drainage basins, records that cover multiple glacial cycles and data on how the ocean and ice sheet interact. To achieve this coverage, sediment cores from the Antarctic continental slope will be needed. The Totten Glacier is a large outlet glacier in East Antarctica which is potentially vulnerable to accelerated melting. The glacier occupies a trough that extends deep into the East Antarctic interior and has displayed rapid thinning, which could draw down of some of the thickest ice in Antarctica. The 2017 Sabrina Seafloor Survey aimed to collect palaeoclimate records from the continental slope seaward of the Totten Glacier to study the interactions of this part of the ice sheet and the Southern Ocean over multiple glacial cycles. Multibeam bathymetry surveying identified large sediment ridges separating submarine canyons. Ridge morphology and seismic stratigraphy suggest that they are composed of canyon overbank deposits. Six long piston cores and 11 Kasten cores were collected. Five of the six piston cores contain cyclic sedimentary facies indicating records going back to Marine Isotope Stage 10 (~350ka.). A single core was aimed at a condensed section and may have sampled Pliocene to Early Pleistocene sediments. Preliminary analysis of the cores suggests that each glacial-cycle sampled has unique features.

On behalf of the Sabrina Seafloor Shipboard Party, Australian National University, Acton, Australia
Holocene Climate Evolution off Northern Victoria Land, East Antarctica

Olivia Truax1,2 (olivia.truax1@gmail.com), Christina Riesselman1,2, Gary Wilson3, Rebecca Parker4, Kyu-Cheul Yoo5, Jae Il Lee4, Richard Levy5, Robert McKay6

1University of Otago, Geology Department, Dunedin, New Zealand, 2University of Otago, Marine Science, Dunedin, New Zealand, 3University of Exeter, Exeter, United Kingdom, 4Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of, 5GNS Science, Wellington, New Zealand, 6Victoria University of Wellington, Wellington, New Zealand

Regionally representative records of how the Antarctic climate system evolved through the Holocene are an essential component of understanding the processes that drive the Antarctic climate. We present a high-resolution multi-proxy record of Antarctic paleoclimate evolution during the last 7,200 yr from a sediment core retrieved by the RV/IB Araon from Robertson Bay, a previously unstudied sector of the Victoria Land Margin. Using diatom assemblages, bulk sediment geochemistry, and the magnetic properties of RS15-GC57, we reconstruct Holocene climate variability at the interface between the East Antarctic Ice Sheet and the Southern Ocean.

A rapid transition at ~3,500 cal yr BP, constrained using novel ramped pyrolysis 14C dating, is evident in all environmental proxies and is coincident with the Hypsithermal-Neoglacial transition recorded in sediment cores from Adélie Land, the Ross Sea, and the Antarctic Peninsula. A sea ice-associated diatom assemblage characterizes a discrete interval from 700 cal yr BP to modern, suggesting an environmental response to the Little Ice Age at the northern margin of the EAIS. High frequency (80-350yr) environmental variations, attributed to solar variability in previous marine Antarctic studies, are superimposed onto these millennial scale regional trends. Preliminary analysis suggests that changes in westerly wind stress and the upwelling of Circumpolar Deep Water were a primary driver of late Holocene climate dynamics in the Antarctic.
Temperature-driven Structure and Activity of the Global Ocean Microbiome

Guillem Salazar1 (guillems@ethz.ch), Tara Oceans Consortium1, Shinichi Sunagawa1
1ETH Zurich, Department of Biology, Zurich, Switzerland

Marine microbes cope with a variety of environmental gradients that may impact their global distribution and their metabolic state. Previous studies have shown that the distribution and structure of microbial communities in low and mid latitudes are largely governed by temperature. Temperature is thus one of the major environmental factors that marine microbes will need to respond to. Given that the rate of seawater temperature change is particularly high in polar regions, a better understanding of microbial responses to temperature change is crucial. Here we analyze a dataset composed of 367 epipelagic and mesopelagic metagenomes and metatranscriptomes from the Tara Oceans Expedition (2009-2013). Sample collection sites are distributed across all main oceanic regions, covering a 143° latitudinal range, and includes a focused sampling effort from a circumnavigation of the Arctic Ocean. We describe a universal relationship between seawater temperature and the structure of microbial communities, which is consistent across the entire temperature gradient (-1.6 to 30.6º C). We define cold-adapted taxa and explore metabolic capacities that are enriched in cold waters using metagenomic data. We combine these data with metatranscriptomic information to analyze how metabolic potential and activities vary across the global ocean. The results are expected to help us predict how microbial communities will respond to the impact of climate change.
The McMurdo Dry Valleys are considered a Martian analog environment due to extremes in aridity, high-speed winds and low temperatures. Life in this environment survives an absence of water for around 9 out of 12 months and is primarily comprised of cyanobacteria mats that harbor bacteria, eukaryotic algae, and micro-invertebrates. During the austral summer, rising temperatures cause glacial melting and streams of freshwater begin to flow downward through the valleys carrying alluvium and rehydrating cyanobacteria mats. Temperature fluctuations of the meltwater streams reach anywhere from 0.1 °C to a maximum of 15 °C with daily shifts between 6°C-9°C. Von Guerard is one of the longest streams (4.9km) in the Taylor Valley, Antarctica and has a record of high interannual stream flow variability. Microbial mat samples from Von Guerard were collected early summer before flow started and continued on a weekly basis until the stop of flow in late summer. This study shows the transcriptional responses of the Von Guerard microbial mat communities compared through the start and end of the season with the inclusion of stream discharge, water/air temperature and conductivity data. Transcriptional profiles under low temperatures and frozen conditions display an upregulation of known stress response genes. This investigation is the first to determine in situ function of Dry Valley transient stream microbial communities through a whole melt season.
Sulphur Cycling and Microbial Dynamics along a Glacial-oceanic Transect

Daniel Aagren Nielsen¹ (danielaagrennielsen@gmail.com), Jean-Baptiste Raina¹, Mark Vincent Brown², Justin Seymour³, Katherina Petrou¹
¹University of Technology Sydney, Broadway, Australia, ²University of New South Wales, Randwick, Australia

Antarctica has been identified as a hot spot of organic sulphur cycling and ocean-atmospheric sulphur fluxes. Organic sulphur compounds, such as dimethylsulfiniopropionate (DMSP) and dimethylsulfide (DMS) produced by Antarctic phytoplankton affect marine food-web interactions, which are key to marine sulphur cycling and flux dynamics. This study examined Antarctic phytoplankton-bacteria associations and their influence on marine sulphur cycling along a coastal transect from an inner fjord of the Sørsdal glacier to the open ocean. Phytoplankton abundance increased with distance from the glacier, while community composition remained fairly constant. There was a corresponding increase in DMS concentrations toward the open ocean, likely attributed to the increased biomass. Through combining nutrient dynamics, 16S next generation sequencing and qPCR, we aim to understand the way in which these observed patterns link to bacterial community composition and specific sulphur-metabolising genes and how environmental gradients produced from glacial runoff influences marine microbial communities and sulphur cycling.
The Colonication and Selection Processes Shaping Frost Flower Communities

Rose Emma Layton1 (r.layton@enoveo.com), Timothy Vogel1, James France2, Catherine Larose1
1École Centrale de Lyon, Laboratoire Ampère, Lyon, France, 2University of East Anglia, Environmental Sciences, Norwich, United Kingdom

The temporal and spatial coverage of frost flowers on sea ice is expected to increase in the Arctic in line with the predicted impact of climate change, and yet, their ecological, biogeochemical and climatic roles are poorly understood. Frost flowers have been shown to host distinct microbial communities relative to the underlying sea ice, sea water and brine as a result of selective colonisation processes. To explore the mechanisms influencing frost flower community structure and the potential of atmospheric deposition as a colonisation route, sea ice and frost flowers were cultivated from sea water in the Roland von Glasow sea ice chamber at the UEA, UK. Samples were subsequently subjected to 16S rRNA gene and metagenomic sequencing. The community structure and the extent of the mobile gene pool were analysed. The formation of multiple niches within the ocean-sea ice-atmosphere profile is probably responsible for shaping the community structure. Metagenomic sequencing revealed an enrichment in mobile genetic elements that are suspected to contribute to the rapid adaptation of microorganisms to alien microhabitats. These results provide novel insights into poorly characterised ecosystems with increasing global significance in terms of their role in biogeochemical cycling. In addition, the mechanisms involved in the colonisation of microorganisms throughout sea ice formation can be deciphered with the metagenomic data.
Climate models predict that Antarctica will warm more rapidly than many other parts of the globe, and more widespread warming of continental Antarctica is expected to accelerate. Much of the productivity and biodiversity is linked to benthic cyanobacteria-based microbial mat communities. However, to identify and forecast biological responses to environmental change, baseline data is essential to understand the level, and time scales over which environmental change affects community assemblages and functioning such as cyanotoxin production. We carried out cyanobacteria-specific 16S rRNA gene high throughput sequencing and cyanotoxin analysis of freshwater cyanobacterial mats collected in 1902-03 during Captain Scott's Discovery expedition in Antarctica. We found that historic cyanobacteria assemblages showed some variation in community structure to modern cyanobacterial mats, but were dominated by the same genotypes. It suggests slow cyanobacterial genotype turnover and considerable community stability. Ultra-performance liquid chromatography-photodiode array detection and tandem mass spectrometry identified microcystins at concentrations from 0.5 to 16.1 µg g⁻¹ dry weight. BMAA (β-N-methylamino-L-alanine) and its isomers were found for the first time in Antarctic cyanobacteria. The results demonstrate the value and potential of historic cyanobacteria collections in temporal investigations of cyanobacteria, freshwater ecosystems and climate in Antarctica.
Climatic variations will have profound effects across the cryosphere. Ecotones are susceptible regions, and are
defined as boundaries between adjacent ecosystems. Macro-organisms within ecotones are sensitive to
variations in climate - which have potentially long-lasting impacts. Here we show, for the first time, that
microbial and viral communities within ecotones can be analysed to monitor biological changes resulting from
warming. Collectively, we show that the Mackay Glacier ecotone, Eastern Antarctica represents a distinct
ecosystem compared to the McMurdo Dry Valleys. We found soil respiration to be an order of magnitude
lower in the ecotone than surrounding bioregions, likely the result of extremely low soil nutrient contents and
soil stoichiometric imbalance. Isotope data indicate that soil carbon is transformed via the Calvin cycle, while
soil nitrogen is recurrently assimilated in situ. These trends were supported by in silico gene analyses of 18
assembled metagenomes, which showed a prevalence of these carbon and nitrogen cycling pathways. These
mechanisms are driven by dominant chemosynthetic heterotrophic bacteria of the Bacteroidetes and
Acidobacteria. Site altitude was the strongest predictor of microbial community structure, which was also
shown to drive viral populations within the ecotone. Finally, we show that viral population constitute the
lowest trophic tier of Antarctic soil communities, and interact with their hosts to maintain diversity and
function.
Comparing L- and C-band Synthetic Aperture Radar Estimates of Sea Ice Motion

Stephen Howell1 (stephen.howell@canada.ca), Alexander Komarov2, Mohammed Dabboor3, Benoit Montpetit2, Michael Brady3, Randy Scharien4, Mallik Mahmud5, Vishnu Nandan5, Torsten Geldsetzer5, John Yackel5
1Environment and Climate Change Canada, Toronto, Canada, 2Environment and Climate Change Canada, Ottawa, Canada, 3Environment and Climate Change Canada, Montreal, Canada, 4University of Victoria, Victoria, Canada, 5University of Calgary, Calgary, Canada

Estimating sea ice motion from synthetic aperture radar (SAR) imagery at C-band is the most reliable approach because of its high spatial resolution and ever increasing temporal resolution given the multiple current and upcoming SAR platforms. However, there is still uncertainty in SAR derived sea ice motion depending on the ice type and its thermodynamic state. There have been suggestions (mostly theoretical) that use of L-band SAR and its inherent longer wavelength (15-30 cm) and subsequent increased penetration capability could be beneficial for estimating sea ice motion, especially during the melt season. Here, we estimate and analyze sea ice motion for 9 pairs of C- and L-band SAR imagery from RADARSAT-2, PALSAR-1 and PALSAR-2 located in the Canadian Arctic over a variety of sea ice types at different thermodynamic states. Results show that the increased signal penetration of L-band SAR into multi-year ice (MYI) during the melt season facilitates the detection of more motion vectors with stronger cross-correlation coefficients compared to C-band SAR. Over newly formed ice and dry first-year ice, the reduced sensitivity to surface scattering and richer texture from L-band SAR imagery facilitates the detection of more motion vectors with stronger cross-correlation coefficients compared to C-band SAR. Over dry MYI, L-band provided stronger cross-correlation coefficients but C-band detected more motion vectors with a more representative spatial distribution.
ZY-3 is the first civilian high-resolution stereo mapping satellite of China, launched in January, 2012. It is equipped with a three-line-scanning camera system to build along track and quasi-real-time (~30 seconds) stereo pairs by a combination of forward, nadir and backward looking images. The along track stereo mapping technique has the advantages of quasi-real-time capturing of the 3D ground movement. The satellite was first time programmed in February 2014 to adjust its sensor parameters to fit the Antarctic setting and collected a collection of Antarctic stereo images for a number of selected sites. Two typical applications in Antarctica remote sensing by using ZY-3 images are investigated. First one is the detection and speed estimation of large scale blowing snow, for which we proposed a stereo photogrammetric technique. Blowing snow is referred as the phenomenon of uplift and horizontal transport of snow by wind. It occurs frequently in Antarctica and is important in many aspects including surface mass balance and surface morphology. The second application is 3D modelling of ice shelf rifts, which are a precursor to iceberg calving. The 3D models of a newly detected large rift in Filchner Ice Shelf from ZY-3 stereo images revealed important topographic information (rift length, width, depth, wall and mélange) that can be used to improve the reliability of ice shelf modeling and support enhanced analyses of ice shelf stability.
Snow Deposition Characteristics at Union Glacier by SAR and Geospatial Analysis

Christian Gobel¹² (cfigobel@gmail.com), Jorge Arigony-Neto¹², Ricardo Jaña³
¹Federal University of Rio Grande, Oceanographic Institute, Rio Grande, Brazil, ²Instituto Nacional de Ciencia e Tecnologia da Criosfera, Porto Alegre, Brazil, ³Instituto Antártico Chileno, Punta Arenas, Chile

Surface mass balance is a key component to assess the net contribution of the ice sheet to the ocean. A precise quantification of the accumulation processes as snow precipitation and wind transport and deposition of snow is required. Union Glacier (UG) is an outlet glacier at the Ellsworth Mountain Range and drains into the Ronne-Filchner Ice Shelf. Previous studies agree that mean surface mass balance for this glacier range from 0.18 to 0.33 m a⁻¹. Although it seems a good estimation, they do not represent spatial variability in snow deposition due to: (i) topographic relief; (ii) wind driven accumulation; and (iii) sublimation rate. Our aim is to identify and delimitate different deposition zones on the glacial drainage basin of UG. Thus, we generate qualitative maps of snow density and grain-size, as derived from backscattering values of five Cosmo-SkyMed X-band images. We interpret these maps together with 7 snow pits dug in different sites through the glacier basin. Results confirmed a distinct pattern of snow deposition and densification along the glacier, strongly driven by wind. Wind exposed areas have larger snow crystals (i.e., 1-4 mm against 0.5-1 mm in wind protected areas), faceted forms due to higher temperature gradient, more deposition layers and layers with higher hardness. In order to delimitate different depositional zones, we run a cluster analysis with the snow density and grain-size maps, together with slope, aspect and wind effect data derived from TanDEM-X.
Mitigating Effects of Penetration in the CS2-Swath Rates of Elevation Change

Flora Weissgerber¹ (flora.weissgerber@ed.ac.uk), Noel Gourmelen²

¹The University of Edinburgh, Edinburgh, United Kingdom

One of the aim of the ESA Altimetry mission CryoSat-2 (CS2) is to identify changes in ice thickness to quantify the contribution of the cryosphere to sea level change. CS2 revolutionary design features SAR and interferometric capacities, that allow to increase spatial resolution while resolving the angular origin of off-nadir echoes occurring over sloping terrain, making it particularly adapted to monitor ice-sheet margins. On top of measuring more precisely the elevation of Point Of Closest Approach (POCA), the standard level-2 product, CS2 SARIn mode allows also the so-called CS2 Swath SARIn (CSSARIn) approach: elevations beyond the POCA are produced, leading to between 1 and 2 orders of magnitude more measurements than level-2 product. Among other products, the ESA project CryoTop Evolution aims to deliver to the community maps of rates of surface elevation change over the Greenland and Antarctic Ice Sheets. To produce accurate rate of elevation changes from the CS2 elevations, changes in the penetration properties of the snow or ice has to be taken into account. If retrackers have been developed to limit the effect of penetration in the POCA retrieval, CSSARIn samples far from the POCA can be heavily subject to penetration changes. Here we will present first attempts to separate changes in penetration from the rate of elevation change by including proxies for penetration in the model linking elevations to elevation changes.
An Integrated Approach to Map Ice-free Areas of the Antarctic Peninsula Region

Thomas Schmid¹ (thomas.schmid@ciemat.es), Stéphane Guillasso²,³, Jerónimo López-Martínez⁴, Ana Nieto⁴, Sandra Mink⁴,⁵, Magaly Koch⁶, Enrique Serrano⁷
¹Centro de Investigaciones Energéticas Medio Ambientales y Tecnológicas -CIEMAT, Environment, Madrid, Spain, ²Computer Vision and Remote Sensing Group, Technische Universität Berlin, Berlin, Germany, ³CNRS GIPSA-lab, Saint Martin d'Hères, France, ⁴Universidad Autónoma de Madrid, Dpt. Geología y Geoquímica, Madrid, Spain, ⁵Instituto Geológico y Minero de España, Madrid, Spain, ⁶Boston University, Center for Remote Sensing, Boston, United States, ⁷Universidad de Valladolid, Dpt. Geografía, Valladolid, Spain

Ice-free areas within the studied Antarctic region are considered highly dynamic and show a complex mosaic of surface covers due to periglacial, glacial and fluvial processes. The objective of this work is to develop an integrated remote sensing approach to map periglacial, glacial and geological structures in ice-free areas of King George, Livingston and Deception islands. This includes using remotely sensed satellite-borne Synthetic-Aperture Radar (SAR) RADARSAT-2 and Sentinel-1 data, and optical Landsat-8 and Sentinel-2 data. A georeferenced data base is compiled containing site specific data that include field measurements, observations and laboratory soil analysis, geomorphological and geological maps that are used as reference and validation data to obtain a distribution of the different landforms. The supervised classification results show the identification of complex and relatively small scale geomorphological features such as periglacial landforms. In this case, characterizing and monitoring the distribution of some of these landforms is often an indicator of the presence of permafrost and related to hydrological changing processes. The integrated approach shows that the synergetic use of SAR backscattering characteristics and optical reflectance properties improves extracting and identifying different surface covers. Furthermore, it has been possible to extrapolate the results to ice-free areas over a larger region where access is limited.
Optical Fractional Snow Cover Retrievals under Development at Three Continents

Igor Appel1 (iappel@earthlink.net)
1TAG, Washington, United States

A large scale international snow products intercomparison and validation project initiated by the European Space Agency was recently completed in the Environmental Earth Observation company at Innsbruck, Austria. The project provides an independent comparison of various approaches to map snow, including subpixel snow fraction, using detailed stratified comparison with almost 500 Landsat reference data sets. The validation of snow fraction demonstrates that the algorithm initially developed by the author of the presentation jointly with Dr. Salomonson, NASA has advantages in comparison with other products both on open land and in forested areas.

The algorithm takes into account that the reflectances of snow and non-snow are characterized by a significant local variability and also by changes from one scene to another. The local snow and non-snow endmembers are approximated by the Normalized Difference Snow Index. The magnitudes of snow and non-snow Normalized Difference Snow Indexes are scene-specific and calculated on the fly to retrieve snow fraction. The development of scene-specific algorithms is an optimal way to fractional snow retrieval from moderate resolution satellite observations.

European Space Agency and Japan Aerospace Exploration Agency recently decided to derive snow fraction using visible observations from Sentinel-3 and GCOM-C respectively. It is assumed that the collaboration between several parties tackling the same problem can be very promising.
OC-1_OC-2b - Innovation, partnership and impact in polar science communication & Polar Research and Citizen Science: Exploring New Platforms and Opportunities

School of Ice: Professional Development Program for College Geoscience Faculty

Louise Huffman¹ (louise.t.huffman@dartmouth.edu), Hilarie Davis²
¹Dartmouth College, Rotonda West, United States, ²Technology for Learning, Inc., Jensen Beach, United States

The School of Ice (SOI) from the US Ice Drilling Program Office (IDPO) is designed for college faculty to increase background knowledge about ice core science and climate change and provide experiences with activities and labs for transferring information to students. This presentation will identify valuable key ideas from our model: pairing researchers and educators as presenters; building a science community willing to participate in education/outreach; increasing participants' background knowledge and confidence; and encouraging teacher buy-in to ensure replication and dissemination. IDPO's drilling technologies also make it an ideal platform for intertwining engineering practices with science research to meet new science standards. Results of the institute evaluations will be shared including the impact on the educators and a longitudinal analysis of data from interviews with past participants concerning continued impacts on their teaching, their courses and their students. Faculty who have attended this institute in the last three years have reported increases in their understanding of the content and how to teach it, as well as increased confidence in their ability to teach ice core science and climate change concepts. Elements of SOI can inform the development of college professional development and student courses, as well as the creation of successful education and outreach programs for science research teams wanting greater impact of their research results.
The Antarctic Legacy of South Africa (ALSA) fulfil various aims within the South African National Antarctic Programme (SANAP), one aim being to promote the human involvement in the South African sector of the Antarctic region. This aim is achieved mainly through attracting post graduate students to the different research disciplines that form part of SANAP through the World Wide Web, social media and awareness activities e.g. museum exhibitions.

The success that the ALSA website has within the reach of South Africa did not go unnoticed by partners in the SANAP environment. This resulted into a collaboration effort with South Africa’s Department of Environmental Affairs (DEA), Branch: Oceans and Coasts. DEA is responsible for the logistics and environmental management of our involvement in the Antarctic region. The collaboration effort entail the design of a new and improved SANAP portal, in the form of a new website. This portal will present information on the logistics and research efforts of South Africa in the Antarctic region. The research efforts will cover the four themes as stipulated by SANAP, namely Earth Systems, Living Systems, Human Enterprise and Innovation: technology and engineering. Therefore, the portal will serve as a contact point within the broader SANAP community, including funding agencies and the public.

This presentation will thus focus on ALSA’s role in promoting South Africa’s involvement in the Antarctic community through the new SANAP portal.
Science Outreach & STEM Education in Antarctica: Virtual Reality and Robotics

Nuno Pereira¹ (nuno.pereira@ipbeja.pt), Ludmila Filipova²,³, João Rocha⁴
¹Polytechnic Institute of Beja, Mathematics and Physical Sciences, Beja, Portugal, ²Sofia University, St. Kliment Ohridski, Sofia, Bulgaria, ³Bulgarian Antarctic Institute, Sofia, Bulgaria, ⁴Independent Scholar, Évora, Portugal

The Antarctic Research & Education Program (AREP) is going to be implemented on the “St. Kliment Ohridski” Antarctic Bulgarian Base during the 2017-18 campaign, as a collaboration between the Physics and Instrumentation Laboratory of the Polytechnic Institute of Beja, Portugal, the Bulgarian Antarctic Institute, and the Sofia University St. Kliment Ohridski. Two schools in each country, with students with ages from 6 to 15 years old, are involved as case studies and proof of concept of the program. This edition of AREP contemplates two projects: ViRAL - Virtual Reality Antarctic Laboratory, and Antarctuino - Physical Computing with Arduino in Antarctica. The first initiative is a Virtual Reality based science outreach project, with the objective of bringing Antarctica closer to the public. Antarctuino aims the development of coding skills with an open source hardware platform, the Arduino, and robot programming with a scratch based language, engaging educators and students in project based learning in the framework of STEM education. The output of these projects will be used in several initiatives to increase public awareness on Antarctica related issues, such as global warming, and the importance of research, and monitoring in this region of the Planet. This communication will report the results of the first edition of AREP in terms of science outreach sessions, STEM education activities, lessons learned, and the future steps for the next campaign.
Using Podcasts to Extend your Audience and Expand Content Communication Options

Nicholas O’Flaherty¹ (nicholaso@camino.co.nz)
¹The Antarctic Report, Auckland, New Zealand

The Antarctic Report is an online portal dedicated to all things on Antarctica and the Southern Ocean, published by Camino, a digital content and publishing company based in Auckland, New Zealand. The site showcases the hard science which underlines the importance of Antarctica as a bellwether of global climate change. It also highlights the continent’s unique political status, as well as the exceptional demands its environment places on people and equipment, and the romantic allure for travelers and explorers as the least discovered continent on the planet.

The weekly podcasts were introduced on the portal in June 2017 as a way to extend content options. The format of the podcasts is an interview with one expert, usually 30 minutes in duration. This long-form interview allows for greater focus on subject matters. It also creates transcript opportunities to extend the channels. The podcast are cost-effective with editing done in-house.

This presentation will outline why The Antarctic Report chose the podcast format, as well as present the practical step-by-step process in getting the podcast launched, and the lessons that were learnt on the way.
A Special Role for Feature Films in Science Communication

Peter Barrett1 (peter.barrett@vuw.ac.nz)
1Victoria University of Wellington, Antarctic Research Centre, Wellington, New Zealand

Through the 19th and 20th centuries scientists communicated within and beyond the community itself through peer-reviewed journal articles and books, advancing knowledge through a self-correcting process for the betterment of many. In the 21st century the pace of technology-driven change and media-driven competition for attention is making it increasing difficult to inform community thinking with evidence-based knowledge on solutions to the pressing problems of our time.

Though technology has made huge advances over its hundred year history, I'll suggest that film continues to appeal as an essentially communal viewing experience for such issues. With a viewing time of typically 1-2 hours a film has time to appeal both intellectually and emotionally on any one of a range of big issues. Arnold Schwarzenegger said recently the challenge is to be “simple and clear and make it a human story.” These days the film maker also needs to ensure self-evident authenticity.

Arguably the most effective in the “pressing problems of our time” genre is Al Gore’s “An Inconvenient Truth” (2006), driven by good timing, sound science and a personal story. Since then there have been half a dozen science-based stories with a similar mission and a TV series “Years of Living Dangerously” (2014, 2016 - a total of 17 1-hour stories) that address both problem and solution. I'll discuss their different qualities and varying degrees of success. We can learn from these stories and need more of them.
Taking Antarctica to the World. ICE101x, an Antarctic Massive Open Online Course

Cliff Atkins¹ (cliff.atkins@vuw.ac.nz), Rebecca Priestley¹, Jacqueline Dohaney¹, Rhian Salmon¹
¹Victoria University of Wellington, Wellington, New Zealand

In 2017 Victoria University of Wellington, supported by Antarctica New Zealand, launched ICE101x Antarctica: From Geology to Human History, a Massive Open Online Course (MOOC) via the edX platform. The fully online, interactive, interdisciplinary course attracted over 5700 students from 128 countries. Students had a wide range of backgrounds: from school and university students to retired people, science lecturers to Antarctic base staff.

ICE101x featured innovative, field-based video lectures filmed in Antarctica and at the 2014 and 2016 SCAR Conferences, supported by open access online resources and a discussion board. It was led by Antarctic experts from VUW and featured guest lectures or interviews with artists and scientists, offering a truly interdisciplinary teaching programme. Given the severely limited opportunities to take students to Antarctica, this MOOC gave students an authentic, yet remote, experience and insight into this unique environment.

Analysis of students’ interactions with the course, and response to an end of course survey, revealed that students were highly engaged and satisfied with the course and emerged from the course with new understandings of issues such as climate change and the process of scientific research. A new version of the course ICE102X (2019) will include a new module on Antarctic biology.

We will present an overview of the course, including our insights, findings, and opportunities for future collaboration.
Impacts of Forest Fires on Discontinuous Permafrost in the Northwest Territories

Jean Holloway¹ (jean.holloway77@gmail.com), Antoni Lewkowicz¹
¹University of Ottawa, Geography, Environment and Geomatics, Ottawa, Canada

Forest fire is rarely taken into account in predictive modelling of permafrost change even though severe fires have been shown to accelerate degradation. Moreover, the frequency and magnitude of fires is increasing as the climate warms. We are examining permafrost change following the 2014 fires in the Northwest Territories, Canada in order to improve predictive modelling of the fate of permafrost in the region. A total of 18 burned and unburned sites representing a range of conditions were established in 2015 and 2016. At each site, air and near-surface ground temperature are being monitored continuously. Direct current electrical resistivity tomography (ERT) surveys and frost table measurements are being conducted annually. Burned sites were warmer than unburned ones: surface offsets averaged 0.5°C greater and the thermal offsets 0.1°C smaller. Average frost table depths at burned sites were 17 cm greater than at unburned sites, and were generally greater in 2017 compared to 2015. This reflects impacts of the burn as mean summer air temperatures differed by only 0.3°C. Results from ERT surveys show the possible loss of permafrost within some sites. The most-affected sites are underlain by coarser-grained substrates with thin organic layers, whereas peatland sites are less impacted. These results indicate the heterogeneity of permafrost reaction to fire at the landscape scale and suggest that permafrost may persist in peatlands while degrading elsewhere in the region.
Thermal modelling is important for a better understanding of the ground thermal regime in Alpine permafrost. We present a modelling approach that makes use of common concepts in engineering sciences (FE-modelling) to represent and quantify convective heat transfer in air in coarse permafrost substrate. The effect of convective heat transfer in air has been addressed in many observation-based studies. Modelling approaches are still rare and often limited to one dimension which neglects lateral heat transfer. Previous results from a 2-D model showed that convective heat transfer may have a significant influence on the ground thermal regime in a talus slope. This modelling approach is now extended to explore the effects of convective heat transfer in other landforms (e.g. rock glaciers) and to more site-specific calibration allowing the validation of the used model approach. Studying different sites and landforms in the Swiss Alps is possible thanks to the availability of long-term monitoring data of different field sites which are systematically processed and stored within the PERMOS (PERmafrost MOnitoring Switzerland) network. Modelling results show that convective heat transfer in air cannot be neglected in Alpine permafrost and it has, at least for some landforms, important effects on ground temperatures. The study also shows that easily available long-term and high-quality monitoring data is of great benefit for model forcing and validation.
We present a Holocene temperature reconstruction at the arctic Greenland Analogue Project (GAP) study area near Kangerlussuaq in western Greenland. The air temperature history is obtained by combining meteorological data from (i) the GAP tundra site, (ii) Kangerlussuaq and coastal sites in South-West Greenland, and (iii) selected Greenland Ice Sheet sites, together with temperature proxy ice-core records. For the glacial stage in the early Holocene, a one-dimensional steady-state ice-sheet model is developed to reproduce the ice thickness and basal thermal conditions of the ice-sheet, and the associated isostatic adjustment. The model uses the geologically-determined ice-margin position and modelled Holocene elevation change of the ice divide. Using the temperature reconstruction and information on present-day vegetation and water bodies, a numerical model, calculating e.g. heat transfer, groundwater flow and salt transport, is used to simulate the thermal evolution of the subsurface including soil and bedrock temperatures, geothermal heat flow and the depth and distribution of permafrost and perennially frozen ground. Seasonal variations in surface processes such as the freezing and thawing of the active layer are taken into account. Comparison with measured soil temperatures and bedrock temperatures measurements down to 570 metres reveals several important factors and processes for the development of permafrost and perennially frozen ground in Greenland.
A High-resolution Coupled Permafrost - Ice Sheet Model

Thomas Zwinger¹ (zwinger@csc.fi), Juha Hartikainen², Denis Cohen³
¹CSC -- IT Center for Science Ltd., Espoo, Finland, ²Tampere University of Technology, Tampere, Finland, ³New Mexico Institute of Mining and Technology Socorro, Socorro, United States

We present the development of a high-resolution coupled permafrost - ice sheet model based on continuum thermodynamics. The model includes heat-transfer within ice, water and soil, including phase change, saturated groundwater flow, salinity transport as well as deformation and stress-distributions of ice, soil and bedrock. It further takes into account important couplings, such as effects of permafrost on glacier sliding and hydraulic conductivity of soil and bedrock, effects of solutes on the development of permafrost, and effects of ice flow and groundwater flow on heat transfer. Implemented in the Finite Element code Elmer, this package provides the possibility to couple a permafrost to a high-resolution glacier or ice-sheet model (Elmer/Ice) that accounts for all stress components (full-Stokes) and thereby - in contrast to usually deployed lower order approximations - has no limitations in spatial resolution. This makes it possible to study detailed processes at places that need high resolutions, such as ice-sheet margins where permafrost may play an important role in controlling the basal ice temperature, or geologically strongly varying bedrocks where permeability changes as a result of permafrost formation or degradation can significantly alter groundwater flow paths. The model is tested on problems of approaching and retreating ice margins using synthetic settings, and real geometries, where measurements for comparison and model constraints are available.
Lacking knowledge on snow properties in high latitude regions poses a major limit to the modelling of the ground thermal regime for permafrost and climate science. To this end a dedicated snow campaign took place in 2013 at the Samoylov permafrost observatory in Siberia. We present estimations of snow thermal conductivity $K_{eff}$ based on X-ray microtomography from Samoylov samples, and investigate the links between snow properties and the polygonal tundra micro-topography. We analyse the consistency of estimated $K_{eff}$ with respect to measured soil temperatures. For that purpose, the snow model SNOWPACK is phenomenologically adapted to Arctic conditions to ensure a bare agreement with snow observations. Our observations describe a relatively conductive snowpack at Samoylov ($0.21 \pm 0.01$ W m$^{-1}$ K$^{-1}$ across grass-covered polygons) where the thermal resistance of the snowpack is mostly controlled by variations in snow height induced by the polygonal micro-topography. The modified SNOWPACK simulates reasonable density and $K_{eff}$ profiles, which strongly improves the simulation of the ground thermal regime. Finally, we use chained SNOWPACK and permafrost modelling to assess the thermal impact of snow spatial variability in both depth and structure: the sensitivity of soil temperatures to snow cover variability is high and most pronounced during the early and dark winter. This highlights the demand for improved snow characterization and snow parameterization in these periods.
Efficient Data Assimilation in a Quasi-distributed Permafrost Modeling Framework

Joel Fiddes\(^1\) (joelfiddes@gmail.com), Kristoffer Aalstad\(^2\), Sebastian Westermann\(^1\)

\(^1\)University of Oslo, Oslo, Norway

The mountain cryosphere is undergoing significant changes globally, yet these changes are in many cases poorly constrained, particularly in remote regions where data is sparse. Previously developed methods for downscaling driving meteorology (Fiddes and Gruber 2014) and a subgrid scheme (Fiddes and Gruber 2012) have proven to be promising approaches to large area transient simulations of permafrost in remote areas due to order of magnitude efficiency gains. However, major sources of uncertainty still remain in the meteorological forcing, particularly precipitation which features high spatiotemporal variability and is heavily modulated by local topographic effects. Additional complexity arises due to the inherent uncertainty in precipitation observations, especially in the solid phase. Solid precipitation is an important target variable to accurately quantify as it is a key control on the ground thermal regime. To address these issues we employ an ensemble data assimilation scheme, based on the particle batch smoother, that assimilates MODIS fractional snow cover observations into the modelling framework. Efficiency gains in the underlying framework, due to the downscaling and subgrid scheme, make this approach particularly suited for the treatment of uncertainty through ensemble simulations and data assimilation.

We present results from validation in the European Alps and test applications in the Himalaya together with new results from the latest ECWMF reanalysis ERA5.

A 20\textsuperscript{th} Century Perspective on Summer Antarctic Pressure Change and Variability

Ryan Fogt\textsuperscript{1} (fogtr@ohio.edu), Chad Goergens\textsuperscript{1}, Julie Jones\textsuperscript{2}, David Schneider\textsuperscript{3}, Julien Nicolas\textsuperscript{4}, David Bromwich\textsuperscript{4}

\textsuperscript{1}Ohio University, Geography, Athens, United States, \textsuperscript{2}University of Sheffield, Sheffield, United Kingdom,  
\textsuperscript{3}National Center for Atmospheric Research (NCAR), Boulder, United States, \textsuperscript{4}Ohio State University, Byrd Polar and Climate Research Center, Columbus, United States

During the late 20\textsuperscript{th} Century, the Antarctic atmospheric circulation has changed and significantly influenced the overall Antarctic climate, through processes including a poleward shift of the circumpolar westerlies. However, little is known about the full spatial pattern of atmospheric pressure over the Antarctic continent prior to 1979. Here we investigate surface pressure changes across the entire Antarctic continent back to 1905 by developing a new summer pressure reconstruction poleward of 60°S. We find that only across East Antarctica are the recent pressures significantly lower than pressures in the early 20\textsuperscript{th} century; we also discern periods of significant positive pressure trends in the early 20\textsuperscript{th} century across the coastal South Atlantic sector of Antarctica. Climate model simulations reveal that both tropical sea surface temperature variability and other radiative forcing mechanisms, in addition to ozone depletion, have played an important role in forcing the recent observed negative trends.
Amazon and Antarctic Stable Isotope Ratios in the Southern Brazilian Rainfall

Francisco Aquino¹, Ronaldo Bernardo¹, Jefferson Simões¹, José Celso Griebler Junior¹, Venisse Schossler¹, Pedro Reis¹
¹Universidade Federal do Rio Grande do Sul / INCT da Criosfera, Geography, Porto Alegre, Brazil, ²Centro Polar e Climático, Geography, Porto Alegre, Brazil

This study examines interactions between the Antarctic air masses and those from tropical South America (SA) responsible for severe and regular precipitations events in Southern Brazil (SB) during 2016. This year also stands out as the warmest in the world since 1921, and the second in SA, but with regional monthly contrast (including negative anomalies in the La Plata Basin and the SB). A Palmex Rain Sampler RS1 collected rain in the city of Porto Alegre; the oxygen isotope ratios were determined by the Cavity Ring-Down Spectroscopy method (Picarro system). To analyze the geopotential height fields, wind vectors, zonal wind, precipitable water and temperature at 925, 750, 500 and 200 hPA, monthly and seasonally, using ERA-Interim Reanalysis data. The presence of polar fronts, coupled with the low and high atmospheric circulations, strengthened convection by developing severe storms in the SB. In addition, we have three moisture sources of intense rainfall in southern Brazil: the Amazon Forest, South Atlantic Ocean and Antarctica. So, it is suggested that temperature contrast observed between advection and circulation of tropical and polar air masses enhance convection and could be one of the reasons for stronger storms in the SB and other parts of the southern SA in 2016. The δ¹⁸O values found in the precipitation present high variability, from -2.93 ‰ to -9.80 ‰ and show the different sources of air masses responsible for precipitation in Porto Alegre.
Simulating the Southern Hemisphere Storm Track Shift

Jonathan Wille¹ [jonathan.wille@univ-grenoble-alpes.fr], Vincent Favier¹, Francis Codron², Gerhard Krinner¹, Hubert Gallée¹, Julien Beaumet¹, Nicolas Jourdain¹
¹IGE, Université Grenoble Alpes, CNRS, IRD, Grenoble, France, ²LOCEAN - Sorbonne Universités - UPMC/CNRS/IRD/MNHN, Paris, France

In accordance with the Clausius Clapeyron equation, a warmer atmosphere will lead to an increase in atmospheric moisture content which theoretically will provide a positive trend in the Antarctic surface mass balance. An increasing surface mass balance over Antarctica would have negative implications on future sea level rise. This is why it is essential to accurately simulate changes to the Antarctic upper-level circulation to determine how circulation changes will impact these potential increases in Antarctic snow accumulation.

During the past century, the Southern Annular Mode (SAM) has been increasingly positive which has shifted the storm track southward. This has resulted in significant warming along the Antarctic Peninsula and increased snow accumulation in West Antarctica and along the western side of the Peninsula. This shift in SAM is poorly represented in climate models along with its potential impact on future surface mass balance changes on the Antarctic continent. To properly simulate the potential Antarctic storm track changes requires a better simulation of the tropical and mid-latitude teleconnections that influence the Antarctic climate. Here we propose to improve the modeling of the storm track location using the stretched grid global model LMDZ6 and analyze the impact on the surface mass balance of Antarctica using the regional circulation model MAR.
This work examines teleconnections between the cyclogenesis in Southern Hemisphere (SH) and its relationship to the Southern Annular Mode (SAM) and to the zonal wave three (ZW3) pattern at the end of October 2016. From 26th to 28th of that month, a strong extratropical cyclone developed on the southern coast of Brazil (SB). Then, from the 29th to the 31st, the southern coast of Australia (AU), including Tasmania (TA), was hit by an extratropical cyclone coming from the Indian Ocean. Both events caused numerous social and environmental damages. That year also stands out as the warmest in the instrumental record, both globally and in the SH, and recorded the smallest Antarctic sea ice extent (SIE) since 1979. This sea ice cover reduction has been attributed to positive sea surface temperature anomalies, the ZW3 and a SAM negative phase. Considering these observations, we reconstructed the geopotential height fields, wind vectors, zonal wind and temperature at 925, 750, 500 and 200 hPA, monthly, seasonally and annually, using ERA-Interim Reanalysis data. The analyzed SAM index and the wave, tidal and wind records show that the two observed anomalous events resulted from a combination of a negative SAM phase and of the ZW3. This association favored intense cyclogenesis, with a baroclinic intensification, as a response to the tropic-pole temperature contrast, and an exceptional atmospheric circulation observed between subtropical and polar latitudes in 2016.
Sensitivity of SH Westerly Winds to Boundary Conditions for the LGM

Seong-Joong Kim¹ (seongjkim@kopri.re.kr), Sang-Yoon Jun¹, Baek-Min Kim¹
¹Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of

The southern hemisphere (SH) westerly wind change in the LGM is critical in understanding the glacial-interglacial carbon cycle since its strength and position influence the upwelling of the carbon rich deep water to the surface. To examine the change in SH westerly wind in the LGM, we adopted CAM5 atmosphere general circulation model (GCM) and performed LGM simulation with sensitivity experiments by specifying the LGM sea ice in the Southern Ocean (SO), ice sheet over Antarctica, and tropical pacific sea surface temperature. The SH westerly response to LGM boundary conditions in the CAM5 was compared with those from CMIP5 LGM simulations. In the CAM5 LGM simulation, the SH westerly wind substantially increases between 40S and 65S, while the zonal-mean zonal wind decreases at latitudes higher than 65°S. The position of the SH maximum westerly wind moves poleward by about 8 degree in the LGM simulation. Sensitivity experiments suggest that the increase in SH westerly winds is mainly due to the increase in sea ice in the SO that accounts for 60% of total wind change. In the CMIP5-PMIP3 LGM experiments, most of the models show the slight increase and poleward shift of the SH westerly wind as in the CAM5 experiment. The increased and poleward shifted westerly wind in the LGM obtained in the current model result is consistent with previous model results and some lines of proxy evidence, though opposite model responses and proxy evidence exist for the SH westerly wind change.
Evolution of Pacific to Southern Hemisphere Teleconnection in the Last Ice Age

William Roberts1 (william.roberts@bristol.ac.uk), Paul Valdes1, Tyler Jones2, Eric Steig3
1University of Bristol, School of Geographical Sciences, Bristol, United Kingdom, 2University of Colorado at Boulder, Boulder, United States, 3University of Washington, Seattle, United States

Jones et al (Nature, 2017) recently showed that the amplitude of the interannual variability in West Antarctica was substantially larger during the last ice age than it is today. They showed that the reduction in the amplitude of the variability can be linked to the height of the Laurentide Ice Sheet. In this presentation we shall show in detail how changes in the tropical Pacific climate altered the interannual variability seen in West Antarctica. Analysing the Rossby Wave source terms in a series of climate model simulations we can show that a shift in the mean convection in the West Pacific makes a more efficient teleconnection from the tropical Pacific to the high southern latitudes, particularly the Amundsen Sea region. By analysing the effect of the different glacial boundary conditions (the presence of ice sheets, lowered greenhouse gases, altered orbital forcing), we can show that the largest single cause of the change is the size of the Laurentide Ice Sheet. The ice sheet alters the position of the mean convection in the West Pacific, which makes a stronger Rossby Wave source. The shifted convection is supported by other paleoclimate proxy evidence. We shall show that although glacial boundary conditions cause changes in the zonal mean westerly winds, which might alter the teleconnection from the tropical Pacific to higher southern latitudes, these changes can not explain the climate variability seen in the water-isotope record of the WAIS divide ice core.
Warming by Moist Air Intrusion and Cloud Radiation in the Arctic and Antarctic

Takashi Yamanouchi\textsuperscript{1} (yamanou@nipr.ac.jp)
\textsuperscript{1}National Institute of Polar Research, Tachikawa-shi, Japan

At Ny-Ålesund, Arctic, two distinct states are seen in downward longwave radiation (LD) during winter 2015/16. After the cold state with the temperature around -10 to -20 °C, a warm state with plus temperature appears and LD increases from about 170 to 320-330 W/m\textsuperscript{2}. This abrupt and large increase of LD might be due to the change of cloud condition, from clear to overcast, which was examined from the cloud radar data taken during GRENE Arctic Research Project. However, only the cloud change could not explain this large change of LD. During the warm state, the atmospheric circulation patterns changes, distortion of tropospheric polar vortex appears with a high pressure ridge (blocking high), and strong low and intrusion of warm and moist air from the Atlantic Ocean together with longwave radiation from clouds influences the warming at Svalbard. This intrusion of warm-moist air from the lower latitude is one of the major processes contributing to the Arctic amplification, just as proposed using GCM by Yoshimori et al. (2017).

In the Antarctic, similar intrusion of warm-moist air brings abrupt temperature increases and high precipitations. These intrusions are called “Atmospheric River”, and attributed to the strong low and/or blocking high. Although the suppression of warming in East Antarctica has been explained by the strengthening of polar vortex in the strat. and trop. due to ozone hole, the role of intrusion and clouds is still an issue of discussion compared to the Arctic.
Ice supersaturation is usually found at high altitudes where cirrus clouds form. At such altitudes, continuous and detailed measurement of the different steps leading to cloud formation and their comparison to climate models is difficult. The Concordia station on the Antarctic plateau offers an opportunity to document supersaturation and cloud formation in similar thermodynamical conditions and over the long term. The 40-m meteorological mast at Dome C was therefore instrumented with two special hygrometers, one at the top and one at the bottom, and haze formation was detected via visibility measurements. Ice supersaturation is found in all seasons and a RH of up to 200% is measured. During summer, in the evening, the RH often reaches 120% and sometimes precedes the formation of haze and a drop in visibility (for more detail, see Genthon et al., this conference). This timing of events is examined in four atmospheric models: the ECMWF IFS, the MAR limited area model, PolarWRF and the IPSL Climate Model, for which the parameterization of supersaturation is being developed. The models predict realistic supersaturations but the detailed diurnal cycle and statistical distributions differ from the observations. Haze is predicted and compared in detail with the observations. The use of the mast also gives access to the vertical gradients of humidity. The strengths and weaknesses of the models are compared, and pave the way to improvements in the different parameterizations.
Clouds, Aerosols and Radiation Measurements during the Polarstern Cruise PS106

Andreas Macke¹ (macke@tropos.de)
¹Leibniz Institute for Tropospheric Research, Leipzig, Germany

As a central experiment of the German Collaborative Centre "Arctic Amplification: Climate Relevant Atmospheric and Surface Processes, and Feedback Mechanisms (AC)³" the Arctic expedition PASCAL (Physical feedbacks of Arctic PBL, Seaice, Cloud And Aerosol, PS106.1) of the German research ice breaker Polarstern has been performed with a focus on clouds, aerosol and radiation measurements from May 24 to June 21 2017, followed by Arctic underway atmospheric measurements at the expedition PS106.2 until July 20, 2017. A 36 GHz cloud radar, a microwave radiometer, a Raman aerosol lidar, a network of pyranometer as well as a tethered balloon with in-situ aerosol, turbulence and radiation observations up to a height of 1500m were deployed on an ice floe at 82°N, 10°E for two weeks. Furthermore, detailed surface near-in-situ aerosol physical and chemical characterizations have been carried out. The presentation provides an overview of vertical aerosol and cloud profiling and discusses the relation to the observed surface fluxes.
Measured Radiation Budget Profiles of Arctic Clouds using a Tethered Balloon

Matthias Gottschalk¹ (matthias.gottschalk@uni-leipzig.de), Ulrike Egerer², Felix Lauermann¹, Holger Siebert², André Ehrlich³, Manfred Wendisch¹
¹University of Leipzig, Leipzig Institute for Meteorology, Leipzig, Germany, ²Leibniz Institute for Tropospheric Research, Leipzig, Germany

Arctic low-level clouds modify the surface energy budget as well as the vertical energy fluxes from the surface to the free troposphere. Thus, understanding the cloud radiative effects and their dynamics is a key factor to identify and quantify the processes leading to Arctic Amplification. However, observations of boundary layer energy flux profiles that determine the interaction of clouds and surface are challenging and limited in the central Arctic.

The Arctic Balloon profiling EXperiment (ABEX) took place north of Svalbard in June 2017 as part of an intense observational campaign coordinated by the Transregional Collaborative Research Centre TR 172 “Arctic Amplification” (AC), which combined the research vessel Polarstern and the Polar 5 and Polar 6 aircraft. During a two-week ice floe camp, radiative and turbulent energy flux profiles were investigated under different cloud conditions using a tethered balloon. Broadband solar and terrestrial irradiance profiles were measured. Furthermore, the cloud top cooling rates driving the cloud dynamics were derived while high-resolution probes measured the turbulent energy fluxes. The radiative energy flux profiles were affected by the cloud water content, the cloud base altitude and the temperature profile of the boundary layer, resulting in changes of cloud surface radiative forcing.

First results of radiative energy flux profiles determined during ABEX will be presented.

This work was supported by DFG Grant TR 172/1 A02.
Cloud Response to Moisture Intrusions into the Arctic

Abhay Devasthale¹ (abhay.devasthale@smhi.se), Michael Tjernström², Erik Johansson¹, Karl-Göran Karlsson¹
¹Swedish Meteorological and Hydrological Institute, Research and Development, Norrköping, Sweden,
²Meteorological Institute, Stockholm University (MISU), Stockholm, Sweden

Moisture transport into the Arctic influences surface energy budget in the time scales ranging from few days to few months. Moisture intrusions, i.e. the episodic extreme moisture transport events, are especially said to have a large impact on air-sea interaction processes, by inducing rapid changes in the thermodynamical structure of the lower troposphere. Persistent intrusions can have lasting impact on the seasonal sea-ice evolution, both during the recovery and melt phases. Apart from their direct radiative impact on the lower troposphere, moisture intrusions potentially modulate cloud frequency and physical properties, which in turn have feedback on the longwave surface forcing. Here we assess this cloud response to moisture intrusions and its seasonal character in detail. We use 10-years of A-Train data (CloudSat, CALIPSO and MODIS) as well as multidecadal climate data record of cloud properties, CLARA-A2, from EUMETSAT’s Satellite Application Facility for Climate Monitoring (CM-SAF) for the period from 1982-2016. We investigate cloud response using two approaches, namely the “large-scale approach” and the “local approach”. In the former, the moisture intrusion events are defined based on the large-scale moisture variability, while in the latter, the local moisture variability is taken into account. We discuss relative merits and significance of these approaches.
Stratocumulus Breakup in Cold Air Outbreaks over the North Atlantic

Gary Lloyd1 (gary.lloyd@manchester.ac.uk), Thomas Choularton1, Keith Bower1, Martin Gallagher1, Jonathan Croser1, Sebastian O'Shea1, Steven Abel2, Stuart Fox2, Ian Boutle2, Richard Cotton2, Phil Brown2

1University of Manchester, Manchester, United Kingdom, 2Met Office, Exeter, United Kingdom

In this paper we show from in-situ field observations that this break-up in cold air outbreaks over the eastern Atlantic is controlled by the development of precipitation in the cloud system while the boundary layer becomes decoupled, with both supercooled liquid and solid precipitation playing a role. Flights were conducted using the UK FAAM aircraft in the North Atlantic region around the U.K. featuring 4 case studies, making detailed microphysical, dynamical and thermodynamic measurements in the cloudy boundary layer during the cold air outbreaks. It is found that as the cloud moves over progressively warmer waters it initially deepens, with increasing drop size and the formation of liquid precipitation. Small numbers of ice particles are observed. In 3 of the cases the aerosol number in the boundary layer and the cloud droplet number, decreased with distance south as the aerosol was scavenged by precipitation, leading to increased precipitation and a reduction in the liquid water path and the eventual break-up of the cloud. It is concluded that it is the precipitation process that dominates the timing of the cloud break-up although both weakening of the capping inversion and boundary layer decoupling also occurred which may play a critical role in determining the timing of precipitation onset.
The Greater than Expected Affect of Temperature on Antarctic Marine Species

Lloyd Samuel Peck\(^1\) (l.peck@bas.ac.uk)

\(^1\)British Antarctic Survey, Biodiversity, Evolution and Adaptation, Cambridge, United Kingdom

Antarctic marine species have evolved over millions of years in cold, thermally stable, but also seasonally intense conditions. In response to this many unique adaptations have been produced including antifreeze in fish, an absence of haemoglobin in Channichthyd fish and the absence of a heat shock response in some species. Recently (Peck 2016) it has been shown that the vast majority of biological processes are slowed in Antarctic marine species compared to those from warmer water sites. For respiration, aerobic capacity and activity the slowing in Antarctic species compared to temperate and tropical species is in line with the expected effect of temperature on biological functions as first described by Arrhenius over 100 years ago. For other processes, such as growth, embryonic development and the duration of elevated metabolic rates after feeding, the slowing is much greater than the expected effect of temperature. This contribution presents these data and then shows why the impact of low temperature on protein synthesis is the likely reason for these differing results.

Polygenic Adaptation Drives Genomic Divergence between Spawning Modes in Capelin

Kim Præbel¹ (kim.praebel@uit.no), Shripathi Bhat²
¹UiT The Arctic University of Norway, Norwegian College of Fishery Science, Tromsø, Norway

Capelin (*Mallotus villosus*) is a small salmonid fish that display two alternative life histories within its circumpolar distributional area: a long distance migrating ecotype that spawns offshore and are strictly semelparous or a more resident ecotype that spawns intertidally and can be considered as facultative iteroparous. Intraspecific divergence in life history may be regarded as a process of incipient speciation and when this process occurs in sympatry, the theory of speciation predicts that adaptive genomic differences will accumulate as a result of divergent natural selection acting against unbeneficial traits. In other words, adaptive genomic differences are expected to be the main driver of divergence between the two ecotypes and spawning modes. Here we addressed this prediction on two replicated systems of capelin spawning offshore vs intertidally from Norwegian waters. We compared divergence from a genome-wide panel of single nucleotide polymorphisms obtained by massively parallel sequencing of Restriction Site Associated DNA libraries (RADseq). Via machine learning approaches we firstly revealed that the ecotypes and spawning modes diverge at the genomic level, and secondly, we revealed that polygenic adaptive genomic differences have accumulated within the two alternative life histories. We discuss these results in light of how a changing Arctic environment may influence the apparent ongoing process of incipient speciation.
Competition within and between species shapes community structure and species distribution. Levels of competition are particularly high when closely related species share limited resources, meaning they must differentiate along multidimensional niche axes in order to co-exist. The degree of competitive dominance may also be affected by climate change. Sympatric central-place foraging seabirds with similar resource requirements experience high levels of competition during the breeding season and often display allochrony (differences in timing of breeding) to reduce this. We used sympatrically breeding Adélie (Pygoscelis adeliae) and Chinstrap penguins (P. antarctica) on Signy Island, South Orkneys, as a model system to quantify the role of allochrony in niche partitioning for the first time.

Foraging location (GPS tag) and dive depth (TDR tag) data were collected during 4 breeding seasons. We determined that the two species display 3D niche partitioning, utilising different core foraging areas during different breeding phases and diving to significantly different maximum dive depths within areas of high spatial overlap. Allochrony reduced horizontal overlap between species by 70%. Both species breed later in colder years and recent cooler springs have seen both delay breeding by 10 days over the last 20 years. Penology changes have occurred in parallel over this time, maintaining allochrony, but if allochrony offset is reduced by a single day competition will increase by 2.6%.
Historically low temperatures have limited skeleton-breaking predation on the Antarctic shelf, facilitating the evolution of a fauna poorly defended against durophy. Now, rapid warming is restructuring Antarctic marine ecosystems as conditions become favorable for range expansions. The lithodid crab Paralomis birsteini currently inhabits some areas of the continental slope off Antarctica. They could potentially expand along the slope and upward to the shelf, where temperatures are no longer prohibitively low. We identified two sites inhabited by different densities of lithodids in the slope environment of the Antarctic Peninsula. Gut contents of crabs on the slope revealed them to be opportunistic invertivores. The abundances of three eurybathic prey—ophiuroids, echinoids, and gastropods—were negatively associated with P. birsteini off Marguerite Bay, where lithodid densities averaged 4280 ind·km^{-2} at depths of 1100-1499 m (range 3440-5010 ind·km^{-2}), but not off Anvers Island, where lithodid densities were lower, averaging 2060 ind·km^{-2} at these depths (range 660-3270 ind·km^{-2}). Higher abundances of lithodids appear to exert a negative effect on invertebrate distribution on the slope. Lateral or vertical range expansions of P. birsteini at sufficient densities could substantially reduce populations of their benthic prey off Antarctica, potentially exacerbating the direct impacts of rising temperatures on the distribution and diversity of the contemporary shelf benthos.
Biodiversity, Distribution and Ecology of Cephalopods in Polar Marine Ecosystems

Jose Xavier¹,² (jccx@cantab.net), Yves Cherel³, Louise Allcock⁴, Rui Rosa⁵, Rushan Sabirov⁶, Martin Blicher⁷, Alexey Golikov⁶
¹University of Coimbra, Life Sciences, Coimbra, Portugal, ²British Antarctic Survey, Cambridge, United Kingdom, ³Centre d'Etudes Biologiques de Chizé (CEBC), Villiers-en-Bois, France, ⁴Ryan Institute and School of Natural Sciences, National University of Ireland Galway, Galway, Ireland, ⁵MARE - Marine and Environmental Sciences Centre, Faculdade de Ciências da Universidade de Lisboa, Lisbon, Portugal, ⁶Kazan Federal University, Department of Zoology, Kazan, Russian Federation, ⁷Greenland Climate Research Center, Greenland Institute of Natural Resources, Nuuk, Greenland

Cephalopods are known to play an important role, both as prey and predators, in polar marine ecosystems. In this review, we compared the biodiversity, distribution and ecological role of cephalopods in the Arctic and in the Antarctic. Sixty-one species have been reported from the Arctic (including the Pacific Subarctic) while 54 species are known from the Antarctic. The only confirmed species known to occur in both poles is the giant squid Architeuthis dux. No cuttlefish species occur in either polar region. The cephalopod fauna of the Arctic and Antarctic are different and have different origins: the Arctic fauna colonized the Arctic relatively recently (< 12 000 years ago), whereas some of the Antarctic fauna has evolved in situ over the past 33 Ma (e.g., most octopods). Polar cephalopods prey on crustaceans, fish, and other cephalopods (including cannibalism), whereas predators include fish, other cephalopods, seabirds, seals and whales. Cephalopods from these regions are likely to be influenced by climate change: Arctic fauna is more subjected to increasing temperatures per se, with these changes increasing species ranges and probably their abundance. Antarctic species are likely to be influenced by changes in mesoscale oceanography, changes of position of oceanic fronts, changes of sea ice and increase of ocean acidification. Polar cephalopods may have the capacity to adapt to environmental change but more studies are needed on taxonomy, distribution and ecology.
Results from the High Elevation Antarctic Terahertz (HEAT) Telescope on Ridge A

Craig Kulesa¹ (ckulesa@email.arizona.edu), Michael C. B. Ashley², Michael G. Burton³, David Lesser³, Christopher K. Walker¹, Mark Wolfire⁴, Abram Young¹
¹University of Arizona, Steward Observatory, Tucson, United States, ²University of New South Wales, School of Physics, Sydney, Australia, ³Armagh Observatory and Planetarium, Armagh, United Kingdom, ⁴University of Maryland, College Park, United States

Deployed to Ridge A in 2012, the HEAT telescope forges entirely new capabilities for ground based infrared and submillimeter astronomy which otherwise would be unachievable except via expensive airborne or space-based platforms. HEAT and PLATO-R represent a new generation of polar instrumentation that permits the excellent conditions available from remote sites like Ridge A to be harnessed without the costs and hazards associated with manned operations. The unparalleled stability, exceptional dryness, low wind and extreme cold make Ridge A a site without equal for astronomy at infrared and submillimeter wavelengths. HEAT operates in the far-IR atmospheric windows in which the most crucial astrophysical spectral diagnostics of the formation of galaxies, stars, planets, and life are found. Through large-scale Galactic surveys, the measurement and impact of the Galactic environment on the life cycles of interstellar clouds and their relation to star formation are gradually being realized. HEAT’s key project is to map, with great sensitivity and precision, portions of the Southern Galactic Plane in the spectral light of the dominant coolants of the interstellar medium from 200-600 microns wavelength. HEAT’s mixer, local oscillator, low-noise amplifier, cryogenic, and DSP technologies will play essential roles in future Terahertz observatories. This pioneering mission paves the way for future astronomical investigations from the high plateau and beyond.
Polar regions represent the best sites on Earth to observe the distant Universe. High atmospheric transparency, low temperature, seasonal presence/absence of the Sun, and circumpolar currents make the polar stratosphere optimal for balloon-borne IR and mm-wave astronomy measurements. The OLIMPO experiment will be launched from Svalbard islands during the arctic summer, and will float at 40 km of altitude in the arctic circumpolar current. OLIMPO is a mm-wave observatory, to be pointed in the direction of many galaxy clusters, to detect the Sunyaev-Zel’dovich (SZ) effect of the Cosmic Microwave Background (CMB) photons crossing clusters. Measurements of the SZ effect provide important morphological and dynamical information on galaxy clusters.

OLIMPO is equipped with a large-aperture telescope (2.6 m), feeding multi-band cryogenic focal planes populated with arrays of kinetic inductance detectors sensitive at 150, 200, 350 and 480 GHz. In addition to photometric measurements, OLIMPO provides spectroscopic measurements taking advantage of a plug-in differential Fourier transform spectrometer (DFTS), enabling the characterization of all the components of the SZ effect and its foregrounds with unprecedented precision and accuracy.

In addition to the scientific target, OLIMPO has a technological target: it will demonstrate that the KIDs and the DFTS can reach the expected performance in a space-like environment, representing the pathfinder of future space missions like Millimetron.
The high Antarctic plateau provides exceptional conditions for infrared observations on account of the cold, dry and stable atmosphere above the ice surface. We describe the scientific goals behind the first program to examine the time-varying universe in the infrared from Antarctica - the Kunlun Infrared Sky Survey (KISS). This will employ a 50cm telescope to monitor the southern skies in the 2.4µmK dark window from China’s Kunlun station at Dome A, on the summit of the Antarctic plateau, through the uninterrupted 4-month period of winter darkness. An earlier paper discussed optimisation of the K dark filter for sensitivity (Li et al. 2016). Here we examine the scientific program for KISS. We calculate the sensitivity of the camera for the extrema of observing conditions that will be encountered. We present the parameters for sample surveys that could then be carried out for a range of cadences and sensitivities. We then discuss several science programs that could be conducted with these capabilities, involving star formation, brown dwarfs and hot Jupiters, exoplanets around M dwarfs, the terminal phases of stellar evolution, fast transients, embedded supernova searches, reverberation mapping of AGN, gamma ray bursts and the detection of the cosmic infrared background.
The BLAST-TNG Experiment

Federico Nati1 (fnati@physics.upenn.edu)
1University of Pennsylvania, Physics and Astronomy, Philadelphia, United States

BLAST-TNG is a long-duration, high altitude, balloon-borne telescope scheduled to fly in the 2018-2019 season from Antarctica. The data from the 28 day flight will provide new insight into the properties of dust and the role of magnetic fields in the interstellar medium through a wide range of densities, producing several degree-scale polarimetric maps at sub-arcminute resolution. It will perform simultaneous measurements in its 3 broad bands centered at 250, 350, and 500 µm. BLAST-TNG is the rebuilt and upgraded Balloon-borne Large Aperture Sub-millimeter Telescope for Polarimetry (BLASTPol), and with a 16-fold increase in mapping speed it will make larger and deeper maps. Major improvements include a 2.5 m carbon fiber mirror (40% larger diameter than the BLASTPol mirror), and ~3000 polarization sensitive detectors. The telescope will also serve as a pathfinder project for microwave kinetic inductance detector (MKID) technology, applied to feed-horn coupled sub-millimeter detector arrays. The arrays are cooled to 270 mK by a closed-cycle 3He refrigerator, all enclosed in a liquid helium cooled cryostat with long hold time (28 days expected). This will enable us to map more targets at a much higher level of detail than any sub-millimeter polarimeter to date. BLAST-TNG will also be the first balloon-borne telescope to offer shared risk observing time to the community.
Cosmic Ray and Air Shower Studies with IceCube

Javier Gonzalez\textsuperscript{1} (javierg@udel.edu)
\textsuperscript{1}University of Delaware, Newark, United States

The IceCube Neutrino Observatory at the South Pole has been in stable operation since it was completed in 2010. The observatory consists of an array of more than 5000 optical modules deployed between 1450m and 2450m deep in the Antarctic ice, and IceTop, an array of detectors on the surface of the ice. These two arrays provide a complementary view of cosmic ray induced air showers, giving us a unique vantage point to study cosmic rays and the air showers they produce. We will review the insights we have gained on the composition of the cosmic ray flux and on high-energy interactions by using this hybrid approach. We will also discuss how the combination of a surface detector with a deep detector can be used to further the search for the sources of astrophysical neutrinos.
Advances in the LAGO Antarctic Node Implementation Design

The LAGO (Latin American Giant Observatory) project is a collaborative network of Cherenkov detectors in water (WCDs) over ten Latin American countries (Argentina, Bolivia, Colombia, Chile, Ecuador, Guatemala, Mexico, Peru, Venezuela, and Brazil). The Scientific Objectives include the study of the energy spectrum and the integrated flux of the secondary particles generated by the primaries at the atmosphere. The collaboration network has nodes at sites with different rigidity cut-offs and different altitudes and assesses the monitoring of the Space Weather conditions through the modulation of the cosmic ray flux. This node will also permit to analyze energetic particles from solar origin, the so-called Ground Level Enhancements (GLEs). We present the update of the testing results for the implementation of the LAGO node in Antarctica. These were obtained at the precampaign of 2017, where the in situ data telemetry testing was performed for the meteorological station designed for the Marambio node, including the testing of the thermic control for the system. The improvements in the new design of the Cherenkov detector in water and first results are also presented.

On behalf of the The Latin American Giant Observatory (LAGO) Collaboration, Ciudad Autónoma de Buenos Aires, Argentina. See List of Members at www.lagoproject.org, lago-pi@lagoproject.org
Dynamic Barriers Preventing Flow of Warm Ocean Currents into Ice Shelf Cavities

Anna Wåhlin¹ (anna@gu.se), Nadine Steiger², Celiné Héuzé¹, Elin Darelius², Mirjam Glessmer¹, Laura Herraiz-Borruguero⁶, Ho Kyung Ha⁹, Adrian Jenkins⁶, Tae Wan Kim⁷, Jean Baptiste Sallee⁸, Joel Sommeria⁹, Samuel Viboud⁹

¹University of Gothenburg, Department of Marine Sciences, Gothenburg, Sweden, ²University of Bergen, Bergen, Norway, ³Kiel University, Kiel, Germany, ⁴University of Southampton, Southampton, United Kingdom, ⁵Inha University, Seoul, Korea, Republic of, ⁶British Antarctic Survey, Cambridge, United Kingdom, ⁷KOPRI, Incheon, Korea, Republic of, ⁸LOCEAN, Paris, France, ⁹LEGI, Grenoble, France

The observed thinning of many of the ice-shelves surrounding the Antarctic Ice Sheet is linked to oceanic heat fluxes, but the dynamics governing the flow of ocean currents towards and into the ice shelf cavities are poorly known. Dynamical constraints cause large scale, geostrophically balanced flows to follow depth contours. The warm salty ocean currents hence move towards the ice shelf cavities mainly in the deep troughs connecting the shelf break to the inner shelf. The water must then pass the ice shelf front - a vertical ice wall with a draft of several hundreds of meter, representing a major discontinuity in the water column thickness. Conservation of potential vorticity is expected to restrict barotropic flow across the front and into the ice-shelf cavity. It is not clear to what extent currents are blocked by the ice shelf front, and whether there is a difference between baroclinic and barotropic flows in entering the cavity.

We present the results of a set of experiments conducted on the Coriolis rotating platform. By inserting an idealized ice shelf on top of a deep trough representing an Antarctic continental shelf and ice shelf cavity, dynamical constraints of this system were explored. Barotropic and baroclinic currents were created by pumping water of different density in the trough and the flow was documented using in situ probes and various image techniques.
Atlantic Water Supply toward the 79N Glacier in Northeast Greenland

Torsten Kanzow¹,² (torsten.kanzow@awi.de), Janin Schaffer³, Claudia Wekerle¹, Wilken-Jon von Appen¹, Sandra Tippenhauer¹, Christoph Mayer³, Paul Dodd⁴, Andreas Münchow⁵
¹Alfred-Wegener-Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, ²Bremen University, Physics and Electrical Engineering, Bremen, Germany, ³Bayerische Akademie der Wissenschaften, München, Germany, ⁴Norwegian Polar Institute, Tromsø, Norway, ⁵University of Delaware, Newark, United States

The ocean plays an important role in modulating the mass of the Greenland Ice Sheet by delivering heat to the marine outlet glaciers. The largest of the glaciers draining the Northeast Greenland Ice Stream is the 79 North Glacier. It is in contact with subsurface, warm Atlantic Water (AW). In order to understand how the AW supplies heat towards the glacier, we analyse mooring-based, shipboard and AUV-based observations obtained between 2014 and 2017 on the shelf of Northeast Greenland, complemented by an eddy-resolving ocean-sea ice model, which realistically represents the AW circulation in Fram Strait.

A sizeable amount of the AW carried northward from the Subtropics toward the Nordic Seas recirculates in Fram Strait, contributing to both the subduction below cold and fresh Polar Water and the formation of the East Greenland Current. A trough system on the shelf allows for the penetration of the subsurface AW across the 300 km wide shelf toward the inner shelf as a narrow boundary current.

Our moored measurements reveal a year-round, subsurface flow of AW towards the glacier, feeding into a hydraulically controlled density plume in the vicinity of the calving front, causing a rapid inflow of AW warmer than 1°C into the subglacial cavity. Historical observations further suggest a coherent decadal increase in AW temperatures both in Fram Strait and on the shelf. A warming-induced increase of basal melt may explain the observed thinning of the glacier over the past 15 years.
A mooring array has been deployed since 2012 north of Svalbard, tracking the Atlantic Water (AW) inflow into the Arctic Ocean as it follows the upper continental slope. This topographically steered boundary current is the largest oceanic heat source for the Arctic Ocean. Heat content in the upper ocean varies significantly throughout the year with largest heat transport and highest heat loss in autumn and winter. Between 22 and 31 deg E, the longitudes of the moorings, the annual mean heat loss along the slope north of Svalbard is 16 W m$^{-2}$ in the upper 200 m. A large part of the AW heat is thus lost to the atmosphere. In autumn and early winter, sea ice is advected into the region on several occasions. This coincides with episodic events of heat fluxes > 100 W m$^{-2}$ which last over several days. These high ocean-to-ice heat fluxes contribute to ice melt and help to keep the slope area ice free well into winter. A persistent ice cover is then established in March 2013, modulating air-sea fluxes and leading to the formation of a cold and fresh mixed layer above the AW core. Local vertical processes such as wind- and tide-driven mixing and shedding of mesoscale eddies contribute to the spatial and temporal variability in the heat content. This study underlines the complexity of the oceanic heat budget in the Arctic Ocean inflow region north of Svalbard and highlights the ocean’s role in modulating the sea ice cover.
Hotspots of Internal Solitary Waves and Mixing in the Ice-free Arctic Ocean

Igor Kozlov¹,²,³ (igor.eko@gmail.com), Evgenia Zubkova¹, Tomas Rippeth⁴, Mattias Green⁴, Benjamin Lincoln⁴, Arild Sundfjord⁵, Vladimir Kudryavtsev¹, Andrey Proshutinsky²
¹Russian State Hydrometeorological University, Satellite Oceanography Laboratory, St. Petersburg, Russian Federation, ²Marine Hydrophysical Institute of RAS, Remote Sensing Department, Sevastopol, Russian Federation, ³Woods Hole Oceanographic Institute, Physical Oceanography Department, Woods Hole, United States, ⁴Bangor University, School of Ocean Sciences, Bangor, United Kingdom, ⁵Norwegian Polar Institute, Tromsø, Norway

In this work we present the results of Arctic-wide observations of internal solitary waves (ISWs) derived from high-resolution spaceborne synthetic aperture radar (SAR) measurements acquired over the seasonally ice-free Arctic Ocean. Analysis of the data reveals key regions of ISW distribution that are primarily found over the shelf/slope regions poleward the M₂ critical latitude. Most of the ISWs are observed in regions where enhanced tide-induced vertical mixing and heat fluxes have been previously reported. We further show that satellite-derived probability of ISWs attributes well to model-predicted sites of high barotropic-to-baroclinic tidal energy conversion. Positive correlation is also obtained between ISW probability and the rate of TKE dissipation derived from microstructure observations over the continental slope, suggesting that internal solitary waves may promote enhanced vertical mixing in these regions. This work is supported by RFBR grant 16-29-02106 mol_a_dk, RSF grant No. 17-77-30019, and FASO Russia project No. 0827-2014-0011. ENVISAT ASAR data used in this study were provided by the European Space Agency (ESA) through Cat-1 Project C1F-29721.
The surface waters of the Southern Ocean act as a control valve through which climatically important tracers such as heat, freshwater, and CO₂ are transferred between the atmosphere and the ocean. The process that transports these tracers through the surface mixed layer into the ocean interior is known as ocean ventilation. Changes in ocean ventilation are thought to be important for both rapid transitions of the ocean’s global overturning circulation during the last deglaciation, and the uptake and storage of excess heat and CO₂ as a consequence of anthropogenic climate change. Here I show how the interaction between Southern Ocean jets, topographic features, and ocean stratification can lead to an abrupt change in Southern Ocean ventilation. For increasing winds, this interaction leads from a state in which tracers are confined to the surface mixed layer, to a state in which tracers fill the ocean interior. This abrupt onset of Southern Ocean ventilation with increasing winds directly impacts the uptake of heat and CO₂ into the global ocean. For the Kerguelen Plateau, in the Indian sector of the Southern Ocean, this abrupt change in ventilation occurs for wind forcing predicted by climate models for the 21st century. These results imply a prominent role for jet dynamics in understanding rapid transitions of the global climate system.
Subsurface Response of the Southern Ocean to Changing Westerly Winds

Edward Doddridge¹ (ewd@mit.edu), John Marshall¹
¹Massachusetts Institute of Technology, Earth, Atmospheric, and Planetary Sciences, Cambridge, United States

Anthropogenic influences have produced a strengthening and poleward shift of the westerly winds over the Southern Ocean. We use observations and a hierarchy of models to explore the subsurface response of the Southern Ocean to a step-change in the westerly wind. The initial response is robust across models and observations, and consists of Ekman driven cooling at the surface and warming below the seasonal ice zone, as well as warming in the seasonal thermocline due to increased vertical diffusion. However, the long-term response is largely inaccessible from the observations and varies across models. The spread between the models can be explained by variations in the response of the residual overturning circulation. Our results highlight the importance of accurately representing the eddy contribution to the residual overturning circulation, and may provide a mechanism to explain the discrepancy between model predicted warming of Southern Ocean sea surface temperatures and the observed cooling.
New Concepts for the Role of Sea Ice in Structuring Southern Ocean Ecosystems

Klaus M Meiners\textsuperscript{1,2} (klaus.meiners@aad.gov.au)
\textsuperscript{1}Australian Antarctic Division, Department of the Environment and Energy, Kingston, Australia, \textsuperscript{2}Antarctic Climate & Ecosystems CRC, University of Tasmania, Hobart, Australia

Studies in different sectors of the Southern Ocean have shown that sea ice structures Antarctic marine ecosystems in multiple and complex ways. Sea ice acts as a biogeochemically active barrier for atmosphere—ocean gas exchange, controls light availability for phytoplankton, serves as habitat for microalgae and provides a refuge for pelagic herbivores. Antarctic sea ice is also changing with different sectors exhibiting opposite trends in both sea ice extent and ice cover duration. Models predict a significant decline in Antarctic ice extent and ice volume by the end of the century, and these changes are expected to have significant ramifications for Southern Ocean ecosystems. In this presentation I will provide an overview of new and emerging concepts for the role of sea ice in different sectors of the Southern Ocean, discuss the applicability of recently developed Arctic concepts of ice algal and phytoplankton phenology on Antarctic marine ecosystems, and highlight new research questioning the paradigm of the Antarctic sea ice – ice algae – krill relationship. Using recent findings on the physical drivers of Antarctic ice algal temporal and spatial variability, I will highlight the need to better understand sea ice quality rather than quantity to understand its role in structuring marine ecosystems. Furthermore I will discuss problems associated with extrapolating cause - effect relationships, identified in one Antarctic sector, to the entire Southern Ocean.
Two facts stand out from recent research: first, many key processes within and external to the Arctic Ocean are linked to its freshwater system, and second, the state and structure of the Arctic Ocean is undergoing rapid and uncertain change. To address these two facts we here propose a revised and integrative conceptual model of the Arctic Ocean’s freshwater system — its internal dynamics and external drivers — that links physics to geochemistry and biology, and land and atmosphere to the ocean. In so doing we follow a scaled hierarchical approach that recognizes regionality, seasonality, pattern and scale. The proposed model extends the Arctic Ocean’s freshwater budget far beyond its classical ’gateway’ boundaries fully to the Tropics and mid-latitudes, and draws attention to smaller scale sources and distributions within the Arctic Ocean.
Arctic Marine Ecosystem Conceptual Model: Interactions Matrix Revealed (Part A)

Kristina Brown1 (kristina.brown@dfo-mpo.gc.ca), Johnna Holding2, Henry Huntington3, Uma Bhatt4, Susana Agusti5, Carlos Duarte5, Eddy Carmack1, Paul Wassmann6
1Institute of Ocean Sciences, Department of Fisheries and Oceans Canada, Sidney, BC, Canada, 2Aarhus University, Arctic Research Centre ARC, Aarhus, Denmark, 3The Pew Charitable Trusts, Eagle River, United States, 4University of Alaska - Fairbanks, Geophysical Institute, Fairbanks, United States, 5King Abdullah University of Science and Technology, Red Sea Research Center, Thuwal, Saudi Arabia, 6University of Tromsø, Faculty of Biosciences, Fisheries, and Economics, Tromsø, Norway

In November 2016, the US Bureau of Ocean Energy Management, Office of Naval Research, and National Science Foundation supported a workshop to create a unifying pan-Arctic conceptual model of the current state and future changes of the Arctic Marine Ecosystem (AME). One component of this conceptual model is a matrix of interactions that determine the functioning of the AME. This matrix was developed using a parsimonious list of Key Elements, distributed between five categories: Atmosphere, Land-Ocean/Shelf-Interior Connections, Physical Environment, Biology, and Human Impacts. To determine the strength and direction of connections between Key Elements, direct interactions were characterized in a matrix array by evaluating directionality, relative magnitude, and scientific (un)certainty. Indirect interactions were removed, because these should be captured by chains of direct interactions. We found a relative paucity of two-way interactions between Key Elements as well as few very strong connections. Further work is needed to explore indirect causal pathways and the existence of multi-element feedback loops. We present the results of this work in two parts. In Part A we describe the iterative process followed creating the interactions matrix, including the challenges of choosing and characterizing direct interactions. Discussion generated during this presentation will be used to refine the matrix.

Models and Methods to Support Marine Ecosystem Assessments for Polar Oceans

Rowan Trebilco\textsuperscript{1} (rowan.trebilco@utas.edu.au), Jess Melbourne-Thomas\textsuperscript{2}, Michael Sumner\textsuperscript{3}, Stuart Corney\textsuperscript{1}, Andrew Constable\textsuperscript{2}

\textsuperscript{1}Antarctic Climate & Ecosystems CRC, University of Tasmania, Hobart, Australia, \textsuperscript{2}Australian Antarctic Division and ACE CRC, Kingston, Australia

A fundamental challenge for marine ecosystem ecology and management is that the properties that determine how ecosystems function are extremely hard to observe and measure - a challenge that is made even more difficult by the remote and challenging environment of the Southern Ocean. Furthermore, because of the scale and complexity of Southern Ocean ecosystems, it is hard to know how to robustly measure and summarize their overall status, and track how status is changing (i.e. to measure trends). In response to these challenges, there is growing international coordination to develop complementary suites of observation and models to enable quantification of ecosystem status and trends at circumpolar scales. At the recent Marine Ecosystem Assessment for the Southern Ocean (MEASO) conference in Hobart in April 2018, we sought to identify and synthesise current capabilities and to identify key future priorities for models and methods to support ecosystem assessment in the Southern Ocean. In this presentation, we summarise the outcomes of these discussions. We also consider similarities and differences between Antarctic and Arctic ecosystems that may help develop synergies in approaches to undertaking polar marine ecosystem assessments generally.
Arctic Continental Slopes

Bodil Bluhm¹ (bodil.bluhm@uit.no), Melanie Bergmann², Antje Boetius², Eddy Carmack¹, Seth Danielson⁴, Maria Gavrilo⁸, Jackie Grebmeier⁶, Ingrid Ellingsen⁷, Katrin Iken⁴, Markus Janout², Russell Hopcroft⁴, Ksenia Kosobokova⁸, Igor Polyakov⁴, Alexandra Ravelo⁹, Mikael Sejr¹⁰, Andrey Vedenin⁸

¹UiT The Arctic University of Norway, Arctic and Marine Biology, Tromso, Norway, ²Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, ³Institute of Ocean Sciences, Fisheries and Oceans Canada, Victoria, Canada, ⁴University of Alaska - Fairbanks, Fairbanks, United States, ⁵National Park Russian Arctic, Moscow, Russian Federation, ⁶University of Maryland Center for Environmental Science, Solomons, United States, ⁷SINTEF, Trondheim, Norway, ⁸P.P. Shirshov Institute of Oceanology, Moscow, Russian Federation, ⁹Sitka Sound Science Center, Sitka, United States, ¹⁰University of Aarhus, Aarhus, Denmark

Arctic continental slopes form a contiguous domain encircling the Arctic Basins and are currently experiencing dramatic climate change. Here we present an integrative conceptual model that connects physical processes to ecological conditions in both the water column and at the seafloor. Vertical gradients in water mass properties above Arctic slopes are relatively large, while horizontal gradients along specific isobaths are weak, thus resulting in lateral belts - intersected by numerous canyons - of similar physico-chemical conditions and biological communities. The upper slope (approx. 200-800 m) is characterized by its contact with boundary currents, while the lower slope (approx. 800-2500 m) is a more quiescent environment. Owing to its contact with inflows from the sub-Arctic Atlantic and Pacific the upper slope domain is more productive, biomass rich and distinct in community structure across trophic levels (from phytoplankton to seabirds). The upper slope also shows evidence of a response to climate change including warming, sea ice loss, increased wind mixing, and shelf-basin exchange. The lower slope, in contrast, is cooler, less dynamic, lower in pelagic and benthic biomass and carbon input, and has not displayed evidence of climate change.
Microbial plankton and zooplankton are the base of the pelagic Arctic marine food web, feeding large-sized zooplankton, fishes, seabirds and marine mammals. Changes in these species can have cascading effects throughout the ecosystem and can represent the first sign of overall ecosystem perturbation. Despite their importance, their biogeography and taxonomic diversity are underappreciated and inadequately known. The Circumpolar Biodiversity Monitoring Program (CBMP) which is the cornerstone program of the Arctic Council’s Conservation of Arctic Flora and Fauna (CAFF) Working Group has recently, published a review of status and trends of Focal Ecosystem Components (FECs) across the Arctic. The CBMP Plankton Expert Network aggregated and reviewed data on Bacteria, Archaea, phytoplankton, heterotrophic protists and zooplankton as FECs across eight Arctic Marine Areas as well as documenting the state of current monitoring efforts for these species. Plankton are strongly affected by climate and differ between open water and ice-cover conditions, oceanic current patterns and salinity. Increased open water and less saline surface water could lead to range shifts and establishment of non-Arctic species, with unknown consequences for the Arctic marine food web. The approach and lessons learned from this exercise by scientists from all of the marine Circum-Arctic nations could be applied to a pan-national initiative to monitor plankton across international claims in the Antarctic.
Towards Data Sovereignty for Indigenous Arctic Communities

Colleen Strawhacker¹ (colleen.strawhacker@colorado.edu), Peter Pulsifer¹, Noor Johnson¹
¹National Snow and Ice Data Center, Boulder, United States

The Exchange for Local Observations and Knowledge of the Arctic (ELOKA, eloka-arctic.org) fosters collaboration between resident Arctic experts and visiting researchers to facilitate the collection, preservation, exchange, and use of local observations and Indigenous knowledge of the Arctic. ELOKA provides data management and user support to Indigenous communities to ensure their data and knowledge are managed, visualized, and shared in an ethical manner in order to work toward information and data sovereignty for Arctic residents. In existence for over a decade, ELOKA’s mission has evolved primarily from a data management project, creating archival and preservation tools for Indigenous Knowledge and information, towards enabling data and information sovereignty for our Indigenous partners. By data sovereignty, we mean that any data collected by, for, and about Indigenous peoples should be held under the control of those Indigenous groups, challenging many of the assertions made under the 'open data' movement. This paper will outline new efforts and future directions of the ELOKA project to ensure sovereignty of Indigenous peoples over their data and information, including full ownership and control over that information, with the development of a new research coordination network to further ensure data sovereignty for Arctic Indigenous peoples.
Community-based Monitoring and Resource Governance in the Arctic

Noor Johnson1,2 (noor.johnson@colorado.edu), Peter Pulsifer1, Colleen Strawhacker1
1University of Colorado Boulder, National Snow and Ice Data Center, Boulder, United States, 2Tufts University, Fletcher School of Law and Diplomacy, Medford, United States

Over the past decades, different actors have approached the Arctic with diverse agendas and visions, from laboratory to resource frontier to wilderness in need of conservation action. For Arctic Indigenous residents, these non-local visions impede a broad recognition of the Arctic as a homeland and adoption of governance models rooted in recognition of Indigenous rights.

Alongside these developments, community-based monitoring (CBM) has been proposed as a mechanism for supporting local involvement in resource governance, including oversight of extractive industry and participation in wildlife management. The scientific community has also embraced CBM based on its potential to contribute observations to broader scientific observing networks.

This paper examines possibilities and limitations of CBM as a mechanism to advance Indigenous peoples' rights and research priorities. We consider examples of the role that CBM has played in co-management approaches to resource governance as well as in community-initiated efforts for knowledge and information sovereignty. We also examine the role of data infrastructure, including current barriers to access for Arctic communities, in facilitating the use of CBM in different governance. We base our discussion on observations from participation in several CBM network building initiatives as well as interviews with CBM practitioners and members of the broader Arctic observing community.
Inuit are heavily reliant on sea-ice travel for harvesting activities to maintain their nutritional and cultural needs (ICC-Canada, 2008; 2014). In response to unprecedented changes in sea-ice due to climate warming, and to augment Inuit decision-making in sustaining safe sea-ice travel, a community-driven sea-ice information service called SmartICE was established in Pond Inlet, Nunavut, Canada (www.smartice.org). A community-based participatory research (CBPR) approach (Castleden et al., 2015) is being followed to ensure SmartICE meets community needs, builds capacity, reclaims leadership and decision-making roles for Inuit, and utilizes Inuit Qaujimajatuqangit (IQ, Inuit Knowledge) on its own scientific merit. While Indigenous scholars find CBPR a decolonizing ally (Kovach, 2009; Smith, 2012), it does not capture the relational accountability inherent in IQ (Price, 2007; McGrath, 2011; Healey, 2014). Thus, SmartICE has partnered with Ikaarvik, a community-based organization in Pond Inlet that engages and empowers Inuit youth in community research (www.vanaqua.org/act/direct-action/ikaarvik). Guided by IQ Societal Values (Government of Nunavut, 2013), Ikaarvik youth are developing an Inuit specific relational accountability model called “scIQ” that bridges the strengths of two ways of knowing between scientific enquiry and IQ. This presentation will highlight key aspects of the developing scIQ-CBPR methodology to guide Inuit and non-Inuit in co-producing Arctic research.
Indigenous Rights and the Sámi in Sweden - An Analysis of the Girjas Trial

Charlotte Wenner1 (charlotte.wenner@gmail.com)
1Eberhard-Karls Universität Tübingen, Tübingen, Germany

In 2009 a Sámi village went to court against the Swedish state to figure out who holds the right to permit fishing and hunting in the village's reindeer herding land, owned by the State. The Girjas trial was the major trial in recent years and gained international interest, especially since the district court granted the village an exclusive right to permit fishing and hunting in the specific area. Hence, the trial is used to reflect the current legislative and juridical situation of the Sámi in Sweden. Amongst others, inappropriate utterances by the state attorney and the handling of the Sámi's status as an Indigenous People need to be taken into account, too. On these grounds, the Girjas trial can also serve as a mirror for the social and sociological development and situation of, inter alia, the relationship Sámi-Swedish state.

Sweden has been criticized repeatedly for not including the Sámi in decision making processes and for not living up to the aims set by the UNDRIP. Therefore, this interdisciplinary study on one hand analyses the Girjas trial by various factors - the legislative and juridical one and the social one- and on the other hand develops a solution-oriented outlook. Since the Sámi are Europe's only Indigenous People, Sweden should work forward to protect and promote their rights and their cultural heritage.
Opportunities & Limitations in Co-managing Water Resources in Yukon, Canada

Sujata Manandhar¹² (smanandhar@yukoncollege.yk.ca), Douglas A. Clark²

¹Yukon College, Northern Climate Exchange- Yukon Research Centre, Whitehorse, Canada, ²University of Saskatchewan, School of Environment and Sustainability, Saskatoon, Canada

Yukon Energy Corporation (YEC) opened the Aishihik Hydroelectric Facility within Champagne and Aishihik First Nations' (CAFN) Traditional Territory in the Yukon, in 1975. Since then, CAFN has repeatedly expressed social and environmental concerns associated with the facility’s operation. As a solution to this persistent issue, YEC and CAFN are currently undertaking to co-manage the water resources for the Aishihik Water License renewal in 2019. One of their objectives is to fully integrate traditional knowledge into understanding the context and issues, as well as making management decisions. However, water resource co-management is a new field of governance, so opportunities and limitations are only just beginning to be identified. Our study assesses opportunities and limitations of the ongoing co-management approach through a conceptual adaptive co-management framework based on collaborative governance models. Data are collected using multiple methods such as semi-structured interviews, and participants observation. We identify some of the complexities and opportunities for improving water resources co-management in the Yukon, across Canada, and elsewhere.
This paper analyzes the extent to which the adoption of various laws on indigenous peoples has affected the dynamics of the number of Clan Communes (кorenныe rodovye obshchiny or KROs), as well as the preparation of concomitant documents (such as certificates and licenses), and cadastral maps. In the 1990s, to establish a KRO required relatively informal documentation. More recently (year here) legally formalized documents are required for the establishment and continued functioning of such indigenous organizations. We look at the experiences of the Union of Clan Communes of South Yakutia, and its experiences with the increased requirement for formalized paperwork. To what extent are those KROs without formalized documents protected in today’s legal environment? To what extent are they seeking the greater protection offered by more extensive documentation? The Law on the Far East Hectare has accelerated the requirement for documentation, a process that had already been initiated by the Government of Yakutia.
Greenland Ice Cores Tell Tales on past Sea Level Changes

Dorthe Dahl-Jensen¹ (ddj@nbi.ku.dk)
¹University of Copenhagen, Niels Bohr Institute, Copenhagen, Denmark

All the deep ice cores drilled to the base of the Greenland ice sheet contain ice from the previous warm climate period, the Eemian 130-115 thousand years before present. This demonstrates the resilience of the Greenland ice sheet to a warming of 5 °C. Studies of basal material further reveal the presence of boreal forest over Greenland before ice covered Greenland. Conditions for Boreal forest implies temperatures at this time has been more than 10 °C warmer than the present.

To compare the paleo-behavior of the Greenland ice sheet to the present in relation to sea level rise knowledge gaps include the reaction of ice streams to climate changes. To address this the international EGRIP-project is drilling an ice core in the center of the North East Greenland Ice Stream (NEGIS). The first results will be presented.
Variability of Terrigenous Supply in the Northern Bering Sea over the Past 23 ka

Yanguang Liu1 (yanguangliu@fio.org.cn), Xuefa Shi1, Tengfei Song1
1First Institute of Oceanography, Department of Marine Geology, Qingdao, China

We use gravity core B11 recovered in the northern Bering Slope to reconstruct millennial-scale changes of paleoproductivity and terrigenous matter supply since 23 ka BP. Based on the geochemical and high-resolution XRF core logging data, our results demonstrate closely interactions between the paleoproductivity and the terrigenous matter supply. Overall, the paleoproductivity is low during the LGM, Heinrich Stadial 1 (HS 1) and Younger Dryas cold phases (YD), and high during Bølling/Allerød (B/A) and Holocene. There are calcium carbonate peaks during B/A which suggest the high calcareous productivity whereas the siliceous productivity increasing rapidly since B/A. The paleoproductivity turns sustained high after YD. Ice rafting debris(IRD) are one of the major terrigenous matter of the Bering Slope, it plays significance role during the cold phases like LGM, especially early HS 1 period. Sea ice extended southward to the Bering Slope carrying masses of shelf sediment by glacier over deepening, the excavation transported vast of clay and terrigenous organic matter into the Bering Slope which responses for the high clay and Total Organic Carbon (TOC) contents during HS 1. The high Fe/S value reveals that the Bering Sea shallower than 1500m was well ventilated under the sea ice cover condition during HS 1. Since B/A, the terrigenous matter source turns to be the submerged shelf which is eroded by the current, tide and the river as the sea level raised.
Late Cenozoic Sedimentary Processes Shaping the Lomonosov Ridge, Arctic Ocean

Lara F. Pérez1 (lfp@geus.dk), Tove Nielsen1, Thomas Funck1, Finn Mørk1, Katrine J. Andresen2, Martin Jakobsson3
1Geological Survey of Denmark and Greenland, Department of Geophysics, Copenhagen, Denmark, 2Aarhus University, Department of Geoscience, Aarhus, Denmark, 3Stockholm University, Department of Geological Sciences, Stockholm, Sweden

With local water depths (wd) shallower than 1000 m, the Lomonosov Ridge is the most prominent feature of the Arctic Ocean. Several tectonic events have shaped the ridge during its Cenozoic history. Moreover, other sedimentary processes have also contributed to the ridge shaping during the recent past. These processes are poorly known, mainly due to the sparse coverage of data in the Arctic Ocean. However, substantial quantities of geophysical data have been collected during the past years in the framework of international research projects or the national UNCLOS programs of the circum-Arctic countries. Detailed analysis of the sub-bottom profiles across the entire Lomonosov Ridge has revealed the regional distribution of sedimentary features in the most recent sedimentary record, suggesting a variety of cryospheric and oceanographic processes involved in their formation. Truncated reflectors are identified in the highs of the Siberian side of the Lomonosov Ridge, above 1000 m wd. They have been linked to grounding ice sheet and iceberg ploughing. Sediment waves are identified between 1000 and 1500 m wd particularly along the ridge flank towards Amundsen Basin, slightly deepening in the surroundings of the North Pole. These sediment waves are linked to the Siberia-Greenland flow of intermediate water masses in the Arctic Ocean constrained by the morphology of the Lomonosov Ridge and following the Arctic cyclonic circulation.

Last Interglacial Meltwater Signal from Far-field Sea-level and Proxy-climate

Ian Goodwin¹ (ian.goodwin@mq.edu.au), Mick O’Leary², Jerry Mitrovica³
¹Macquarie University, Sydney, Australia; ²Curtin University, Perth, Australia; ³Harvard University, Boston, United States

Most of the geological record of Antarctic Ice Sheet extent during warmer interglacials has been lost due to glacial expansion and retreat cycles, and the ice-core record is geographically sparse. We take the novel approach of using the Southern Hemisphere (SH) coastal and specifically the Australian region imprint of sea-level history to identify ice sheet instability during the last interglacial (MIS5). The unique sea level signal archived in the coastal sediments and morphology contains evidence for a pulse of meltwater input during the mid-late MIS5e of ~2-3 m of sea-level equivalent. The spatial pattern of the differential sea-level rise during MIS5e, after correction for Glacio-Isostasy is matched to the gravitational meltwater fingerprint for each of the three polar ice sheets to determine the origin of the excess meltwater and hence, the source of ice sheet instability.

We also report our progress in reconstructing the MIS5e SH atmospheric pressure and wind field evolution. We apply a coastal and climate proxy-data-model assimilation by using a Last Interglacial simulation together with a regionally distributed multivariate proxy dataset, to produce atmospheric reanalysis for 129 ka BP, 125 ka BP and 120 ka BP (after Goodwin et al., Clim. Dyn., 2013). Ultimately, we compare the atmospheric circulation patterns together with the meltwater fingerprint pattern to the MIS5e ice core record and the Antarctic shelf-sedimentary record of meltwater discharge.
Antarctic snow petrels (*Pagodroma nivea*) produce stomach oil, which is ejected against predators to defend their nests. In some locations stomach oil accumulates and fossilizes and forms centimetre to decimetre thick deposits of so-called Antarctic mumiyo.

We studied mumiyo deposits from different sites in central Dronning Maud Land to explore their potential as a paleoclimate archive. Comprehensive $^{14}C$-analysis shows that the finely-laminated deposits provide consistent age depth profiles. Besides from organic compounds, which are derived from stomach oil (mainly wax-ethers), the deposits contain inorganic minerogenic particles sourced from bedrock and from guano. High-resolution XRF elemental scans indicate that changes in inorganic composition are consistent within one deposit and likely reflect local environmental conditions. Mumyio profiles from one region can be correlated based on their age and chemical composition, which suggests that the deposits provide a regional signal.

Our data confirm the existence of un-glaciated areas during the Last Glacial Maximum (LGM) and extend the archive far into Marine Isotope Stage (MIS) 3, which is poorly understood in coastal Antarctica.
New Constraints on post-LGM Ice Sheet Dynamics in the Southern Weddell Sea

Jan Erik Arndt1 (jan.erik.arndt@awi.de), Claus-Dieter Hillenbrand2, Hannes Grobe1, Gerhard Kuhn1, Lukas Wacker3, Robert D. Larter2, Boris Dorschel1, Simon Sørli4, Matthias Forwick4
1Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, 2British Antarctic Survey, Cambridge, United Kingdom, 3ETH Zurich, Zürich, Switzerland, 4UiT The Arctic University of Norway in Tromsø, Tromsø, Norway

Past ice sheet conditions in the southern Weddell Sea remain poorly known. Previous studies have led to contradicting scenarios of maximum ice extent during the Last Glacial Maximum (LGM). Scenario A is mainly based on terrestrial data indicating limited ice sheet thickening in the hinterland and suggests a LGM grounding-line position on the inner shelf. Scenario B is based on marine geological/physical data and concludes that the grounding line was located on the outer shelf (~650 km further offshore than in scenario A). In addition, studies suggest a complex history of ice retreat and drainage pattern since the LGM that needs further constraint. We investigated hydroacoustic data acquired during 17 expeditions. A key finding is a previously unknown stacked grounding zone wedge (GZW) located in Filchner Trough on the outer shelf showing that a palaeo-ice stream stabilized at this position at least twice. Radiocarbon dates from sediment cores indicate that (i) the GZW was formed in the early Holocene and (ii) grounded ice did not extend seaward at the LGM. Hence, the grounding line in Filchner Trough experienced dynamic changes in the Holocene and ice sheet retreat after the LGM was not linear. Ice-flow switches in the hinterland possibly explain this behaviour. Further interesting findings are made in Brunt Basin suggesting the existence of cold-based ice or impacts of large icebergs. In addition, new data will be acquired in the area with RV Polarstern in Jan-Mar 2018.
OC-4 - Art meets Science: That Which Cannot Be Transmitted  
19.06.2018 14:00-15:30, A Seehorn

That Which Cannot Be Transmitted

Sandra Kuehne¹ (info@sandrakuehne.ch), Tamsin Relly², Daniel Kukla³  
¹Visual Artist, Zürich, Switzerland, ²Visual Artist, London, United Kingdom, ³Visual Artist, New York, United States

In 2014 a group of visual artists sailed in a tall ship up the west coast of Svalbard. They all witnessed the same landscape, yet, as they filtered the experience through their individual thematic and aesthetic concerns, a series of translations occurred, across a range of media including photography, video and drawing. In response, seven of the artists developed That Which Cannot Be Transmitted, a project which considers how the process of translation can shape contemporary discourse about the Arctic. Exploring overlapping themes of temporality and the Anthropocene, three of these artists will each present their work.  
Tamsin Relly works with the fluid and unpredictable qualities of printmaking and photography to disrupt the translation of landscape into image, and offer impressions of environments in states of uncertainty or impermanence.  
Paper, lines and cutting are central to Sandra Kuehne’s practice. Printed materials such as polar maps are frequently used as media. Kuehne employs the variations of the line, its formal lyricism, but also challenges the absolute assertion of any printed map by making references to topography that is in continual flux. 
Daniel Kukla’s work is informed by the intersection of his art practice and formal training in the biological and anthropological sciences. He is interested in the shifting tensions towards the natural world as our society expands with an insatiable appetite for resources.
Invisible Dust: Making the Invisible Visible

Victoria Burns1 (victoria@invisibledust.com)
1Invisible Dust, London, United Kingdom

Invisible Dust’s mission is to encourage awareness of, and meaningful responses to, climate change and environmental issues. We facilitate dialogue between leading visual artists, creative technologists and scientists.

We aim to connect with people on a personal level through making the invisible visible. Visibility plays a key role in creating understanding around the need to live sustainably and dramatically reduce climate change. Artists have many ways of making things visible and, particularly since the Land Art movement in the 60s and 70s (such as the ephemeral works of Richard Long and Robert Smithson) have responded to changes in the natural environment in a variety of forms.

How can people understand their own effect on the environment when the resulting gases disappear into the sky? Since the industrial revolution there have been huge gains to society but the creation of many of the gases are now poisoning the earth. Invisible Dust creates partnerships to illuminate these consequences and bring a sense of something human and fantastical to often very invisible problems.

Our lecture will case study Kasia Molga’s Human Sensor which premiered in the streets of Manchester in 2016 - Molga created striking wearables which change colour in response to air pollution; and our 2017 exhibition Offshore - Artist Explore the Sea which included 23 artists works and 10 new commissions which were created in consultation with Ocean Scientists.
2220
There Is Always Something More Important

Mariele Neudecker¹ (mail@marieleneudecker.co.uk)
¹Bath School or Art and Design - Bath Spa University, Fine Art, Bath, United Kingdom

Both scientific scrutiny and intuitive artistic exploration can give insights to the blurred zones between subjectivity and objectivity and alter our perception of the world. I am a visual artist and often use technology’s virtual capabilities in order to reproduce a heightened experience, often of Northern or Arctic landscapes. I am interested in notions of a contemporary sublime and have worked with scientists and engineers and their methods and research with the on-going quest to make the immeasurable measurable, the invisible visible.

I find it inspiring to look at places and situations that are overtly international, with a communal goal of seeking new knowledge, often situated on the fringes of civilization. In these “borderless” places, we find academic research centres that prioritize humanity to a social and political unit, where egos, politics and nationalities have become secondary.

I have travelled in Arctic Scandinavia and Greenland. With works that followed these journeys, I have been exploring the interphases and overlaps of imaginary and factual realities, the two and three-dimensional, as well as the analogue and digital.

In this talk I will present my projects that connect to the Poles or the Arctic in some way. I work with a variety of media, including sound, sculptural installations and scale.

I am interested in how knowledge: past, present and future, can come to life and what it means to be human in age of the Anthropocene.
Resonant Evidence: Music and Soundscapes from the Ice

Douglas Quin\(^1\) (dhquin@syr.edu), Jay Needham\(^2\)
\(^1\)Syracuse University, Television, Radio & Film, Syracuse, United States, \(^2\)Southern Illinois University Carbondale, Carbondale, United States

This 15-minute panel focuses on the work of Jay Needham and Douglas Quin, two sound artists with extensive polar experience.

Needham utilizes multiple creative platforms and his works often have a focus on recorded sound, archives and the interpretation of artifacts. His field recordings from Antarctica have become the basis for his composition Chronography: Animal, that premiered at the Internationale Ferienkurse für Neue Musik Darmstadt in 2012. An interest in soundscape and where art and science intersect are threaded throughout Quin’s practice: from direct collaboration with scientists in field-based bioacoustics research into Weddell seal vocalization to drawing inspiration from and using ice-core data to inform compositional strategies and outcomes. Quin was the first composer and sound artist to be selected by the US National Science Foundation's Antarctic Artists and Writers Program in 1996. Over the past 20 years, his varied polar projects include site-specific and interactive sound installations, soundscape recording, composition, performance, live satellite broadcasts, and film.

The panel will include discussion and listening to samples of their compositions.

Modern Hyperboreans

Evgenia Arbugaeva1 (arbugaeva@gmail.com)
1 Freelance Visual Artist, Yakutsk, Russian Federation

I am a documentary photographer, most of my life has been spent traveling in the North and pursuing personal stories and editorial assignments: I have been visiting hard-to-reach scientific stations; migrated with Nenets reindeer herders; explored the rush for natural resources across the Arctic; and lived on New Siberian islands with “pirates” who excavate mammoth tusks from melting permafrost.

In my journeys, I’m attracted to the visual simplicity of the Arctic landscape, and to the emotional complexity of the humans who inhabit it. I am curious about the motives that bring people to remote Arctic locations — a land that, quite honestly, is not made for living. But its remoteness offers refuge to those souls that seek isolation.

In this presentation, I would like to share the story of Slava - chief of the meteorological station Khodovarikha located on the narrow peninsula in the Barents Sea in Russia. Slava has been living at the station for 13 years. He is the kind of rare character that you meet only in the Arctic - Polyarnik, a specialist in the polar north, a hermit who chooses to live away from the rest of the world. Looking at him, I had a strange feeling that he is not only measuring the weather, but that he also lights up the sky with the Aurora Borealis, exchanges news with the wind, and converses with the sea. I tried to capture this impression in my photographs of a weather magician living in extreme solitude.

Geospatial Tracking of Antarctic Iceberg Calving via Indian Space-borne Missions

Shridhar Jawak¹ (shridhar.jawak@gmail.com), Alvarinho Luis¹
¹National Centre for Antarctic and Ocean Research (ESSO-NCAOR), Ministry of Earth Sciences, Vasco da Gama, India

This study focuses on the tracking of iceberg calving events in the vicinity of Larsemann hills and environ, Ingrid Christensen coast, east Antarctica using multispectral images from Linear Imaging Self Scanning Sensor (LISS-IV) aboard IRS-P6 satellite. The two images captured specifically 384 days apart from LISS-IV, enabled a detailed understanding of the changes that have occurred during this short epoch. A careful and expert-guided onscreen manual digitization was used for tracing icebergs present in both the images. A total of 369 common icebergs present in both images were identified on the basis of their shape, size and texture for analyzing the changes in their dimensions because of melting or disintegration. Also, several among these were found to have deformed and diminished during the period from December 31, 2013 and January 19, 2015. Our analysis estimates that the number of icebergs is decreased by 70 from 2013 to 2015, suggesting the complete disintegration of these icebergs over the ≈1 year period. In case of 369 common icebergs, the total surface area has been decreased by 12.51%, suggesting the melting of icebergs in the given time period. The average deviation of the newly disintegrated icebergs from the coastline is found to be 51.59 m for 384 days. This study demonstrates the quantitative analysis of iceberg calving, changes in iceberg numbers, rate of iceberg disintegration, and rate of iceberg drift in the Prydz bay of the Larsemann hills area.
Snowmelt in Antarctica as Derived from SMOS Observations

Marion Leduc-Leballeur\textsuperscript{1} (m.leduc@ifac.cnr.it), Ghislain Picard\textsuperscript{2}, Giovanni Macelloni\textsuperscript{1}, Arnaud Mialon\textsuperscript{3}, Marco Brogioni\textsuperscript{1}, Yann H Kerr\textsuperscript{3}

\textsuperscript{1}IFAC-CNR, Sesto Fiorentino, Italy, \textsuperscript{2}IGE, UGA-CNRS, Grenoble, France, \textsuperscript{3}CESBIO, CNES, CNRS, IRD, UPS, Toulouse, France

In the polar regions, the state of the surface is essential to understanding and predicting the surface energy and mass budgets, which are two key nivo-meteorological variables for the study of the climate and the contribution to the sea level rise of ice-sheets. The inter-annual variations of melt duration and extent are valuable indicators of the summer climate in coastal regions of the ice-sheets, especially on ice-shelves where melt water contributes to their fate.

Liquid water have a significant impact on the microwave emissivity of the surface and several studies exploited the 19 and 37 GHz long time series to detect snowmelt events. The European Space Agency (ESA)'s SMOS satellite carried on board a microwave radiometer operating at 1.4 GHz. At this low frequency, the signal is sensitive to a large thickness of snow when it is dry contrary to higher microwave frequencies, which are sensitive up to the first meters of the snowpack. Thanks this large penetration depth, SMOS observations could detect if melt water persists at depth and impacts on snowpack stability. In this study, we developed algorithms based on previous studies in order to detect melt from the SMOS brightness temperature at horizontal polarization. Snowmelt product is obtained from July 2010 and June 2015 with SMOS observations. Here, we explore the potential of combined low and high frequencies to provide a synergetic description of surface melting events in Antarctica and investigate their variations.
Long-term Antarctic Elevation Change from Multi-mission Satellite Altimetry

Ludwig Schröder1 (ludwig.schroeder@tu-dresden.de), Martin Horwath1, Reinhard Dietrich1, Veit Helm2
1Technische Universität Dresden, Institut für Planetare Geodäsie, Dresden, Germany, 2Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

The contribution of the Antarctic Ice Sheet to present-day sea level change still contains large uncertainties. In several regions of West Antarctica, changing ice flow leads to rapid dynamic thinning while in East Antarctica the rates are relatively small. The time period of a single satellite altimetry mission is not long enough to distinguish between long-term elevation changes and interannual variations. Therefore, we apply a multi-mission approach to combine the observations of different missions and thus are able to create a joint long-term elevation time series. We show that a consistent reprocessing of ice sheet altimetry from different missions is not only a prerequisite for the combination, but also improves the accuracy and precision of conventional pulse limited radar altimetry by about 30%. We will discuss which special aspects have to be considered when combining conventional radar altimetry with the high resolution SARIn-mode data of CryoSat-2 and the high precision ICESat laser altimeter measurements. Therefore we will present a novel approach to create a joint time series. Our results provide an unprecedented insight into the variations of the interior of East Antarctica and help to separate the long-term trends from interannual variations.
Satellite radar altimetry has proven to be a valuable tool for remote sensing of the polar oceans, with techniques for estimating sea ice thickness and sea surface height in the ice-covered ocean advancing to the point of becoming routine, if not operational, products. Scheduled for launch in 2021, the Surface Water Ocean Topography mission (SWOT) payload, the Ka-band Radar Interferometer (KaRIn), will employ radar interferometry to estimate an ~120km across-track swath of surface elevation. In the polar oceans, SWOT will provide high resolution two-dimensional maps of sea level and sea ice elevation, offering the potential to derive instantaneous 2-D ocean currents and a detailed picture of the sea ice thickness distribution. Here, we present results from preliminary investigations into the KaRIn retrieval performance in the ice-covered oceans. First, we utilise the available near-incidence Ka-band airborne and satellite data to study the range of possible radar backscatter profiles. Second, the range of possible radar backscatter profiles will be applied in the SWOT mission simulator to produce synthetic data and evaluate the expected measurement capability.
Recent Achievements in Deriving Sea Ice Thickness from Radar Altimetry

Robert Ricker¹ (robert.ricker@awi.de), Stefan Hendricks¹, Stephan Paul¹, Lars Kaleschke², Xiangshan Tian-Kunze²
¹Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, ²University of Hamburg, Hamburg, Germany

The retrieval of Arctic sea ice thickness is one of the major objectives of the European CryoSat-2 radar altimeter mission and the 7-year long period of operation has produced an unprecedented record of monthly sea ice thickness information. We present CryoSat-2 results that show changes and variability of Arctic sea ice for the period 2010 to 2018. CryoSat-2, however, was designed to observe thick perennial sea ice, while retrieving thin seasonal sea ice accurately is more challenging. We have therefore developed a method of completing and improving Arctic sea ice thickness information by merging complementary satellite retrievals. The European SMOS satellite can detect thin sea ice, whereas its companion CryoSat-2 lacks sensitivity. Using these satellite missions together overcomes several issues of single-mission retrievals and provides a more accurate and comprehensive view on the state of Arctic sea-ice thickness at higher temporal resolution. Nevertheless, standalone CryoSat-2 observations can be used as reference data for the exploitation of older radar altimetry data sets over sea ice. In order to observe trends in sea ice thickness, it is required to minimize biases between subsequent satellite missions. We show a climate data record of sea ice thickness derived from satellite radar altimetry that has been developed for both hemispheres, based on the 15-year (2002-2017) monthly retrievals from Envisat and CryoSat-2 and calibrated in the 2010-2012 overlap period.
Satellite remote sensing cover Antarctica to varying degrees, leaving polar data acquisition gaps, depending on satellite orbit inclination. While GRACE provided mass change data for all of Antarctica, radar and laser satellite altimetry missions such as CryoSat, IceSat and EnviSat covered only regions in the range from 88-83°S from the South Pole; recent geophysical missions such as GOCE (gravity field) and SWARM (magnetic field) covered only regions north of 83°S and 87°S, respectively. To improve the coverage of the polar gap region, especially for the GOCE mission, the European Space Agency funded a major airborne remote sensing campaign - PolarGap 2015/16 - to provide a first systematic fill-in of the southern polar gap data. The PolarGap campaign were carried out by a British Antarctic Survey Twin-Otter operating from two deep interior field camps and Amundsen-Scott South Pole station, collecting a variety of lidar, radar, gravity and magnetic data. In the presentation the results of the PolarGap campaign are presented, along with comparisons to satellite data in the overlap zones, and some of the major discoveries summarized. The comparisons confirm large errors in existing data compilations such as BEDMAP2, ADMAP and ANTGRAV, and also provide new understanding of CryoSat Ku-band radar firm penetration on the Antarctic Plateau, confirming the sub-meter accuracy in ice sheet radar elevation mapping.
Using Digital Resources to Stimulate International Public Engagement

Jean Holloway¹ (jean.holloway77@gmail.com), Alexander Thornton², Jilda Caccavo³, Gabriela Roldan⁴, Hanne Nielsen⁵, Gerlis Fugmann⁶

¹University of Ottawa, Geography, Environment and Geomatics, Ottawa, Canada, ²University of Alaska - Fairbanks, Fairbanks, United States, ³University of Padova, Padua, Italy, ⁴University of Canterbury, Christchurch, New Zealand, ⁵University of Tasmania, Hobart, Australia, ⁶Association of Polar Early Career Scientists, Alfred-Wegener Institute, Helmholtz Center for Polar and Marine Research, Potsdam, Germany

The Association of Polar Early Career Scientists (APECS) is a multidisciplinary, international organization dedicated to maintaining a network of early career researchers to share ideas, develop collaborative research directions, provide career development opportunities, and promote education and outreach related to polar research. APECS has stimulated polar literacy through innovative science communication, well-integrated public outreach and engagement, and partnerships with Arctic and Antarctic organizations. Examples of one- and two-way engagement between APECS' members and the general public are illustrated in our involvement with digital events and social media initiatives. Successful events include Antarctica Day, webinars, and APECS' annual online conference. One of our popular social media initiatives is the biannual Polar Week celebration. This includes Twitter campaigns, Reddit “Ask Me Anything” discussions, and photo and video contests. Benefits to using modern technologies and techniques for stimulating public engagement about polar research include easier dissemination of ideas across geographical distances as well as to remote areas with minimal cost and a low carbon footprint. While this presentation focuses on APECS' experiences, we will highlight how innovative communication promotes international discussion and cooperation across disciplines, then offer suggestions on how to incorporate similar elements into other outreach programs.
The Power of the Tourism Fleet to Contribute to Science and Create Ambassadors

Annette Bombsch1,2 (annette.polarcollective@gmail.com), Robert W. Gilmore1, Lauren Farmer2, Alex Cowan2, Ted Cheeseman3, Susan Adie2, Brandon Harvey1
1Polar Latitudes, White River Junction, United States, 2G Adventures, Toronto, Canada, 3Southern Cross University, Lismore, Australia

Polar Regions are the focus of scientific research due to accelerated effects of climate change. Yet data collection in these areas is often limited by its remoteness and financial constraints. At the same time these areas experience increased traffic due to a heightened interest amongst travellers and a growing tourism fleet. Often visitors are well-educated and eager to gain a deeper understanding of the places they visit. Citizen science has developed into a recognised and indispensable means for robust data collection and guest education.

Expedition ships operate entire seasons in Polar Regions, providing cost-effective platforms for data collection over longer time periods than research cruises. Benefits of citizen science projects aboard encompass valuable data for the scientific community as well as turning guests into active polar ambassadors by increasing awareness and concern for the conservation of the Polar Regions.

Here we present how to successfully undertake citizen science programs aboard, using examples from tour operators Polar Latitudes and G Adventures, as well as how to coordinate data collection amongst the tourism fleet. Possibilities for guest engagement cover activities aboard, during Zodiac and land excursions. Challenges addressed include selecting suitable projects ensuring both data quality and feedback from scientists. Also an ambitious platform for coordinating and facilitating industry-wide citizen science efforts is introduced.
Antarctic Ambassadors Explore Meltwater Influence on Phytoplankton within Fjords

Allison Lee¹ (allisonlee9@gmail.com), Maria Vernet¹
¹Scripps Institution of Oceanography, UC San Diego, Biological Oceanography, La Jolla, United States

The Antarctic Peninsula has experienced rapid warming for decades, leading to an increase in glacial meltwater input within the coastal fjords. This freshwater released at the glacier front creates changes that may drastically impact various levels of the food web, particularly with phytoplankton. Small environmental variations may favor different compositions of phytoplankton and shift the timing of blooms during the season. These seasonal and interannual variations regarding phytoplankton phenology and community composition are not available within the fjords and detailed monitoring can provide insights into changes that may occur. A great opportunity exists for scientists to collect this vital data by engaging the Antarctic tourism community. The International Association of Antarctic Tour Operators (IAATO) brings visitors throughout the year, occupying coastal fjords during the austral growth period. This established community can collect scientific data thereby improving the knowledge gap of phytoplankton composition and phenology. This citizen science partnership with the IAATO operators, in which tourists can participate, will supplement our current scientific datasets gaining a more comprehensive view of phytoplankton community structure and bloom dynamics in the Antarctic fjords. This new knowledge will not only provide a better understanding of glacial meltwater impacts on biodiversity and ecology, but also increase public engagement and understanding of science.
Harnessing correctly, citizen science can be a huge asset to Antarctic science. During the 2017/18 season, the IAATO fleet alone is expecting more than 46,000 tourists to visit Antarctica. In recent years, such visitors have begun observing and cataloguing animals including humpback whales, orcas and leopard seals. There is a huge potential to further utilise this resource to create crowd-sourced observation data.

In 2011, when I created a fellowship program to host Antarctic scientists, I initially hoped to add value to my passengers' Antarctic experience through their engagement with (and assistance to) guest scientists. In doing so, I picked up valuable lessons in the planning, permitting, organising and onboard management of small vessels support of both 'citizen' and government science.

During the 2017/18 season alone, I will be supporting seven different science projects, ranging from visual observations by tourists, to dedicated research voyages for national Antarctic programs. To date, these voyages have resulted in 28 published papers, 175 citations, the support of nine national Antarctic programs and 40 institutions, the transport of 90 scientists and 915 tourists. On voyages with both passengers and scientists, the interaction between the two has not only assisted scientists in their data gathering, but resulted in passengers returning north as true Antarctic ambassadors.
Operational Ice Service Perspectives on Collaborations with Polar Tourism

Penelope Wagner¹ (penelope@met.no), Nick Hughes¹, Keld Qvistgaard²
¹Norwegian Meteorological Institute, Norwegian Ice Service, Tromsø, Norway, ²Danish Meteorological Institute, Copenhagen, Denmark

With the increase of polar tourism, the Norwegian and Danish Ice Services have been collaborating with polar tourism to better understand data needs of ship operators when making tactical decisions travelling through or along icy waters. A main challenge that has been identified from an operational perspective is providing ship operators with sufficient and reliable daily ice information, including high quality sea ice and iceberg detection in the marginal ice zone, along the ice edge, and in harbours, and inshore. The operational ice services are developing better methods to provide better outlooks and forecasts which may require customized products, particularly for large ships that have less flexibility to change their planned trajectory. Near-real time data transmission continues to be unreliable in specific areas. It is essential that ice services supporting maritime safety in navigation consolidate efforts to work with the polar tourism industry and develop strategies to improve the coordination between data providers and users. Additionally, increasing citizen science endeavours on ships is ideal for ice services to exchange routine ship observations and satellite information. It also allows passengers to fully engage with operational and science activities. Using case studies of ice services providing support to Arctic and Antarctic cruise ships and participating in citizen science activities, we demonstrate how we can improve collaboration between the two groups.
Encouraging Citizen Science with Community-based Science Month Events

Regina Brinker¹,² (brinker.science@gmail.com)
¹Livermore Valley School District, Science, Livermore, United States, ²Polar Educators International, Livermore, United States

Science and Engineering Month (SEM) is celebrated during February in Livermore, California. Over 40 programs encourage the community to learn about science and engineering, get outdoors and observe the natural world around them, and contribute to citizen science projects. Many events, including lectures, bio-blitz surveys, water quality testing, and nature walks, relate to environmental and climate awareness.

A range of public agencies, including government, K-12 and college education, libraries, park and recreation centers, and businesses participate in SEM. Programs are publicized through the internet, local newspapers, and social media.

Goals of SEM are to engage the community in science, make citizens more knowledgeable of and connected to local ecosystems, and increase awareness of local impacts of climate change.

This presentation will discuss SEM's concepts, planning, and implementation. As the program coordinator, I will share best practices and lessons learned for creating a successful community-wide program. SEM may be modeled in other communities to fit the needs and interests of that area, including engaging citizens in community science project related to polar science.
Variable Connectivity between Glacial Melt and Streamflow, McMurdo Dry Valleys

Anna Bergstrom\(^1\) (anna.bergstrom@colorado.edu), Michael Gooseff\(^1\)
\(^1\)University of Colorado, Boulder, United States

The Dry Valleys of Antarctica are a system closely tied to the energy balance. In the summer months with air temperatures around 0 degrees C, slight shifts in incoming radiation, temperature, or albedo can have drastic effects on both the magnitude and partitioning of glacial ablation for sublimation and melt water generated for streamflow. Snowmelt is a very minor contributor to streamflow. The McMurdo Long Term Ecological Research site has been collecting records of glacial ablation, streamflow, and meteorological data for over 23 years. In the 2001-2002 season, unusually high persistent temperatures and solar flux caused unprecedented glacial melt and streamflow orders of magnitude higher than average. After this season, relationships between glacial melt and streamflow have shifted. There is better correlation between streamflow and ablation for all studied streams after the warm season. It is hypothesized that the melt event reorganized and concentrated sediment at or near the surface of the glaciers, lowering the albedo. This research utilizes the long-term records of streamflow, glacier ablation, and meteorological data to assess how the melt event may have resulted in lasting changes in the energy balance dynamics and degree of melt water generation from the Dry Valley glaciers. This work will help us better understand the controls on glacial melt as well as the connection between glaciers and the downstream ecosystems.

Investigating Large Active Subglacial Lake Drainages in East Antarctica

Matthew Siegfried¹ (siegfried@stanford.edu), Susheel Adusumilli², Helen Fricker⁷, Ted Scambos³,⁴, Dustin Schroeder¹, Benjamin Smith⁵

¹Stanford University, Department of Geophysics, Stanford, United States, ²Scripps Institution of Oceanography, UC San Diego, Institute of Geophysics and Planetary Physics, La Jolla, United States, ³National Snow and Ice Data Center, Boulder, United States, ⁴University of Colorado Boulder, Boulder, United States, ⁵University of Washington, Seattle, United States

Spatially coherent surface-height anomalies have been mapped in regions of fast ice-flow across Antarctica. These features have been interpreted as the surface manifestation of a dynamic subglacial water system, with up to cubic kilometers of water moving into and out of active subglacial lakes on timescales of months to decades. By impounding and episodically releasing water, these subglacial lakes have been hypothesized to drive regional hydrological variability and modify the flow of the overlying ice. However, no datasets have been available with high enough time resolution to simultaneously observe surface-height motion, map velocity changes, and image the ice-bed interface through a hypothesized subglacial lake drainage event, leaving the relationship between surface-height anomalies, the basal environment, and ice dynamics unclear. Using satellite and airborne altimetry from the CryoSat-2 mission and Operation IceBridge, Landsat 8 feature tracking, MODIS image differencing, and repeat airborne radar sounding, we investigate two large (> 10 m) surface-height anomalies on Slessor and Recovery glaciers, East Antarctica. By mapping regional basal reflectivity and velocity changes before, during, and after surface-height changes, we explore the cause of these enigmatic, widespread features and their ultimate impact on ice flow in Antarctica.
A Regional System of Briny Aquifers in the McMurdo Dry Valleys, Antarctica

Slawek Tulaczyk1, Esben Auken2, Hilary Dugan3, Peter Doran4, Jill Mikucki5, Ross Virginia6, Krista Myers4 (kmyer19@lsu.edu)

1University of California, Santa Cruz, Earth and Planetary Sciences, Santa Cruz, United States, 2Aarhus University, Geosciences, Aarhus, Denmark, 3University of Wisconsin, Center for Limnology, Madison, United States, 4Louisiana State University, Geology and Geophysics, Baton Rouge, United States, 5University of Tennessee, Microbiology, Knoxville, United States, 6Dartmouth College, Environmental Studies, Hanover, United States

Liquid water is relatively scarce in high-latitude polar environments but plays an outsized role by influencing, and integrating, biological, biogeochemical, glaciological, and geological processes. Whereas surface hydrology and its role in ecosystem processes has been thoroughly studied over the last several decades, it has been difficult to map out and characterize subsurface water reservoirs and to understand their interactions with regional lakes, glaciers, and coastal waters. As part of the NSF-funded AntAEM project, we are using ground-based and airborne Time-domain ElectroMagnetics sensors to provide the first integrative system-scale overview of subsurface water distribution and hydrological connectivity in a partly ice-free coastal region of Antarctica, the McMurdo Dry Valleys. Our previous survey documented existence of a briny aquifer in Taylor Valley (Mikucki et al., 2015) and new data indicate similar subsurface features in neighboring valleys. In particular, we see that Don Juan Pond, the second saltiest waterbody on Earth, is likely connected to a subsurface aquifer, as is the largest lake in the Wright Valley, Lake Vanda. Airborne data collection in 2018 will further elucidate these relationships between surface and subsurface water systems. It will also focus on clarifying the connectivity between these inland groundwaters and the coastal zone. The briny groundwater systems found by us in the Dry Valley region may be common in coastal Antarctica.
Using GPR to Investigate the Subglacial Hydrology of an Alpine Glacier

Pascal Emanuel Egli¹ (pascal.egli@unil.ch), Stuart Nicholas Lane¹, James Irving², Martino Sala¹
¹University of Lausanne / Institute of Earth Surface Dynamics, Lausanne, Switzerland, ²University of Lausanne / Institute of Earth Sciences, Lausanne, Switzerland

Hydrological inference suggests that subglacial drainage networks under temperate valley glaciers are dendritic, meaning that their subglacial conduits have both streams and stream junctions. These networks, at their most developed, comprise subglacial conduits. They are typically associated with the combined effect of opening by hydraulic-pressure-driven ice melt and closure by ice overburden pressure. Inference from dye breakthrough curves has supported theoretical arguments that:
(1) these channels open up progressively during the summer; and
(2) close during the winter to leave a more inefficient drainage network at the start of spring.
This model has dominated modern glaciology for over 50 years, but geomorphological reasoning questions this domination. Temperate valley glaciers, when they retreat, commonly reveal beds of soft sediments. Borehole imagery as well as speological investigations have confirmed that the channels have potentially erodible beds. As such, they might better be viewed as rivers under ice rather than channels eroded into ice.
Here, we present the results of ground-penetrating radar (GPR) surveying on the Glacier d'Otemma in the south-western Swiss Alps. By looking at spatially dense grids of GPR measurements with a line spacing of 2 m, we aim to determine the locations and geometry of sub-glacial conduits below the glacier tongue, for ice thicknesses between 30 m and 80 m.
Drainage of meltwater and rainwater plays an important role in glacier dynamics. Behavior of drained water within the drainage system is poorly known and understood. During the years 2016 and 2017, our study focuses on the well-explored perennial conduit, known as Crystal Cave, present inside the tidewater glacier Hansbreen located in the southern part of the Svalbard archipelago. The polythermal regime of this glacier allows the development of a well-channelized internal drainage system.

Innovative ice cave monitoring techniques have been created in order to instrument the central part of an englacial conduit, preventing it to move because of water circulation and to freeze into the walls. Results are the first temperature and water pressure fluctuations recorded at 30 min frequency during the whole hydrological year inside an englacial system.

During the winter period, when the internal drainage system is inefficient, water levels rise up in the englacial conduits in response to positive air temperature and precipitation events with a few days of delay. On the contrary, during the summer period, when the internal drainage system is efficient, water level rises up in the englacial conduits synchronously with higher air temperature and precipitation events. In addition, during the winter period we observed reverse flow—water coming from the lower part of the internal system toward the upper part. Finally, presence of liquid water storage during the winter season was monitored.
Measuring Glacier Dry Calving with SAR Interferometry

Brian Moorman¹ (moorman@ucalgary.ca), Ken Whitehead², Allison Gunther³
¹University of Calgary, Geography, Calgary, Canada, ²SAIT, Calgary, Canada, ³Solas Energy Consulting, Calgary, Canada

The glaciers of the Canadian Arctic Archipelago are currently undergoing rapid retreat. There is considerable interest in the mechanisms leading to ice loss in this region, as these glaciers have been identified as being a significant contributor to rising sea levels. Unlike surface melting or direct calving into the ocean, little is known about the contribution of meltwater from dry calving. This is where ice breaks off steep glacier edges and melts in place at a greatly increased rate. This results in accelerated water contributions to the ocean for which there are no reliable estimates available. A measure of the location and discharge rate of dry calving is required to better model glacial contributions to sea level rise.

For this project we developed a methodology for estimating calving potential, using estimates of glacier velocity at the main calving faces, derived from SAR interferometry. This study uses Fountain Glacier on Bylot Island as a case study because of the extensive baseline data in the region. Specifically, the SAR data enabled the identification of calving faces and their activity level, the speed and direction of glacier motion and along with ancillary data discharge estimates of the glacier from the calving front. It is believed that this is a practical approach, which will allow for the estimation of mass loss through dry calving for specific glaciers and the identification of calving potential at a regional level.
Acclimation Potential of Polar Cod from the Rapidly Warming Arctic Ocean

Helen Drost¹ (helen.drost@dfo-mpo.gc.ca), Mandy Lo², Eddy Carmack¹, Tony Farrell², Nadja Steiner¹

¹Department of Fisheries and Oceans Canada, Sidney, Canada, ²University of British Columbia, Vancouver, Canada

The physics and biogeochemistry of the Arctic Ocean have changed significantly in the past century and are predicted to continue changing as rapidly. Missing, however, is a general knowledge on the thermal tolerance ranges for Arctic ectotherms and their acclimation potential, which are minimum knowledge requirements to accurately forecast the distributional patterns of marine species and their chances of survival in a changing environment. Thus, it is imperative to understand thermal optima, tolerance and acclimation potential of Arctic fishes to predict food web consequences with continued warming of the Arctic Ocean.

Polar cod (Boreogadus saida) are able to acclimate to different temperatures over time. We quantified acclimation potential using 3 methods including: the critical thermal maximum of 3 acclimation groups (0.5, 3.5, 6.5°C); the aerobic scope (AS) of similarly acclimated B. saida; and the heart rate of long term acclimated fish. A variety of compensatory responses to thermal acclimation were observed that would benefit B. saida in a warmer environment. These compensations include an increase in $T_{cmax}$, a $>2°C$ increase in the $T_{opt}$ window for AS, and a significant down regulation of heart rate.

Climate models that predict species distribution and survival rarely include plasticity of thermal tolerance. We are developing a comprehensive physiological limits and acclimation potential database of key Arctic marine species to help improve model predictions.
The cryopelagic Arctic gadids, *Boreogadus saida* and *Arctogadus glacialis*, occurs in North Eastern Greenland fjords and shelf areas, where they occupy the same habitats and have partly overlapping feeding niches. We have previously shown that populations of *B. saida* occupying fjords vs. shelf areas can be genetically discriminated at microsatellite loci suggesting that ecological, environmental, and/or spatial factors fuels the divergence. However, nothing is known about the population genetic structure of *A. glacialis* from this area. Here we tested whether replicated fjord vs. shelf population-pairs of *B. saida* and *A. glacialis*, respectively, show genome-wide differentiation. We compared divergence at a genome-wide panel of single nucleotide polymorphisms obtained by massively parallel sequencing of Restriction Site Associated DNA libraries (RADseq). Via machine learning approaches we firstly explored the genomic divergence within and between species, and secondly, we explored whether the footprint of the environment, ecology and life history, and spatial separation have resulted in parallel divergence in polygenic adaptive genomic traits. We discuss the results in light of how climate change may influence intra and interspecific divergence in these Arctic key-species.
Historical DNA Metabarcoding of Trematomid Fishes using Museum Samples

Franz Maximilian Heindler¹ (franzmaximilian.heindler@kuleuven.be), Bart Hellemans¹, Henrik Christiansen¹, Agnès Dettai², Anton P. Van de Putte³, Gregory E. Maes⁴, Filip A. M. Volckaert¹

¹KU Leuven, Laboratory of Biodiversity and Evolutionary Genomics, Leuven, Belgium, ²Muséum National d’Histoire Naturelle, Paris, France, ³Royal Belgian Institute of Natural Sciences, Brussels, Belgium, ⁴KU Leuven, Laboratory of Cytogenetics and Genome Research, Leuven, Belgium

The Southern Ocean hosts delicate and unique ecosystems. Despite its distance to densely populated areas, human influence includes direct impacts such as commercial fishing, tourism and research, as well as indirect impacts such as global warming and pollution. With the exception of fishing, the largest increase of these impacts occurred within the past 100 years. Unfortunately, the knowledge on biodiversity in support of management remains small. This study focuses on prey item and microbiome composition of members of the circumantarctic genus *Trematomus*, which are amongst the most abundant members of the Antarctic icefish community. We collected tissue, stomachs and guts from 400 specimens curated at the Natural History Museum London. Specimens were had been collected between 20 and 120 years ago, were fixed in formalin and later transferred to ethanol. A 450 bp fragment of the cytochrome c oxidase subunit I (COI) was amplified and sequenced for prey item identification in the stomach and a 313 bp region of the 16S gene to investigate microbiome composition in the gut system. We evaluated various protocols for the suitability to infer DNA information from historically formalin-fixed samples. Based on the best protocol, we identified interspecific prey and microbiome variation. Unlocking information from museum stored samples holds great potential for microevolutionary insights that will benefit efforts to prioritize conservation units in the Southern Ocean.
Characterization of Protein Turnover and Proteome Stability in Antarctic Fish

Sean Place\(^1\) (places@sonoma.edu)
\(^1\)Sonoma State University, Biology, Rohnert Park, United States

How susceptible are endemic fauna to the rapid changes in environmental parameters? Are stenothermal animals more at risk of global climate change impacts as a consequence of their evolutionary history? These are critical questions limited by a lack of basic understanding with regards to the drivers of divergence in the cellular stress response that has occurred in many endemic species of the Southern Ocean. The focus of this study is to understand how changes in seawater temperature impact protein homeostasis in Antarctic fishes. Previous studies have reported a permanent activation of the heat shock response and have suggested this change in regulation is related to an imbalance in protein folding efficiency at sub-zero temperatures in these fishes. Thus, these endemic fish may, at some level, benefit by the increase in sea surface temperatures expected to accompany global climate change. However, if protein folding efficiency does not increase with warming seawater then that would suggest the disruption is genetically hardwired. In this study we utilize fluorescent non-canonical amino acid tagging to assess the impact of increased seawater temperature on protein turnover in the proteome of Antarctic notothenioid fish acclimated to +4 °C for up to a month. We further link the changes in rates of protein synthesis and degradation to tissue specific changes in energy budgets in order to gain insight into the energetic cost of maintaining a stable proteome in a warming ocean.
Metabolic Capacity to Acclimate to Multiple Stressors in an Antarctic Fish

Anne Todgham¹ (todgham@ucdavis.edu), Brittany Davis²
¹University of California Davis, Animal Science, Davis, United States, ²University of California Davis, Davis, United States

Although the Southern Ocean is experiencing some of the fastest rates of ocean change, few studies have explored how Antarctic fishes may be affected by co-occurring warming and acidification, and even fewer have examined early life stages. To date, no studies have characterized potential trade-offs in physiology and behavior in response to projected multiple climate change stressors on Antarctic fishes. Juvenile Trematomus bernacchii were exposed to three PCO₂ treatments at two temperatures. After 2, 7, 14, and 28 days, metrics of physiological performance including cardiorespiratory function, metabolic rate, and cellular enzyme activity were measured. Behavioural responses, including scototaxis, activity, and escape response were assessed after 7 and 14 days. Elevated PCO₂ independently had little impact on either physiology or behaviour in rockcod, whereas warming resulted in significant changes across acclimation time. Increased physiological costs were accompanied by behavioural alterations including increased dark zone preference, reduced activity and reduced escape time. After 28 days, fish demonstrated a degree of temperature compensation; however, temperature compensation was only evident in the absence of elevated PCO₂. Our results provide evidence of stressor-induced energetic trade-offs in physiology and behaviour that may be an important mechanism leading to vulnerability of Antarctic fishes to future ocean change.
Reproduction in Parachaenichthys charcoti (Bathydraconidae) in West Antarctica

Manuel Novillo1,2 (jmanuelnovillo@gmail.com), Eugenia Moreira3, Gustavo Macchi4,5, Esteban Barrera Oro1,2,6
1Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Buenos Aires, Argentina, 2Museo Argentino de Ciencias Naturales 'Bernardo Rivadavia', Ictiología, Buenos Aires, Argentina, 3Instituto Antártico Argentino, Biología, Buenos Aires, Argentina, 4Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Mar del Plata, Argentina, 5INIDEP, Ecología Reproductiva, Mar del Plata, Argentina, 6Instituto Antártico Argentino, Biología, Buenos Aires, Argentina

The reproductive biology of dragon fishes is poorly understood and particularly in P. charcoti (PCH). A histological analysis of PCH ovaries together with reproductive effort data using fish caught at Potter Cove, South Shetland Islands (SSI), are compared with data reported for the South Georgia’s congener P. georgianus (PGE). In gravid females of PCH, GSI of 16-31%, mature oocytes of 1.8-3.9 mm and total fecundity (TF) of 9790-18937 oocytes/individual (mean 13216) were recorded. The histology of the ovaries confirmed the common characteristics of the suborder Notothenioidei observed macroscopically, i.e., two distinct batches of oocytes, one in previtellogenic stage, and the other in vitellogenesis and likely to be released in the current season. A longer incubation period of PCH compared to PGE is associated to colder waters at the SSI. Our sampling and reproductive effort data and the known nesting behavior of PCH, everything recorded at Potter Cove, suggest that this species spawns nearshore in summer, from late Dec to Feb. Spawning periods of both congeners differ from those reported for other notothenioids in the Seasonal Pack-ice Zone, suggesting divergence in some aspects of the life strategies in the genus Parachaenichthys. Likewise, although there are no substantial differences between PCH and other notothenioids regarding gonadal development, this genus shows distinct features in its reproductive strategies (e.g. higher TF) in comparison with other bathydraconids.
Sources of Ice Crystals and Cloud Droplet in Orographic Mixed-Phase Clouds

Ulrike Lohmann\(^1\) (ulrike.lohmann@env.ethz.ch), Alexander Beck\(^1\), Olga Henneberg\(^1\), Jan Henneberger\(^1\), Larissa Lacher\(^1\)
\(^1\)ETH Zurich, Zürich, Switzerland

Knowledge about the phase and longevity of mixed-phase clouds (MPCs) is important for the radiative balance and the hydrological cycle. The co-existence of cloud droplets and ice crystals in MPCs is thermodynamically unstable due to the lower saturation vapor pressure over ice than over liquid water. Thus, MPCs are expected to quickly glaciate, as ice crystals grow at the expense of cloud droplets. In-situ measurements have, however, shown that MPCs can be persistent. As will be shown in the talk, this was confirmed by km-scale model simulations pointing to the dominant role of updraft velocities as a source of cloud droplets.

In addition, the ice crystal number concentration (ICNC) in MPCs regularly exceeds the ice nucleating particles (INP) concentration by several orders of magnitude. Therefore, additional sources of ice crystals, e.g. secondary ice production and ice outside the cloud, have to contribute significantly to ICNCs in MPCs. Here, we will present results estimating the various ice crystal sources. Measurements of cloud droplets and ice crystals, obtained with our digital holographic imager HOLIMO, and INP measurements taken with our continuous flow diffusion chamber, were performed at 3580 m asl at the Jungfraujoch (JFJ) in the Swiss Alps. To estimate the importance of blowing snow, in-situ observations of cloud particles were taken at different heights above ground taken at the Sonnblick observatory in Austria.
Recent Observations of Arctic INP and their Variation over the past 500 Years

Markus Hartmann$^1$ (markus.hartmann@tropos.de), Sandra Brügger$^2$, Xianda Gong$^1$, Hartmut Herrmann$^3$, Manuela van Pinxteren$^3$, Julia Schmale$^4$, Margit Schwikowski$^5$, Alexander Vogel$^5$, André Welti$^1$, Heike Wex$^1$, Sebastian Zeppenfeld$^3$, Frank Stratmann$^1$

$^1$Leibniz-Institute for Tropospheric Research, Experimental Aerosol and Cloud Microphysics, Leipzig, Germany, $^2$University of Bern, Institute of Plant Sciences, Bern, Switzerland, $^3$Leibniz-Institute for Tropospheric Research, Atmospheric Chemistry, Leipzig, Germany, $^4$Paul Scherrer Institute, Laboratory of Atmospheric Chemistry, Villingen, Switzerland, $^5$Paul Scherrer Institute, Laboratory of Environmental Chemistry, Villingen, Switzerland

Measurements of ice nucleating particle (INP) concentrations in the Arctic are scarce, and historical records did not exist until now. Here, present-day observations onboard the RV Polarstern (PASCAL cruise from May to July 2017 in the area around Svalbard up to 83.7°N) and ice core-derived concentrations for the past 500 years are presented.

During PASCAL, the INP concentrations were measured online with the Spectrometer for Ice Nuclei (SPIN; DMT), and determined from filter samples by application of freezing array techniques. By combining these methods, the whole temperature regime relevant for mixed phase clouds is covered. The ice cores originate from Summit (Greenland) and Lomonosovfonna (Svalbard), and cover a time range from 1457 to 1989 AD and 1480 to 2001 AD, respectively. The ice core samples were analyzed by the freezing array techniques only.

The contribution of local sources to present-day INP is assessed by comparing the INP populations,
(a) from different sources such as the sea surface micro layer, deeper sea water, snow and fog,
(b) the correlation to meteorological parameters, and
(c) the use of back trajectory modelling. The sensitivity of the historical INP concentrations to other ice core-derived parameters is investigated to identify potential INP sources.

These datasets can be used in climate models to study the role of INP in the observed Arctic Amplification. The works were carried out in the framework of the DFG-funded TR 172 (Arctic Amplification).
Variations in Ice Nucleating Particle Concentrations at Four Arctic Locations

Heike Wex¹ (wex@tropos.de), Lin Huang², Hayley Hung³, Rita Traversi⁴, Rebecca Sheesley⁵, Claire Moffett⁵, Tate Barrett⁵, Rossana Bossi⁶, Markus Hartmann¹, Frank Stratmann¹
¹Leibniz Institute for Tropospheric Research, Experimental Aerosol and Cloud Microphysics, Leipzig, Germany, ²Environment & Climate Change Canada, Climate Research Division, Toronto, Canada, ³University of Toronto Scarborough, Department of Physical and Environmental Sciences, Toronto, Canada, ⁴University of Florence, Department of Chemistry ’Ugo Schiff’, Florence, Italy, ⁵Baylor University, Department of Environmental Science, Waco, United States, ⁶Aarhus University, Department of Bioscience - Arctic Research Centre, Roskilde, Denmark

Filter samples collected at four Arctic measurement stations, Alert, Barrow, Ny-Ålesund and Villum were analyzed with respect to number concentrations of ice nucleating particles (N\textsubscript{INP}). Measurements were done following the method proposed by Conen et al. (2012), examining immersion freezing. The obtained temperature dependent freezing curves were used to derive N\textsubscript{INP}.

For Ny Alesund, samples from spring and summer months were examined, while a yearly coverage existed for the other stations. Differing values of N\textsubscript{INP} were observed during the year, and in general during summer and fall, particles were more ice active than during winter and early spring, indicating that different sources of ice nucleating particles contributed to the pan-arctic area, their influence varying with season and site. The highest values determined for the Arctic samples were comparable to N\textsubscript{INP} determined from precipitation samples collected in North America and Europe (Petters & Wright 2015), but the lowest values were more than two orders of magnitude lower. Ice nucleating particles have an influence on Arctic cloud glaciation and hence influence Arctic warming. This study reveals open questions and suggests future pathways concerning the examination of Arctic ice nucleating particles.

Literature:
Arctic Mixed-phase Cloud Sensitivity to Surface Forcing and Aerosol Perturbation

Gesa Eirund¹ (gesa.eirund@env.ethz.ch), Anna Possner², Ulrike Lohmann¹
¹ETH / IAC, Zurich, Switzerland, ²Carnegie Institution for Science, Stanford, United States

Arctic clouds play a key role in the radiative balance of the Arctic region. In summer, the reflection of the incoming radiation dominates, while during the rest of the year the absorption and emission of longwave radiation prevails, causing a warming effect at the surface. The radiative properties of these clouds are strongly linked to the relative abundance of both phases (liquid and ice), which in turn is governed by a multitude of processes operating in conjunction across a wide range of spatial scales. The large-scale dynamical forcing, surface processes as well as the ambient aerosol concentration all impact mixed-phase cloud (MPC) amount and phase partitioning. Up to now, the persistence as well as the formation of Arctic MPCs remain largely unclear and their representation in models of all complexities poses a considerable challenge.

In this study we focus on the relative importance of different aerosol conditions on MPC formation and persistence in the Arctic. To address this issue, we perform COSMO-LES simulations (Possner et al., 2017) and designed a case study for the ACCACIA campaign in March 2013 in the European Arctic (Young et al., 2016). In our setup we successfully simulate a MPC with properties close to observations. In several sensitivity studies we explore the mechanisms in MPCs across different temperature ranges and aerosol loadings. Moreover, we contrast these effects in MPCs over ocean and sea ice.
How Important Are Local Marine Sources for Arctic Mixed-phase Clouds?

Luisa Ickes\textsuperscript{1,2}, Corinna Hoose\textsuperscript{2}, Annica M. L. Ekman\textsuperscript{1} (annica@misu.su.se)
\textsuperscript{1}Stockholm University, Department of Meteorology, Stockholm, Sweden, \textsuperscript{2}Karlsruhe Institute of Technology, Institute of Meteorology and Climate Research, Karlsruhe, Germany

Arctic low-level clouds are highly sensitive to microphysical processes, which can either sustain or break down the unstable mixed-phase state and thereby determine the longevity of the clouds and their radiative impact. They are influenced by the availability of aerosol particles, which can act as ice nuclei (IN) or cloud condensation nuclei (CCN). Potential sources of aerosols in the pristine Arctic include local marine aerosol emissions and long-range transport, but it is not very well known what governs the Arctic background aerosol concentration and its variability. Therefore, it is important to quantify Arctic aerosol concentrations and the associated impact on cloud microphysics.

We derive characteristic vertical profiles of CCN and IN for two different situations in the Arctic and investigate the influence on the cloud microphysics and the evolution of a mixed-phase Arctic cloud. We compare a situation where the aerosol concentrations are predominantly governed by local sources (emitted at the surface) with one dominated by long-range transport (introduced above the boundary layer inversion). To compile the vertical profiles for different aerosol scenarios we use field measurements in combination with regional modeling using the regional model COSMO-ART (Vogel et al., 2009). The influence of the different vertical aerosol profiles on the cloud microphysics is investigated using the LES model MIMICA (Savre et al., 2014).
Understanding the Sources of Arctic Biological Ice Nucleating Particles

Jessie Creamean¹,² (jessie.creamean@noaa.gov), Amy Solomon¹,², Regina Hanlon³, David Schmale⁵, Rachel Kirpes⁶, Kerri Pratt⁶, Nicholas Spada⁷, Jessica Cross⁶, Robert Pickart⁷, Vaughan Phillips⁸
¹University of Colorado Boulder, Boulder, United States, ²National Oceanic and Atmospheric Administration, Boulder, United States, ³Virginia Tech, Blacksburg, United States, ⁴University of Michigan, Ann Arbor, United States, ⁵University of California, Davis, United States, ⁶National Oceanic and Atmospheric Administration, Seattle, United States, ⁷Woods Hole Oceanographic Institution, Woods Hole, United States, ⁸Lund University, Lund, Sweden

The Arctic is warming at an alarming rate, yet the wide range of processes that contribute to the surface energy balance are not well constrained. The effects of clouds and aerosols on the extent of sea ice is particularly not well represented in models. Specifically, relatively little knowledge exists regarding aerosols that serve as ice nucleating particles (INPs) and their subsequent impact on Arctic cloud ice formation. In general, biological aerosols such as bacteria, algae, and phytoplankton have been hypothesized to serve as some of the most efficient INPs in the Arctic region. The Arctic Ocean is a large vessel for biological productivity, but such productivity is highly variable depending on time of year and location. Here, we present results from ice nucleation studies in a relatively polluted coastal location in Prudhoe Bay during the spring and from a shipborne expedition through the Bering Strait and Chukchi Sea during the following summer of 2017. Prudhoe Bay is largely influenced by local oil extraction activities, while the marine measurements were conducted in a cleaner oceanic environment. INP concentrations and onset freezing temperatures were found to widely vary, but were highest in both locations when air masses originated from exposed ocean water from fresh sea ice melt and near phytoplankton blooms and coastal upwelling. Overall, these results demonstrate the crucial role the ocean plays as a source of cloud nuclei in disparate Arctic locations.
The Changing form of Antarctic Biodiversity

Steven L Chown¹, ACE Expedition Members¹ (steven.chown@monash.edu)
¹Monash University, Melbourne, Australia

Antarctic biodiversity was once thought to be poor, recent and isolated. Over the last two decades, this perception has been wholly altered. Both in marine and terrestrial systems, diversity is greater, with more structure and regular connections, both among sites and to areas beyond the polar front or Southern Ocean, than previously thought. Molecular approaches have been instrumental in revealing the substantial structure and dynamics of Antarctic biodiversity. But so has interdisciplinary work, combining new surveys, modern and palaeoclimatic information, data from marine and terrestrial sediment cores, and novel forms of analyses. In this talk, an overview is provided of these developments, how they are changing fundamental understanding of the biodiversity of the region and its evolution, and what they imply for conservation. Particular emphasis is given to work demonstrating links across the entire Antarctic and Southern Ocean regions, including the Southern Ocean islands.
Both Arctic and Antarctic ecosystems are affected by global change drivers, such as elevated temperatures and changing precipitation regimes. These effects can be investigated by experiments and research along gradients. In this presentation the results of our long-term warming experiments in sub-arctic Sweden (since 2000) and the Antarctic Peninsula (since 2004) will be presented and a bi-polar comparison will be made of the warming effects on the diversity and functioning of the various components of the food web, including soil micro-organisms, soil arthropods, cryptogams and vascular plants. Moreover, we will also compare the results of our geographical gradient studies with those of the experiments in order to investigate if geographical temperature gradient studies can be used as an analogue for experimental studies.

Can Antarctic Lichens Acclimatise to Changes in Temperature?

Claudia Colesie1 (claudia.colesie@slu.se), Burkhard Büdel2, Vaughan Hurry3, Allan Green4,5
1Swedish University of Agricultural Sciences (SLU), Forest Genetics and Plant Physiology, Umeå, Sweden,
2University of Kaiserslautern, Plant Ecology and Systematics, Kaiserslautern, Germany, 3Swedish University of
Agricultural Sciences (SLU), Forest Genetics and Plant Physiology, Umea, Sweden, 4Universidad Complutense,
Departamento de Biologia Vegetal II, Farmacia Facultad, Madrid, Spain, 5University of Waikato, Department of
Biological Sciences, Hamilton, New Zealand

The Antarctic Peninsula, a tundra biome dominated by lichens and bryophytes, is an ecozone undergoing
temperature shifts. Such changes may demand a high physiological plasticity of the local species in order for
them to maintain their role as key drivers in this habitat. We investigated how increasing temperatures vary
the physiological responses of lichen species with different ecological response amplitudes. The main goal was
to find out whether thermal acclimation occurs as biological feedback which would ameliorate the effects of
temperature changes. All species tested at 5, 15 and 22°C were negatively affected, with 15°C representing the
upper thermal limit for two endemic species. A widespread lichen species was able to recover its homoeostasis
by a consistent increase in net photosynthesis. As a result, we postulate that any acclimation processes in
lichen are species specific. This, together with the high degree of response variability and sensitivity to
temperature in different species that co-occur spatially close, complicates predictions regarding future species
composition. Our results suggest that species with a broad ecological amplitude may be favoured with ongoing
changes. Such community shifts could lead to regional-scale biotic homogenization, which could alter
ecosystem functioning and productivity in Antarctic ice-free habitats. The consequences for the conceptual
view of physiological acclimation are highlighted and future research perspectives discussed

Drivers of Soil Bacterial Community Structure in Antarctic Water Tracks

Kelli Feeser¹ (kfeeser@unm.edu), David Van Horn¹, Jordan Okie², Becky Ball², Andrew Fountain³, Michael Gooseff⁴, Joseph Levy⁵, Maciej Obryk³
¹University of New Mexico, Biology, Albuquerque, United States, ²Arizona State University, Tempe, United States, ³Portland State University, Portland, United States, ⁴University of Colorado at Boulder, Boulder, United States, ⁵Colgate University, Hamilton, United States

Water availability is a key limitation of ecosystem function in the McMurdo Dry Valleys, Antarctica. Climate change in this region is projected to alter precipitation and promote melting of ground ice, resulting in the creation and expansion of water tracks that transport water, solutes, and heat downslope. We utilized surveys and perturbation experiments to understand the microbial communities associated with two water tracks. In the first track, diversity (Chao1; means of 4438/2593, P < 0.005) and abundance (16S copy number; means of 20055/10266, P = 0.076) were higher inside the track, corresponding to decreased salinity (EC; means of 59/307 µS, P < 0.001). Salinity did not vary significantly across the second track, although in the middle reach, diversity and abundance decreased inside where salinities were elevated (Chao1; means of 1638/4223, P < 0.001; 16S copy number; means of 1462/8522, P = 0.017). Overall, salinity was negatively correlated to diversity (r = -0.43, P < 0.001) and abundance (r = -0.32, P = 0.003). Experiments designed to simulate changes in water and solutes associated with the expansion of water track systems into dry soils suggested that lowering moisture and raising salt content increase the abundance of Acidobacteria and decrease Proteobacteria. These results highlight the sensitivity of endemic dry soil communities to future climate change and potentially provide insights into the limits of life with applications to astrobiology.
Physiological and Genomic Responses of Chlorella to UVR across a Global Gradient

Chiew-Yen Wong1,2 (wongchiewyen@imu.edu.my), Aniqah Zulfa Abdul Latif3, Wan-Loy Chu4, Jeannette W.S. Lai5,6, Sze-Wan Poong3, Phaik-Eem Lim5, Siew-Moi Phang5,6, Peter Convey7

1International Medical University, School of Health Sciences, Kuala Lumpur, Malaysia, 2University of Malaya, National Antarctic Research Center, Kuala Lumpur, Malaysia, 3International Medical University, School of Postgraduate Studies, Kuala Lumpur, Malaysia, 4International Medical University, Institute for Research, Development and Innovation (IRDI), Kuala Lumpur, Malaysia, 5University of Malaya, Institute of Ocean & Earth Sciences, Kuala Lumpur, Malaysia, 6University of Malaya, Institute of Biological Sciences, Kuala Lumpur, Malaysia, 7British Antarctic Survey, High Cross, Madingley Road, United Kingdom

Changes in the global environment, which resulted in increased UVR fluxes can have far-reaching impacts on microalgae, affecting their physiological processes and productivity. The present study investigated the physiological response of Chlorella strains isolated from the Antarctic, Arctic, temperate and tropical regions to UVR stress. Transcriptomic approach was used to investigate genetic responses of Chlorella to UVR stress. Chlorella originating from different latitudes exhibited different growth trends and photosynthetic performance. UVB inhibited the growth of the both polar Chlorella, but enhanced the growth of temperate and tropical Chlorella, compared to those exposed to PAR alone. Chlorella from polar regions appeared to be more responsive towards the damaging effects of UVB while tropical Chlorella tended to have higher tolerance towards UVB stress. However, the cellular contents of carotenoids and chl-a increased under UVB stress in both polar Chlorella while the pigment contents decreased in the tropical and temperate strains. Differentially expressed genes, relating to the fatty acid degradation, amino acid metabolism, starch metabolism and peroxisome pathways, suggest that conservation and remobilisation of energy resources, maintenance of newly synthesised protein and inhibition of protein degradation, ensuring membrane lipid homeostasis and regulating antioxidative mechanisms, are important in the acclimation strategies expressed in response to UVR stress.
PAIX: Opening a New Window into the Universe

Meriem Chadid¹ (chadid@unice.fr)
Université Nice Sophia Antipolis, Nice, France

PAIX, the first robotic multi-color photometer Antarctica project, has been successfully launched during the polar night 2007. This ongoing program gives a new insight to cope with unresolved stellar enigmas and stellar oscillation challenges with a great opportunity to benefit from an access to the best astronomical site on Earth, Dome C. PAIX achieves astrophysical measurement time-series of stellar fields, challenging photometry from Space. A continuous and an uninterrupted series of multi-color photometric observations has been collected each polar night - 150 days - without regular interruption, Earth’s rotation effect. PAIX shows the first multiband photometric light curves from Antarctica and the first steep for the Astronomy in Antarctica giving new insides in remote polar observing runs and robotic instruments towards a new technology.
Developing a Spectrograph for Observing the Atmospheric Emission in K-dark Band

Kohji Tsumura1 (tsumura@astr.tohoku.ac.jp), Takashi Ichikawa2, Yoshifusa Ita2
1Tohoku University, Frontier Research Institute for Interdisciplinary Science, Sendai, Japan, 2Tohoku University, Astronomical Institute, Sendai, Japan

We are developing a spectrograph for observing the spectrum of the atmospheric emission in the K-dark band (~2.4 µm) from the Antarctica.

Low atmospheric foreground environment can be obtained at the K-dark band at the Antarctica because there is a “window” of the dense forest of OH emission lines and the low temperature of the atmosphere (~200 K). Although the absolute brightness of the atmospheric emission at the K-dark band from the Antarctica is several tens of times brighter than the zodiacal light (Phillips et al. 1999), it is still beneficial for observations of diffuse radiations such as the zodiacal light and the extragalactic background light (EBL). Spatial structures with arcminute to degree scale of the atmospheric emission and its time variations are critical for subtracting the atmospheric foreground for the study of EBL.

To validate the atmospheric foreground environment for the EBL study, we are planning to observe the spectrum, spatial structure, and time variance of the atmospheric emission in the K-dark band from the Antarctica. We have developed an Antarctica-proof near-infrared camera in Tohoku University, and it will be a 5-cm aperture telescope with 2-degree FoV by putting a small lens on the camera. To obtain a simple spectrograph, we are developing a linear-variable filter (LVF) covering 2.2-2.55 µm with Δλ~0.02 µm, which will be installed in a filter wheel in the camera. We want to bring the camera with the LVF to the Antarctica by 2020.
Opening the Dynamic Infrared Sky from Antarctica

Anna Moore\textsuperscript{1} (anna.moore@anu.edu.au)
\textsuperscript{1}Australian National University, Research School of Astronomy and Astrophysics, Canberra, Australia

While optical and radio transient surveys have enjoyed a renaissance over the past decade, the dynamic infrared sky remains virtually unexplored. The infrared is a powerful tool for probing transient events in dusty regions that have high optical extinction, and for detecting the coolest of stars that are bright only at these wavelengths. The fundamental roadblocks in studying the infrared time-domain have been the overwhelmingly bright sky background (250 times brighter than optical) and the narrow field-of-view of infrared cameras (largest is VISTA at 0.6 sq deg). To address this challenge, we propose a low risk, economical and agile instrument located in the high polar regions to take advantage of the low thermal sky emission in the 2.5 micron region in particular. Such an instrument has the ability to observe the entire hemisphere sky to a depth of the VISTA VHS survey every 4 hours.
An all-sky camera KunLun Cloud and Aurora Monitor (KLCAM) was installed at Dome A, Antarctica in January 2017 and has been working automatically through the austral winter. The unattended KLCAM aims for long-term monitoring for site testing and has collected tens of thousands of images used to evaluate usable observing time and optical sky background at Dome A. We have analyzed the data and developed methods to automatically classify the cloud cover and aurora contamination to the night sky. We present the results on the site characteristics in 2017.
Introduction of Chinese Antarctic Optical Telescopes

Zhengyang Li1 (zyli@niaot.ac.cn), Xiangyan Yuan1, Xuefei Gong1
1Nanjing Institute of Astronomical Optics & Technology, National Astronomical Observatories, CAS, Nangjing, China

The Antarctica plateau is widely considered to be an excellent astronomical site for the superb seeing conditions. The preliminary site testing performed since the beginning of 2008 shows that Antarctic Dome A is an excellent astronomical site for observing wavelengths ranging from visible to infrared and sub-millimetre. In polar nights, the in-situ Antarctic telescopes manage to continuous observe for three months, which is quite suitable for the transits detection and time domain astronomy. Several Chinese wide field Antarctic telescopes have been built. The first generation is Chinese Small Telescope Array known as CSTAR, which is composed of four identical telescopes with 145mm entrance pupil, 20 square degrees FOV. CSTAR was fixed to point at the South Pole, and mainly used for variable stars detection and atmosphere extinction measurement, and deployed on Antarctica in 2008 and its automatic operation continued for four consecutive winters. The second generation is three Antarctic Survey Telescopes (AST3), with 500mm entrance pupil, 8.5 square degrees FOV can precisely pointing and tracing. AST3-1 and AST3-2 were respectively mounted on Antarctic plateau in 2012 and 2015, fully remotely controlled for supernovae survey, exoplanets search and GW counterpart photometry.
Modeling Ice Birefringence from SPICEcore for ARA Stations

Jennifer Cooper\textsuperscript{1} (jrc323@cornell.edu), ARA Collaboration\textsuperscript{1}
\textsuperscript{1}University of Kansas, Lawrence, United States

The Askaryan Radio Array (ARA) is an in-progress ultra-high energy (>10^{17} \text{ eV}) cosmic neutrino detector composed of 37 radio receiver stations located \textasciitilde 200 meters below the surface in the ice at the South Pole. Interactions of neutrinos with the ice generate radio pulses that can be detected and observed in the 150 - 850 MHz range through the Askaryan Effect. The structure of the ice plays an important role in signal propagation between production and measurement point. The nearby South Pole Ice Core (SPICEcore) has been used to study changes in the Earth’s climate from an ice core drilled to a depth of 1751 meters. This core has ice grain orientation data, which can be related to the birefringence properties of ice in the vicinity of ARA. Here we model an incoming signal propagating through a 3-axis ice crystal bulk orientation from SPICEcore data for a range of depths relevant to ARA stations, and compare with ARA data.
The exceptionally dry and cold Antarctic climate is ideal for CMB observation. I will discuss lessons learned over the past 20 years and prospects for future searches for primordial gravitational waves in CMB polarization.
The rapid follow-up of transient sources will become an increasingly important aspect of astronomy over the next decade. This is primarily driven by new facilities coming on-line, such as LSST, more sensitive gravitational wave detectors, and precursors to SKA. Positioning a telescope in Antarctica has the obvious advantage that, during mid-winter at least, the sun has no effect on whether a source can be observed. Cloud permitting, observations can commence rapidly and continue uninterrupted for weeks, producing a higher quality and more uniform dataset than a network of telescopes from a lower latitude. There are a host of other advantages such as low-scintillation noise, low-airmass variations, low aerosols, and low & stable water vapor. There are also some more subtle advantages such as lower variations in CO$_2$ content. On the negative side, aurora need to be taken into account. On the whole, Antarctica offers significant improvements for precision photometry and spectroscopy, making it an excellent location for following up transient sources.
Photometric Monitoring of Proxima Centauri at the Chinese Zhongshan Station

Peng Jiang¹ (jiangpeng@pric.org.cn), Huigen Liu², Fujia Du³, Jian Wang⁴, Zhengyang Li³, Xiaoyan Li³, Haiping Lu³, Minghao Jia⁴, Awiphan Supachai⁵

¹Polar Research Institute of China, Shanghai, China, ²Nanjing University, Nanjing, China, ³Nanjing Institute of Astronomical Optics & Technology, National Astronomical Observatories, CAS, Nanjing, China, ⁴University of Science and Technology of China, Hefei, China, ⁵National Astronomical Research Institute of Thailand, Chiang Mai, Thailand

Proxima Centauri is known as the closest star from the Sun. Recently, radial velocity observations revealed the existence of an Earth-mass planet around it, with an orbital period of 11 days. If the planet transits, it would be interesting to probe its radius, internal compositions and atmospheric properties. We took a photometric monitoring campaign of Proxima Centauri using the Bright Star Survey Telescope at the Zhongshan Station in Antarctica. A candidate transit event occurring on September 8th, 2016, is identi
ed tentatively. Its transit epoch, 2,457,640.1990±0.0017 HJD, is consistent with the predicted ephemeris based on RV orbit in a 1σ con
idence interval. Time-correlated noise is pronounced in the light curve of Proxima Centauri, affecting detection of transits. The candidate transit event reported in this work, has a con
Kipping et al. (2017) reported two candidate transit events of Proxima Centauri b, observed by the Microvariability and Oscillation of Stars space Telescope in 2014 and 2015, respectively. The midtransit time of our detection is 138 minutes later than that predicted by their transit ephemeris. If all the transit events are real, the misalignment of the epochs plausibly suggests transit timing variations of Proxima Centauri b induced by an outer planet in this system. We plan to perform follow-up observation of Proxima Centauri in next Polar night at the Chinese Kunlun Station in Antarctica.
Thailand has established a Polar Sciences Committee, under the Information Technology Foundation under the Initiative of Her Royal Highness Princess Maha Chakri Sirindhorn and has become an associate member of SCAR since August 2016. Due to the long and continuous 6 months dark clear winter sky and the stable atmospheric condition with excellent sky seeing, Polar region (Arctic/Antarctic Plateau) is a perfect place for astronomical observations. Some Astronomy and related sciences research proposals initiated by NARIT have been planned to be performed in Polar region with some collaborative institutes.

NARIT signed the MoU with the Yunnan Observatories (YNO) since February 2007 and the Polar Research Institute of China (PRIC) since April 2016. The study on the evolution of close binary systems was closely collaborated with YNO. Several deep contact binary systems were observed and analyzed using observational data from optical telescopes at Dome A in Antarctica. Result from the collaborative meeting, NARIT and PRIC agree to cooperate on several fields of astronomical research, for example, on the search for exoplanets, astroseismology of oEA and other pulsating stars, the study of the growth of supermassive black holes and co-evolution of host galaxies etc. Other related sciences such as Jupiter’s and Earth’s aurora activities, latitude survey project etc. will also be discussed.
Neutron monitors are ground-level detectors of cosmic ray induced atmospheric secondary particles (mostly neutrons) in the GeV regime. The neutron monitor standard design (NM64) minimizes detector response to neutrons below $\sim 10 \text{ MeV}$ produced by cosmic ray interactions in the ambient medium. Bare detectors or simply “bares”, which lack the lead and polyethylene of NM64 detect such neutrons and therefore respond on average to cosmic rays of lower energy. The array of NM64 and bares at the South Pole has been used for many years to measure SEP spectra relying primarily on relative response functions derived from a single latitude survey in 1976. We have recently completed analysis of a second survey from Nov, 1995 to Feb, 1996 from three bares operated together with a 3NM64. The solar modulation conditions in 1995 and 1976 were remarkably similar but the results from the 1995-6 survey differ significantly from the interpretation of the 1976 survey most commonly used for the determination of SEP spectra. We present results from a third survey from Nov, 2009 to Apr, 2010 with two bares that are now installed at the South Pole. A significant correction to the 2009-10 data due to highly different modulation conditions, and implications for interpretation of SEP spectra will be discussed.

Supported in part by Thailand Research Fund grants MRG6080086 and RTA5980003.
ITM (International Telescope Maffei) Improvements: A New Robotic Interface

Jean Marc Christille¹ (jeanmarc.christille@gmail.com), Yuri De Pra², Daniele Tavagnacco³, Stefano Sartor³, Maurizio M. Busso⁴, Albino Carbognani¹, Marco Bagaglia⁵, Giuliano Nucciarelli⁶

¹Fondazione Clément Fillietroz - ONLUS, Nus, Italy, ²CNR, Perugia, Italy, ³Astronomical Observatory of Trieste, Trieste, Italy, ⁴University of Perugia, Physics and Geology, Perugia, Italy, ⁵University of Perugia, Physics and Geology, Perugia, Italy

IRAIT-ITM is a s a f/21.16 Cassegrain-like reflector with two Nasmyth foci and a 0.8m parabolic primary mirror and a wobbling secondary mirror suitable for the specific techniques for mid and near IR but is also suitable for observations in the visible spectrum. During these first ten years of activity several modification has been done in order to provide a more robust control system in terms of hardware and software, using new technologies and materials. We present the status of the project ITM (International Telescope Maffei) formerly Irait (International Robotic Antarctic Infrared Telescope), that is located at Dome C in the Italo-French Concordia station and hosted by PNRA (Programma Nazionale di Ricerche in Antartide) and CNR (Consiglio Nazionale delle Ricerche). Managing a robotized telescope in Antarctica is not a trivial job. A thermal excursion about more than 70°C during the year with minimal peak around -84°C and a mean pressure of 630 hPa are not the best conditions to deal with for a telescope which goal is to perform continuous observations. In this presentation we want to present all the hardware/software features provided during this period of activity in order to achieve a remote continuous complete monitoring and control. The management system, basing on rts2 open software, has been fully customized for our altazimuthal mount. The first rts2 webapp has been released for a remote VPN management of all devices connected to the telescope.
Neutron monitors are ground-level detectors of cosmic ray-induced atmospheric secondary particles (mostly neutrons) employed worldwide to study variations in the flux of galactic cosmic rays and solar energetic particles in the GeV regime. Proper geographic distribution of the monitors is critical due to two characteristics of a particular location resulting from the geomagnetic field. One is the geomagnetic cutoff, or minimum primary particle energy that can reach the location, and the other is asymptotic direction - a rather specific direction outside the magnetosphere from which the primary particles must come to reach the location. Locations near the auroral zones are particularly important for observation of low energy but highly anisotropic solar energetic particles. In the late 1990's an informal collaboration of station operators known as Spaceship Earth was formed to coordinate observations from this critical region. Primarily due to retirement of several key people it is necessary to restructure this collaboration; some preliminary steps have been taken. The South Pole NM64 and Bares are now being operated by the University of Wisconsin, River Falls. Move of the McMurdo monitor to the South Korean station at Jang Bogo should be complete in 2018. A partial move and common data taking in 2016 provide for continuity of data. We are continuing to search for opportunities to keep the other Spaceship Earth monitors running, but a complete path forward has not yet emerged.
Following the first observation of an astrophysical high-energy neutrino flux with the IceCube observatory in 2013, planning for a next-generation neutrino telescope at the South Pole - IceCube-Gen2 - is under way. Instrumenting 5 - 10 km$^3$ of the deep clear ice with up to 15,000 sensors, the envisioned detector will significantly expand the sensitivity both towards high and low neutrino energies. The sensors, so-called digital optical modules (DOMs), record the Cherenkov light emitted by charged secondaries created in the interaction of neutrinos in the ice, allowing the reconstruction of the energy and direction of the original particle. Apart from the larger volume, a significant increase in sensitivity and reconstruction precision is anticipated to be achieved by advanced optical module technology. The devices currently under development, include the modernization of the conventional IceCube DOM as well as new concepts featuring increased sensitive areas, homogeneous angular acceptance, UV sensitivity, directional information as well as reduced sensor self-noise. This contribution, presented on behalf of the IceCube-Gen2 collaboration, will introduce the new module concepts and introduce the planned detector infrastructure and readout scheme.
Recently funded by NASA’s Explorer Program, the Galactic ULDB Spectroscopic THz Observatory (GUSTO) will dramatically improve our understanding of the Universe by probing the topology and ecology of interstellar gas throughout the Milky Way and Large Magellanic Cloud (LMC). GUSTO is a cryogenic balloon-borne, 0.9m Cassegrain telescope designed to stay aloft on a long duration balloon for 100 days or more. During this time GUSTO will survey 124 square degrees of the Milky Way and all of the LMC in three important interstellar lines: [CII], [OI], and [NII] at 158, 63, and 205 um, respectively. From these data the global structure, dynamics, energy balance, pressure, and evolution of the interstellar medium within these objects will be discerned for the first time. The mission will be one of the first to utilize the 100+ day flight potential of the Super Pressure Balloon, also known as the Ultra Long Duration Balloon (ULDB), provided by NASA’s Balloon Program Office. GUSTO features a proven measurement approach, a high-heritage payload, and a simple, repeatable observing strategy that, combined with the ultra-long duration capability of the SPB, enables these important new galactic and extragalactic observations at a fraction of the cost of a comparable orbital mission. GUSTO is slated to fly in 2021 from the LDB payload integration facility near McMurdo Station, Antarctica.
The exceptional atmospheric transparency and stability above the high Antarctic plateau at Terahertz frequencies (50-500 microns wavelength) lends itself to two important applications for astronomy: wide-field (spectroscopic) imaging, and interferometry. With the advent of the ALMA interferometer in Chile, the power of submm-wave interferometry is having a dramatic impact on astronomy. However, at the highest frequency ALMA bands near and beyond 1 THz, the number of days with suitable observing conditions is scant. Coupled with the high costs of outfitting dozens of stations with advanced receivers, it is unlikely that the Band 11 capability will ever become a reality. To this end, the Ridge A site that hosted the pathfinding HEAT telescope and PLATO-R observatory can play an enabling role. Recent, cross-cutting advances in low-cost telescope construction, sensitive receivers at temperatures above 4K, low-power cryocoolers, and low-cost hybrid correlators make the case compelling: a capable THz interferometer can tackle the critical Band 11 science questions at a small fraction (5%) of the cost of outfitting ALMA. Here, we explore the science questions, capabilities and requirements that can be advanced by a Twin-Otter-deployable THz interferometer at the most remote, space-like site on Earth. We also highlight the technological prototyping efforts that demonstrate its feasibility. Terahertz phase closure at Ridge A could happen as early as 2021.
We have calculated the absorbed effective radiation doses on a human phantom flying on route SKBO-SKCL-SCEL-SCCI-SCRM-SAWB with software CARI-7A from the Federal Aviation Agency FAA using the model ISO TS15390:2004-MSU-NYMMIK of Galactic Cosmic Rays GCR. Additionally we have calculated the same on a human phantom modelled as a sphere with radius equals to 30 cm, composed of water, flying in the same routes by using a simulation chain involving CORSIKA and GATE/GEANT4. Equivalent radiation doses are going to be measured with four particle detectors SAFECAST bGeigie Nano inside the aircrafts that will be used in the fourth Colombian scientific expedition to the Antarctic flying on the route mentioned above. We also are going to measure the equivalent dose around the scientific base of Marambio in the Antarctic. With the characterization of major, minor elements and trace done on the geological material collected in the fourth and second Colombian scientific expeditions to the Antarctic, we build new simulated materials according to their element mass fraction on each geological material compound sample and incorporate them into the GATE materials database and calculate the absorbed effective radiation dose by the spherical phantom due to the presence of radioactive elements in the samples. With the information obtained in the simulations and measured data, we establish a criterion for cellular repair and estimate the risks caused by exposure to radiation.
The first Chinese Small Telescope ARray (CSTAR, with entrance pupil of 145mm) was successfully mounted on Dome A at 2008. The first inland station of Chinese, called Kunlun, has been erected in 2009, and then two Antarctic Survey Telescopes (AST3) with entrance pupil of 500mm has been installed. Now Chinese astronomers have proposed a plan to build a 2.5-meter optical/infrared telescope at Dome A. Kunlun Dark Universe Survey Telescope, one of two major facility of Antarctic Observatory at Chinese Kunlun Station, is a 2.5-meter optic/infrared telescope. It is intended to take advantage of the exceptional seeing conditions, as well as the low temperature reducing background for infrared observations. KDUST will adopt an innovative optical system, which can deliver very good image quality over a 2 square degree flat field of view. KDUST will be perched on a 14.5-meter-high tower to lift it above the turbulence layer.
Neutrino Point Source Searches in IceCube Using a Multi-messenger Approach

Imen Al Samarai$^1$ (imen.alsamarai@unige.ch)
$^2$Université de Genève, DPNC, Genève 2, Switzerland

The IceCube high energy neutrino detector is deployed in Antarctica, with highly sensitive photodetectors buried deep within the ice sheet at the South Pole. Its construction started in 2005 and was completed in 2010. It is the first experiment to report the detection of high energy neutrinos of astrophysical origin. Given the low astrophysical neutrino fluxes expected, and the high atmospheric background, multi-wavelength observations are used to further enhance the sensitivity to potential neutrino sources. By requiring space and/or time correlation between neutrinos and gamma-rays, or high-energy cosmic rays, the background associated to a neutrino detection is reduced as uncorrelated backgrounds from different observatories are considered. This contribution will present the various aspects of multi-messenger searches for cosmic sources in IceCube. The latest results of targeted source searches and all-sky source searches will be presented.
Radio Frequency and Optical Measurements of the Glacial Ice at the South Pole

Michael DuVernois1 (duvernois@icecube.wisc.edu)
1University of Wisconsin - Madison, Wisconsin IceCube Particle Astrophysics Center, Madison, United States

A unique opportunity to investigate the radio glaciological properties of the glacial ice has become available through the SPICE core hole. A program and is in preparation to perform measurements of RF transmitters deployed in the SPICE core hole to a depth of more than 1500 m. Optical measurements are also planned. The signals will then be recorded with multiple radio detector stations of the Askaryan Radio Array and possibly other instruments for the RF signals. First results will be presented from a field campaign in 2017/18. The measurements are especially interesting the radio neutrino detector community that uses the almost 3 km thick glacial ice with experiments such as IceCube and ARA and future extensions of these programs.
A Brief Review of the Science Potential of Antarctic Astronomy

Hans Zinnecker$^1$ (hzinnecker50@gmail.com)

$^1$University of Stuttgart, Deutsches SOFIA Institut, Stuttgart, Germany

In 2007, I chaired a conference on "The Astrophysical Science Cases at Dome C" in Antarctica, the results of which are published in Vol. 33 of EAS/EDP Sciences (Zinnecker, Epchtein, and Rauer 2008, eds.) Being cold, high, dry, stable, and completely dark for 3 long winter months, Antarctic astronomy offers exceptional ground-based atmospheric conditions to achieve unique astronomical observations and wide-field surveys (from the near- and mid-IR part of the spectrum to the far-IR/submm domain). Antarctic astronomical sites may also provide an outstanding platform for far-IR interferometry (perhaps at Ridge A) and for follow-up of future space missions of the 21st century.

In my presentation, I will briefly recall and review some of these science cases, including the potential for daytime and twilight astronomy as well as long time-series monitoring (particularly in the Magellanic Clouds). In the far-IR (30-300 micron or 1-10 THz), future Antarctic THz astronomy (high-resolution spectroscopy, particularly of the interstellar medium) from the Chinese Kunlun station at Dome A with a 5m or larger aperture dish might compete with the airborne infrared observatory SOFIA (a 2.5m telescope in B747SP flying in the stratosphere, funded by NASA/DLR). Finally, I discuss the potential of balloon-borne far-IR astronomy from the Antarctic continent (e.g. GUSTO), compared to SOFIA and the ground-based facilities ALMA/APEX or TAO/CCAT".
The BICEP Array and 10m South Pole Telescope are a suite of small and large microwave telescopes at the South Pole working together to detect polarization patterns in the cosmic microwave background (CMB) arising from primordial gravitational waves. Cosmologists believe that the entire observable Universe may have been spawned in a fraction of a second by the rapid “inflation” of a sub-atomic volume. Inflation provides a testable prediction: the same quantum process that plants the seeds of structure also produces a gravitational-wave background that may be detectable now via faint “B-mode” patterns imprinted in the polarization of the CMB. Detecting this faint pattern requires making maps of unprecedented sensitivity, while separating the faint polarization signals intrinsic to the CMB from other signals including polarized emission from dust and electrons in our own galaxy and patterns caused by weak gravitational lensing of large scale structure. The small-aperture BICEP/Keck Array telescopes have produced the deepest-ever maps of CMB polarization in four frequency bands. They are exploiting the unique Polar atmosphere to push these maps to high (up to 270 GHz) and low frequencies (down to 30 GHz) to separate galactic emission from CMB signals. The 10m SPT has deployed a new receiver with 17000 detectors and resolution sufficient to reconstruct the weak lensing patterns. Together they are producing the most sensitive constraints yet on primordial gravitational waves.
Mixed phase clouds, consisting of ice particles and super cooled liquid droplets, are frequently found in the Arctic. The impact of these clouds on sea ice, cloud radiation feedbacks, and the Earth’s surface radiative energy balance, critical to climate is poorly represented in various climate models. This research addresses the need for improved modeling capabilities in describing the role of Arctic clouds in climate models. This study hypothesizes that mixed phase Arctic clouds affect the surface energy budget due to unique cloud optical properties and positive cloud surface feedback in the near infrared wavelength channels. Therefore, it is important to estimate inherent cloud optical properties in wavelength channels including near infrared channels to provide an understanding about the cloud radiative forcing that affects the radiative transfer (RT) and energy budgets. A unique tethered balloon campaign carrying 4π radiometer, a cloud particle imager, and a meteorological package on board was conducted in 2008 in Ny-Alesund, Spitzbergen. Sikand et al. (2010, 2013) concluded that it would be valuable to build a next-generation radiometer that would include near-infrared channels. This research performs a feasibility study based on RT simulations using measurements from a test flight carrying an improved 4π radiometer including near-infrared wavelength channels that will be useful in the planned May 2018 Tethered Balloon Campaign to be conducted in Ny-Alesund, Spitzbergen.
Black Carbon in the Russian Arctic Atmosphere: Anthropogenic and Wildfire Sources

Anna Vinogradova¹ (anvinograd@yandex.ru)
¹A.M.Obukhov Institute of Atmospheric Physics, Russian Academy of Sciences, Moscow, Russian Federation

Black carbon (BC) emissions from Russian territory (2000-2014) were analyzed basing on official RF datasets and satellite data GFED. Some corrections for BC emissions from Russian intensive flaring zones of gas/oil mining industry are discussed. Total anthropogenic emission from Northern Eurasia (to the North of 52ºN) is estimated as 315 kt BC annually (with about 2/3 from Russia). The best estimate of air BC concentration from RF wildfires (with 25% deviation for every point of the Russian Arctic) is the mean value calculated from Russian and GFED emission data.

Spatial divergences of air BC concentrations along the Arctic coast are up to 100 times and more. Anthropogenic air BC concentrations prevail annually, but in summer wildfire's BC concentrations may in some years at some points be higher than anthropogenic ones. Also, there are high variations in BC pollution from year to year due to variations in atmospheric circulation processes. Great inter-annual and seasonal variations in BC air concentration through Russian Arctic territory do not allow to use the measured BC air concentrations (obtained at one point during one season or even one year) for long term conclusions/forecasts concerning the Arctic region and climate in general.

The work is supported by RFBR (grant No. 17-05-00245).

Long Term Aerosol Optical Measurements in Polar Regions from the GAW-PFR Network

Stelios Kazadzis¹,² (skazan@auth.gr), Natalia Kouremeti¹, Georg H. Hansen³, Kerstin Stebel⁴, Aaltonen Veijo⁵, Edith Rodríguez⁵, Stephan Nyeki¹

¹Physikalisch-Meteorologisches Observatorium Davos, World Radiation Center, Davos, Switzerland, ²IERSD, National Observatory of Athens, Athens, Greece, ³NILU - Norwegian Institute for Air Research, Tromsø, Norway, ⁴NILU Norwegian Institute for Air Research, Tromsø, Norway, ⁵Finnish Meteorological Institute, Helsinki, Finland

Long term ground-based sun-photometer measurements conducted at 2 Arctic (Ny-Ålesund 50 m asl, 8.91 N, 11.88 E, Summit 3238 m asl 72.58 N, 38.46 W) and 2 Antarctic sites (Marambio 205 m asl, 64.24 S, 56.62 W, Troll 1309 m asl, 72.01 S, 2.54 E) were examined to investigate aerosol optical depth (AOD) seasonal and year to year changes. Together with the AOD’s at 368, 412, 500 and 865 nm, Ångström’s exponents have been calculated for spring to autumn in the Arctic and for austral summer in Antarctica. Sun-photometers used are part of the GAW-PFR network, where instrument calibration and data processing is performed by PMOD/WRC. Higher AODs have been measured in Ny-Ålesund (0.5 for 500nm) with a pronounced decreasing trend from spring to autumn and Summit (0.4 for 500nm) showing also a less pronounced change. This has been commonly attributed to the position of the Arctic polar front. During the winter, the front is situated at ~50°N, hence allowing long-range transport from major industrial regions in Europe, Russia and N. America into the Arctic. The circulation pattern is different in summer when the front is situated further to the north (about 70°N), hence preventing polluted air masses from effectively reaching the Arctic. Lower AODs (from 0.2 to 0.4 for 500 nm) have been found for the Antarctic sites.
Development and AOD Measurements with a Lunar Photometer at Ny-Ålesund

Natalia Kouremeti¹ (natalia.kouremeti@pmodwrc.ch), Stelios Kazadzis¹,², Mauro Mazzola³, Georg H. Hansen⁴, Kerstin Stebel⁴, Julian Groebner¹
¹Physikalisch-Meteorologisches Observatorium Davos, World Radiation Center, Davos, Switzerland, ²IERSO, National Observatory of Athens, Athens, Greece, ³National Research Council of Italy, Bologna, Italy, ⁴NILU Norwegian Institute for Air Research, Tromsø, Norway

Atmospheric aerosols are known to impact the climate, but they still represent one of the largest uncertainties in climate change studies. Night-time AOD measurements could provide valuable information on the climatology of aerosols at high latitude stations, where direct sun measurements are not possible throughout the year. For example, in the northern hemisphere they can be used to monitor the arctic haze during polar winter. In passive remote sensing techniques, the moon or the stars are used as the light source.

The growing interest in night-time observations of aerosol optical depth (AOD) has led to the development of a lunar Precision Filter Radiometer (PFR) at PMOD/WRC. In addition to the retrieval of nocturnal AOD, the radiometric calibration of the lunar PFR aims to provide absolute lunar irradiance measurements with an expanded uncertainty of less than 5% (k = 2).

A lunar PFR was installed at Ny-Ålesund, Norway in October 2014 and it provides measurements from October to February.
Cloud Condensation Nuclei and Ice Nucleating Particles in the Southern Ocean

Silvia Henning1 (henning@tropos.de), Welti André1, Markus Hartmann1, Mareike Löfler1, Andrea Baccarini2, Heini Wernli3, Frank Stratmann1, Julia Schmale2, ACE-SPACE Team1,2,3
1Leibniz Institute for Tropospheric Research, Leipzig, Germany, 2Paul Scherrer Institute, Villigen, Switzerland, 3ETH Zurich, Dep. of Environmental Systems Science, Zurich, Switzerland

The Southern Ocean (SO) region is the most pristine aerosol environment on Earth, however almost the entire region is considered as heavily under-sampled. As partner of the "Study of Preindustrial-like-Aerosol Climate Effects" (SPACE) project, we participated in the unprecedented Antarctic Circumnavigation Expedition (ACE, December 2016 - March 2017), which gave us the unique opportunity to conduct high quality aerosol measurements in this remote region. ACE-SPACE in general aims at a detailed characterization of the pristine aerosol which is unaffected by anthropogenic pollution and therefore represents an aerosol comparable to that in a pre-industrial atmosphere. Our, i.e., TROPOS' special focus in context of ACE-SPACE is on aerosol particles involved in aerosol cloud interactions, specifically on particles able to act as cloud condensation (CCN), as well as particles able to nucleate ice (INP). We will present results concerning the spatial distribution of CCN and INP concentrations around the Antarctic continent, CCN hygroscopicity and INPs' freezing characteristics, and possible CCN and INP sources based on the analysis of back trajectories. Please notice two further contributions on ACE-SPACE at this conference giving (a) an ACE-SPACE overview and (b) results on new particle formation events.
Climate change is most pronounced in the Arctic, which is generally known as Arctic Amplification. The Transregional Collaborative Research Centre TR 172 "Arctic Amplification" (AC) aims to improve the understanding of climate relevant atmospheric and surface processes and feedback mechanisms by different modeling and observational projects. Quantifying vertical energy fluxes in the Arctic Atmospheric Boundary Layer (ABL) is most important for understanding the exchange of energy between the surface and higher altitudes, and therefore is a key factor to understand the changing atmosphere in a warming Arctic. However, observations of vertical profiles of energy fluxes in the central Arctic are still rare due to the challenging conditions in that region.

One major field campaign of (AC) is PASCAL: a cruise of R/V Polarstern into the Arctic sea ice north of Svalbard in June 2017. From an ice floe camp, we measured vertical profiles of turbulent energy fluxes with a tethered balloon under different stratification and cloud conditions. Turbulence parameters were measured with a hot-wire anemometer and an ultrasonic anemometer, which enables us to determine turbulent fluxes of heat and momentum. Additional radiation packages, developed by the University of Leipzig, complete the observations. Within the conference, we will present first results of balloon-borne turbulence and radiation measurements performed during PASCAL.

This work was supported by DFG Grant TR 172/1 A02.

Assessing Aerosol-cloud-rainfall Associations at a High Altitude Himalayan Site

Sachchida Tripathi¹ (snt@iitk.ac.in), Alok Gautam², Vijay Kanawade³
¹Indian Institute of Technology Kanpur, Department of Civil Engineering, Kanpur, India, ²Hemwati Nandan Bahuguna Garhwal University, Department of Physics, School of Science, Srinagar - Pauri Garhwal, India, ³University of Hyderabad, Centre for Earth and Space Sciences (UCESS), Hyderabad, India

The lack of an accurate understanding of the interplay between aerosol, cloud, and rainfall is one of the major scientific questions for global climate studies. Aerosols can affect cloud formation processes via activation of cloud condensation nuclei (CCN) and thereby modifying the cloud as well as rainfall patterns. The aerosol-mediated changes in cloud is termed as aerosol-indirect effect (AIE), and is a major source of uncertainty in assessing climate change, largely due to the regional variability in aerosol, clouds, and the complexity in aerosol-induced microphysical and/or dynamical feedbacks at different spatio-temporal scales. In an anthropogenically warming Earth, the accurate understanding of aerosol-cloud-rainfall interactions is essentially required to better project the future changes in the rainfall patterns and climate. In this context, we are in the process to setup a High Altitude Aerosol-Cloud Physics Laboratory (HAACPL) at Swami Rama Tirtha (SRT) campus of Hemwati Nandan Bahuguna Garhwal University (30.08°N, 78.61°E, 1706 amsl) to conduct continuous and long-term measurements of various aerosol and cloud properties together with weather observations in Himalayan ecosystem. The HAACPL research station is designed to address current shortcomings in aerosol-cloud-rainfall interactions. In this presentation, we will present a conceptual framework for studying aerosol-related impacts on climate from a high altitude site in Himalaya and preliminary data.
Evaluation of Satellite Derived Cloud Top Properties on the Antarctic Peninsula

Marta Caballero\textsuperscript{1} (marta.caballero@fau.de), Matthias Braun\textsuperscript{1}, Thomas Mölg\textsuperscript{1}
\textsuperscript{1}Friedrich Alexander-Universität Erlangen-Nürnberg, Institut für Geographie, Erlangen, Germany

Clouds play a key role in the energy balance of the atmosphere due to their radiative effects, and have a critical influence on the ice sheet's radiation budget. Changes in the glacier system on the Antarctic Peninsula (AP) have been observed: disintegration of ice shelves, acceleration and thinning of glaciers, variations in the limits between glacier faces and retreat of glacier fronts. However, rising surface air and ocean temperatures, as well as substantially increased snowfall in some regions, are also known, with tendencies linked to changes in atmospheric circulation. Hence, a better understanding of the processes and mechanisms leading to such changes is required, and the role of clouds over AP has not been yet studied well in this context. The measurement of cloud properties through satellite sensors is still a challenge, since discrepancies between data from passive and active sensors exist. Here, retrievals of satellite-derived cloud top properties from MODIS and CALIPSO are compared with cloud top properties derived from radiosonde measurements in Rothera and will be presented. This has the goal to identify undetected clouds in these sensors over the AP. The data is being analyzed in the special light of improving parameterizations in the Polar Weather Research and Forecasting model. This aims to ultimately enhance our understanding of how variations in the cloud cover and properties impact the energy balance on the Antarctic Peninsula at regional scales.
Mineral Dust Radiative Forcing in the Arctic

Arve Kylling¹ (arve.kylling@nilu.no), Christine Groot Zwaaftink¹, Andreas Stohl¹
¹NILU-Norwegian Institute for Air Research, Kjeller, Norway

The polar regions experience relatively large temperature changes due to feedback processes leading to Arctic amplification of global climate change. It has been suggested that mineral dust contributes to Arctic amplification. We use recent dust load estimates from Groot Zwaaftink et al. (2016), to quantify the direct mineral dust radiative forcing (RF) in the Arctic. The annual direct mineral dust RF in the Arctic is estimated to be 0.43 W/m² and 0.21 W/m² at the top (TOA) and bottom (BOA) of the atmosphere, respectively. The largest individual source contributions to the TOA mineral dust RF come from dust transported from Asia south of 60°N (~35 %) and Africa (~24 %), while all high-latitude dust sources contribute ~37 % to the TOA RF. The albedo reduction due to deposited mineral dust accounts for half of the TOA RF when there is snow on the ground. In terms of Arctic RF efficiency, i.e. TOA RF in the Arctic per emitted kilogram of mineral dust, high-latitude (>60°N) dust sources are about one to two orders of magnitude more efficient than lower latitude dust sources. Mineral dust deposited on snow accounts for nearly all of the BOA RF of 0.21 W/m². More than half of the BOA RF is caused by dust from high-latitude sources, indicating substantial regional climate impacts not accounted for in current climate models.
Continuous measurements of aerosol particle hygroscopicity and volatility have been performed on board the German research ice-breaker *Polarstern* in the high Arctic during June and July 2017, using a volatility hygroscopicity tandem differential mobility analyzer (VH-TDMA).

Here we present first results obtained by the VH-TDMA, combined with particle number size distributions (PNSDs) measured by a mobility particle size spectrometer (MPSS).

While being run in H-TDMA mode, the instrument measures the hygroscopicity of particles of a certain mobility diameter, which was chosen according to the maxima of the measured PNSD. When run in VH-TDMA mode, the measured signal is a result of the volatility of particles of the selected size and the hygroscopicity of their cores, i.e. the part of the particle that is left after volatilization at 300°C. In combination, these measurements give an indirect information about the chemical composition and mixing state of the atmospheric aerosol in a higher temporal resolution than e.g. filter or impactor samples.

We will present preliminary results of particle hygroscopicity and the refractory fraction encountered for discrete mobility diameters of the atmospheric aerosol in the high Arctic. These findings will be used to discuss the contribution of different compounds to the composition of the Arctic aerosol and thus its origins.
Dissolved methane (CH$_4$) was measured at various depths in the western Arctic Ocean. The CH$_4$ concentrations at the surface show an increasing trend northward toward stations at the shelf break and a decreasing trend toward stations in the Canada Basin. The mean sea-to-air flux is estimated to be 10.08 µmol/m$^2$/d, indicates that the Chukchi Sea shelf (CSS) is an active site of CH$_4$. Methane concentrations at the shelf stations increase from the surface to the bottom, and the maximum nutrient concentrations occur in the bottom layer. Strong correlations exist between CH$_4$ and PO$_4^{3-}$, SiO$_4^{2-}$, or NO$_2^-$, suggesting that the production of CH$_4$ is likely related to the degradation of organic matter in the sediment, supporting a biogenic source. At the slope and basin stations, the maximum values were observed in the subsurface of the upper halocline layer (UHL), and the concentrations decrease with increasing depth. The CH$_4$ concentrations are elevated by ~7.9 nmol/L in the UHL compared with the homogeneous CH$_4$ concentrations observed in the deep water. The elevated values in the UHL result primarily from northward spreading of CH$_4$-rich water from the shelf. The mass balance model shows that effluxes of CH$_4$ from the sediment-water interface and the in situ production of CH$_4$ represent the major sources of CH$_4$ over the CSS (95%). The main outputs for CH$_4$ in the CSS are the sea-to-air flux and oxidation of CH$_4$ in the water column, which account for 95% of the CH$_4$ exports.
Comparing Three Kinds of Satellite Retrieval Cloud Data in Tibet Plateau

Jian Liu1 (liujian@cma.gov.cn)
1National Satellite Meteorological Center, Beijing, China

The Tibet Plateau is called the third polar in the earth. It plays a key role in weather and climate in the Asia, even the North Hemisphere. Cloud is an important parameter in either climate monitoring or weather analysis in Tibetan. Tibet Plateau has complex surface types, but there are less ground observation stations that are mainly located in the eastern part of Plateau. Satellite observation is a good supplement for ground based observations because of its advantage in wide observation rage and higher temporal resolution. Since the first meteorological satellite was launched in 1960, the operational meteorological satellite data have been accumulated more than 40 years. There are several long term cloud data sets that can be used to research cloud properties. CLARA-A2, Patmos-x and MODIS-ST cloud data records are used in this research. Firstly three kinds of cloud fraction are evaluated by comparing with synoptic observation data from 2003 to 2015. The compared results show that except different retrieval algorithm and observation ability, temporal and spatial properties may be a reason to cause different results. Based on different time scale, MODIS and Patmos-x cloud fraction data were analyzed. The data record of Patmos-x and CLARA-A2 are used to do cloud fraction tendency analysis. Associated with precipitation, cloud properties such as the different phase cloud fraction, cloud top temperature, cloud optical thickness, water path are discussed in Tibet Plateau.
Single Particle Mass Spectrometry of Arctic Ambient Aerosol and Cloud Residuals

Oliver Eppers1,2 (o.eppers@mpic.de), Franziska Köllner2, Hans-Christian Clemen2, Heiko Bozem1, Stephan Mertes3, Emma Järvinen4, Martin Schnaiter4, Regis Dupuy5, Marco Zanatta6, Andreas Herber6, Johannes Schneider2, Peter Hoor1, Stephan Borrmann1,2

1Johannes Gutenberg University Mainz, Institute for Atmospheric Physics, Mainz, Germany, 2Max Planck Institute for Chemistry, Particle Chemistry, Mainz, Germany, 3Leibniz Institute for Tropospheric Research, Leipzig, Germany, 4Karlsruhe Institute of Technology, Karlsruhe, Germany, 5Laboratoire de Météorologie Physique, Clermont-Ferrand, France, 6Alfred Wegener Institute, Bremerhaven, Germany

The composition and origin of cloud forming particles in the Arctic is currently not fully understood. We show first results of aircraft-based particle measurements that were conducted during the ACLOUD campaign in May/June 2017 in the Svalbard region. An aerosol inlet was used for air sampling outside clouds, while a Counterflow Virtual Impactor (CVI) inlet allowed sampling of clouds residuals and ambient aerosol. Using the single particle aerosol mass spectrometer "ALABAMA", particle size in the range of 0.2 - 0.9 µm and chemical composition of single particles were investigated. Simultaneous measurements of gaseous air mass tracer such as CO, CO2 and O3 were used to identify different air masses. The results show a significant difference between boundary layer and free troposphere particle chemical composition. The boundary layer composition was largely characterised by particles from marine origin like sea spray aerosol and organic particulate matter, such as trimethylamine (TMA). In contrast, pollution plumes with high fractions of elemental carbon (EC) and levoglucosan were measured above the boundary layer up to 4 km. More than 50 % of the analysed spectra from cloud residuals show signatures of amines. The molecular structure of these amines differ significantly from particulate TMA sampled in ambient air. Furthermore, the large abundance of amines in cloud residuals shows the importance of amines in cloud processes in the Arctic.
Characterizing Tropospheric Clouds and Precipitation Using LIDAR in Antarctica

Claudio Duran-Alarcon¹ (claudio.duran-alarcon@univ-grenoble-alpes.fr), Alexis Berne², Brice Boudevillain¹, Valentin Simeonov², Dana Veron³, Audrey Teisseire⁴, Julien Jumelet⁴, Christophe Genthon¹
¹Université Grenoble Alpes, Institut des Géosciences de l’Environnement (IGE), CNRS - UMR 5001, Saint Martin d’Hères, France, ²École Polytechnique Fédérale de Lausanne (EPFL), Laboratoire de Télédétection Environnementale (LTE), Lausanne, Switzerland, ³University of Delaware, Department of Geography, Newark, United States, ⁴Laboratoire Atmosphères, Milieux, Observations Spatiales (LATMOS), CNRS - UMR 8190, Stratosphère, Haute Troposphère et Interfaces, Paris, France

Studying Antarctic atmospheric composition and processes with in-situ observations is challenging due to operational difficulties, implying a limited understanding of their interactions with climate and weather. Despite this complex scenario, significant efforts have been carried out using LIDAR techniques to monitor clouds, mainly to analyze cloud effects on the radiation budget, aerosols and ozone distribution both in troposphere and stratosphere. Recently a single-wavelength depolarization LIDAR has been deployed at Dumont d’Urville station on the coast of East Antarctica in February 2017 to characterize tropospheric clouds and precipitation in the framework of the Antarctic Precipitation Remote Sensing from Surface and Space project (APRES3). The observations are complemented with measurements from an automatic weather station, a Micro Rain Radar, a precipitation weighing gauge and daily radiosoundings. Profiles of backscattering coefficient and particle linear depolarization ratio (Dp) are used to analyze the vertical distribution of supercooled liquid water (SLW) and mixed-phase (MP) clouds, as well as the extent and occurrence of blowing snow (BS). Dp is retrieved using elastic assumptions of the backscattering and attenuation coefficients. Preliminary results show the predominance of low-level clouds, with high frequency of low depolarization ratio between 1-3 km height, suggesting the presence of SLW and MP clouds. BS has been mainly observed during the winter.
Atmospheric aerosols influence radiative forcing through direct interaction with radiation and by acting as cloud condensation nuclei (CCN). Up to 45% of CCN are formed via new particle formation (NPF), with a large fraction formed in the free troposphere (FT). While in the planetary boundary layer (PBL) new particle formation events have been frequently observed, measurements at high altitude because of intrinsic technical difficulties are scarce. The high-altitude research station Jungfraujoch (JFJ), Switzerland (3580 m above sea level) is a research site in the Swiss Alps and is in the FT for a substantial fraction of the time (especially in winter). NPF events often occur at JFJ (Tröstl et al., 2016) and it has been shown that they involve either sulphuric acid-ammonia or highly oxygenated molecules (HOMs) (Bianchi et al., 2016). Nitrate chemical ionization atmospheric pressure interface time of flight mass spectrometry (CI-APi-TOF) has been shown to be selective in detecting gas phase sulfuric acid and HOMs at extremely low concentration (ppq) (Ehn et al., 2014). Here we present the results of two winter periods during intensive campaigns involving CI-APi-TOF measurements. We describe the chemistry linked to NPF. A special focus is given to HOMs and their temporal variability, which provides various scenarios, in which HOMs from biogenic and anthropogenic precursors were identified to participate in NPF.

Changes in OLR over Arctic as Depicted by AIRS, CERES, and MERRA-2

Jae N. Lee1 (jae.n.lee@nasa.gov)
1University of Maryland, Baltimore County, Joint Center for Earth Systems Technology, Greenbelt, United States

In this presentation, we compare the temporal and spatial characteristics of monthly mean level-3 anomaly time series of OLR contained in the AIRS Version-6 with those in the CERES Edition 4 and MERRA-2 data sets over the 14 year period September 2002 through August 2016. Fourteen year global mean OLR average rates of change (ARCs) of AIRS and CERES data sets show slightly positive trends. The increase of OLR and clear sky OLR over Barents and Kara Sea region is noteworthy. The clear sky OLR changes more rapidly with surface warming, since it is more sensitive to surface skin temperature than the OLR. AIRS and CERES OLR time series agree extremely well in this aspect. This agreement validates the results of both data sets. Agreement of AIRS OLR with CERES also validates to some degree the AIRS retrieved geophysical parameters, which are used to calculate the AIRS OLR.

Analogous results are shown with regard to the MERRA-2 OLR data set. Some aspects of the MERRA-2 OLR data set perform reasonably well. MERRA-2 OLR has a serious short-coming however: The MERRA-2 OLR data set has a discontinuity, which results in a large spurious global mean OLR trend over the last 14 years.
To enhance the understanding of the role of Saharan mineral dust in the Arctic climate system, this study focuses on the mechanisms by which Saharan dust emitted over North Africa reaches the Arctic. The poleward transport of dust was associated with an intense Saharan cyclone that occurred over North Africa in early April 2011. Satellites observations are used in this study in order to characterize qualitatively and quantitatively the dust activity over North Africa associated with the Saharan cyclone as well as the transport of dust toward the Arctic and its deposition over Greenland. Beside the observations, a simulation at high resolution is performed using the MesoNH model in order to estimation the dust load transported northward and to evaluate the dust deposition north to 60°N. In this study, we identify a new mechanism for the transport of dust over long distances toward the northern pole: the poleward migration of the Saharan cyclone, in which the dust is transported toward the Arctic, was favorite by a negative-Arctic-Oscillation like situation associated with a slowed polar vortex and polar jet stream, which caused the intrusion of a lobe of low pressure further south with which the Saharan cyclone has merged and moved northward. A total dust load of about 38.35 Tg was carried by this cyclone to north of 40 N and dust deposition was estimated to be 1.3 Tg to the north of 60N.
Possible Feedbacks of Arctic Cirrus Clouds on the Composition of the UTLS

Florian Haenel¹ (florian.haenel@kit.edu), Wolfgang Woiwode¹, Michael Höpfner², Roland Ruhnke¹, Farahnaz Khosrawi¹, Oliver Kirner², Felix Friedl-Vallon¹, Anne Kleinert¹, Björn-Martin Sinnhuber¹
¹Karlsruhe Institute of Technology, Institute of Meteorology and Climate Research, Karlsruhe, Germany,
²Karlsruhe Institute of Technology, Steinbuch Centre for Computing, Karlsruhe, Germany

Cirrus clouds in the UTLS can affect the vertical distributions of the important greenhouse gas H2O via the direct processes of condensation and sedimentation of ice particles. They are further capable of trapping and redistributing nitric acid. The modification of the chemical budget of these gases may affect the distributions of ozone and methane. The role of high latitude and particularly arctic cirrus clouds is hardly understood. The aim of the project ICECREAM is to use measurements by the airborne infrared limb sounder GLORIA (Gimballed Limb Observer for Radiance Imaging of the Atmosphere) during the POLSTRACC (Polar Stratosphere in a Changing Climate) campaign for the detection of cirrus clouds and to analyze the vertical distribution of the critical trace gases H2O, HNO3, O3 and CH4 during an entire arctic winter. The data will be compared with model simulations by the high-resolution forecast model ICON-ART (ICOsahedral Nonhydrostatic - Aerosols and Reactive Trace gases) and the climate-chemistry model EMAC (ECHAM/MESSy Atmospheric Chemistry) including and omitting cirrus cloud particle sedimentation and HNO3 trapping. The aims are to gain insight, how well cirrus cloud feedbacks on the vertical distributions of H2O, HNO3, O3 and CH4 at high latitudes can be simulated in the models, and to estimate the significance of the vertical redistribution of H2O and HNO3 in the UTLS at high latitudes for the distributions of the greenhouse gases H2O, O3 and CH4 in the UTLS.
Black carbon (BC) is important for the Earth’s climate because it absorbs sunlight efficiently, heats the atmosphere. BC particles originate from the incomplete combustion of fossil fuel or biomass burning. In pristine regions, local emission and their influence on the regional climate are typically neglected. The Antarctica exploration mode can be questionable, as the sustainability of occupation and daily activities have not been considered. The sampling site of this study was the King George Island, close to the flight’s arrival point. The aerosols were assessed using a multi-wavelength Aethalometer-AE33 and Scanning Transmission X-ray Microscopy with near edge X-ray absorption fine structure spectroscopy (STMX/NEXAFS). BC data indicate that fossil fuel combustion is the main source of carbonaceous aerosols, with the total average of 41.8 ng.m$^{-3}$, much higher than the average of related studies. STXM/NEXAFS was used for the carbon-specific characterization, demonstrating that almost all particles on site have a considerable portion of carbon content. Considering growing Antarctica tourism and scientific activities during austral summer among the last years, the main sources of BC particles can be related to the presence of ships and flights. The above conclusions reaffirm the urgency of a new discussion on sustainability issues in the exploration of Antarctica, highlighting the duty of all government authorities to take into account the impact of these actions in Antarctica.
Changes in Antarctica ice sheets and ice shelves are of primary concern to the regional and global climate. We hypothesize that the West Antarctic warming can be related to the aerosols transported and/or formed in this region. Rather than being inert, snow is highly active, with snowpack impurities being photolysed to release reactive trace gases such as OH, NO/NO₂ and O₃ into the troposphere. The impact of solar radiation, enhanced by O₃ depletion, creates the optimal conditions for heterogeneous gas-to-particle reaction, modifying the chemical and physical properties of aerosols substantially. This study shows evidence of atmospheric processing, via microscopic and molecular speciation of individual aerosol by Scanning Transmission X-ray microscopy with near edge X-ray absorption fine structure spectroscopy (STXM/NEXAFS). Specifically, STXM reveals an accurate fraction of internally mixed particles with NaCl cores and nitrate coatings. The scattering efficiency of sea salt particles may decrease as a consequence of the external nitrate covering since the hygroscopicity of a mixed nitrate-salt particle is weak. The unique signal of ClO-type molecules could be possibly associated with OH radical oxidation products of NaCl particles. Considering the perchlorate has a supercooling property, it is possible to assume that perchlorate could produce a small melting effect especially at ablation zones of Antarctic glacier experiencing severe mass loss due to warming.
Sea-air Transfer Measurements of Marine Carbohydrates in the Arctic

Sebastian Zeppenfeld¹ (zeppenfeld@tropos.de), Markus Hartmann¹, Manuela van Pinxteren¹, Frank Stratmann¹, Hartmut Herrmann¹
¹Leibniz Institute for Tropospheric Research, Leipzig, Germany

Marine polysaccharides in sea spray aerosol are being discussed as an important source of ice nucleating particles in the Arctic. They may enter the planetary boundary layer by sea-air phase transfer processes such as bubble bursting and breaking waves. In this connection, the sea surface microlayer (SML) may play a key role as the direct interface between the ocean and the atmosphere. To date, there are only very few concerted measurements for carbohydrates in all these compartments in the Arctic available.

During the field campaign PS 106 aboard the German research vessel Polarstern during summer 2017 concerted sampling of aerosol particles, SML and underlying water was performed. The monosaccharide composition of these samples was determined via HPAEC-PAD, a very sensitive method for sugar analysis, before and after acidic hydrolysis. For avoiding analytical problems due to the high sea salt content in sea water samples a newly developed desalination step via electrodialysis has been applied. The concentrations of neutral sugars, aminosugars and uronic acids in arctic sea water were determined in the low to middle µg L⁻¹ range. Depending on the kind of monosaccharide enrichment in SML samples could be determined up to a factor of 2.0. Via enrichment factors in aerosol samples, sea spray aerosol will be discussed as an important local source of organic matter in arctic aerosol particles.

This work was supported by the DFG-funded TR 172 (Arctic Amplification).
We present size-resolved and vertical profile (up to 3 km) measurements of single particle chemical composition conducted during the aircraft-based measurement campaign NETCARE 2014 in July 2014 in the Canadian high Arctic (Resolute Bay, Nunavut). The single particle laser ablation aerosol mass spectrometer ALABAMA (0.2 - 1 µm vacuum aerodynamic diameter (Brands et al., 2011)) was deployed to identify different particle types and their mixing states.

We found that a significant fraction (approximately 60 %) of particles within the Arctic boundary layer contained trimethylamine (TMA). Several pieces of evidence suggest that this particulate TMA results from secondary conversion of precursor gases released by the ocean (Köllner et al., 2017). In contrast, a large fraction of particles above the local boundary layer contained levoglucosan (approximately 20 %). Mass spectra of levoglucosan-containing particles indicate the internal mixing with organic acids (e.g., dicarboxylic acids) (Sullivan and Prather, 2007; Zauscher et al., 2013), sulfate, potassium etc. Air mass history predicted by FLEXPART shows that those particles partly originated from remote biomass burning sources.

GFDL’s CMIP6 model CM4 contains a prognostic treatment of cloud-aerosol interactions. The analysis of a suite of simulations (e.g., with variable or fixed droplet number concentrations) yields a number of interesting findings related to the strength of negative cloud feedback and climate sensitivity. Besides this comprehensive model, an effort is made to use an idealized model for understanding those findings at the process level. The potential utility of satellite observations for constraining (or falsifying) model physics is also explored.
The opening of a polynya in the North Water (NOW) region of the Arctic introduces positive fluxes of heat and moisture to the overlying atmosphere. This perturbation in surface radiative energy fluxes can impact cloud formation over the open water and cloud evolution over the nearby icepack as the rising plume of moisture and heat is advected downstream. With polar regions experiencing warming at a rate much greater than the global average, the effects of polynyas on the surface energy budget will become increasingly important. As such, it is imperative that models accurately capture resultant changes in the overlying atmospheric column to reduce intermodel spread, better quantify surface-atmosphere feedbacks, and improve precision in climate projections. This research uses the CALIPSO-Cloudsat-CERES-MODIS merged product (C3M) to study surface cover and associated cloud fraction, liquid water path, and ice water path profiles over and adjacent to wintertime polynyas in the NOW region between 2006 and 2010. Moisture and sensible heat fluxes, derived from NASA’s EOS are combined with C3M-derived cloud and radiative heating rate profiles to quantify relationships between polynya-induced surface turbulent fluxes and lower tropospheric (0-3 km) clouds, testing the hypothesized link. It is expected that the opening and extent of a polynya strongly correlates with increases in heat and moisture to the atmosphere forcing a cloud response that supports longer polynya events.
Processes Governing Arctic Cloud Formation in CMIP5 Models

Robyn Boeke1,2 (robyn.c.boeke@nasa.gov), Patrick Taylor1
1NASA Langley Research Center, Hampton, United States; 2Science Systems and Applications, Inc., Hampton, United States

CMIP5 models simulate rapid Arctic climate change by 2100 and large intermodel spread in cloud amount (CA). Many processes govern Arctic cloud formation, namely 1) surface-atmosphere interactions (clouds affect surface temperature and sea ice, and indirectly surface turbulent fluxes and BL stability), 2) microphysical processes (e.g. cloud ice formation), 3) temperature/humidity advection that provides a moisture source for cloud formation, and 4) the vertical structure of temperature/humidity. We use a multilinear regression methodology to determine CA using these variables as predictors: upper and lower tropospheric stability (UTS; LTS), 500-hPa vertical velocity ($\omega_{500}$), temperature ($T_{surf}$; $T_{air}$), sensible and latent heat fluxes, and sea ice concentration (SIC). These variables were chosen because their effects on CA can be attributed to unique climate processes: UTS and LTS are thermodynamic indicators of the relationship between CA and stability, SIC and $T_{surf}$ determine surface-cloud interaction, $T_{air}$ governs cloud microphysical processes, and $\omega_{500}$ is a metric for dynamical change. Vertical profile data are obtained from the CMIP5 historical simulation, and statistical significance tests are used to confirm the regression equation and test the models for their ability to capture observed CA and behavior. Lastly, the intermodel spread in Arctic CA will be attributed to individual processes to shed light on emergent constraints in the Arctic climate change.
Modelling Sulfate Aerosols over the Southern Ocean

Laura Revell¹ (laura@bodekerscientific.com), Stefanie Kremser¹, Vidya Varma², Jonny Williams², Mike Harvey², Olaf Morgenstern²

¹Bodeker Scientific, Alexandra, New Zealand, ²NIWA, Wellington, New Zealand

Dimethyl sulfide (DMS) is estimated to be the largest source of natural atmospheric sulfur over the Southern Ocean. It is released into the atmosphere via biogenic activity of marine phytoplankton, and subsequently undergoes several oxidation reactions ultimately leading to sulfate aerosol formation. Atmospheric aerosols affect Earth's radiative balance, and can act as cloud condensation nuclei, thereby altering cloud properties. Uncertainties in simulating aerosols in global climate models cascade to uncertainties in cloud formation, absorption of shortwave radiation by the ocean, and atmospheric circulation, thus reducing confidence in climate change projections for the Southern Ocean and surrounding countries. This presentation outlines an investigation into the representation of DMS in the HadGEM3(GA7)+chem coupled chemistry-climate model. We show the effects of different sea-air transfer velocities on atmospheric DMS concentrations, the role that modelled sea ice plays in blocking oceanic emissions of DMS, and results from a sensitivity study on increasing the complexity of simulated DMS oxidation chemistry. Finally, we present the sensitivity of Southern Ocean clouds to atmospheric DMS concentrations.
Models on various scales are notoriously poor at reproducing the persistent mixed-phase stratocumulus (MPS) clouds commonly observed in the Arctic. The role of microphysics-dynamics interactions in sustaining these unstable clouds is poorly understood; therefore, it is imperative to assess such feedbacks to gain a holistic view of their role in the Arctic system. Large-scale subsidence, associated with high pressure systems, is often imposed in cloud-resolving models to maintain the height of these boundary layer (BL) clouds; however, the interaction between subsidence and mixed-phase cloud microphysics has not been previously studied.

Using the UK Met Office Large Eddy Model (LEM), we find strong cloud microphysical sensitivities to large-scale subsidence: by enforcing BL inversion strength and reducing entrainment from above, widespread subsidence dynamically stimulates Arctic marine MPS, promoting a greater cloud liquid-water path and efficient precipitation formation. Convection development is driven by longwave radiative cooling at cloud top, and rain evaporative cooling and latent heating from snow growth below cloud base. Our results indicate that high pressure systems in the ocean-exposed Arctic regions have the potential to affect resident BL MPS by enhancing their liquid fraction, thus helping to sustain them for longer against cloud glaciation.
Systematic Investigation of Shortterm Variability in Antarctic Aethalometer Data

Anna E. Jones¹ (aejo@bas.ac.uk), Neil Brough¹, Stephen Edmundson¹, Zoë L. Fleming², Tom Lachlan-Cope¹, Steve R. Colwell¹
¹British Antarctic Survey/NERC, Cambridge, United Kingdom, ²University of Leicester/NCAS, Leicester, United Kingdom

Combustion processes at lower latitudes are primary sources of black carbon (BC) to the polar regions. Deposited BC can alter albedo of snow/ice surfaces, so reliably recording variability and trends in atmospheric BC is critical. Within ice cores, soot records changes in combustion activities over historic time periods, but data interpretation requires understanding of present-day mechanisms delivering BC to the poles. Various instruments, including Aethalometers, measure BC via filter-based absorption methods. Being robust and easy to operate, Aethalometers have been widely used in the polar regions to determine, e.g. BC seasonality and long-term trends. Concerns exist, however, over possible artefacts in data from filter-based instruments. While these have been partially addressed through laboratory studies, they have not been adequately tested under field conditions.

Here we present a systematic investigation of short-term variability in Aethalometer data, measured over 1 year in coastal Antarctica. We find no direct correlation with wind speed (a concern raised in the literature) but episodes of high sea salt aerosol loading clearly influence observed BC values. Equally, 10-day air mass footprints link episodes of high BC in coastal Antarctica to biomass burning activities, primarily in South America, but occasionally in Africa. We thus demonstrate that filtering of Aethalometer data can render useful datasets to study BC variability over long- and short-timescales.
Modelling Aerosol-cloud Interactions over the Weddell Sea, Antarctica

G. Young¹ (giyoung@bas.ac.uk), T. Lachlan-Cope¹, C. Listowski², S. O’Shea³, K. N. Bower¹, T. W. Choularton³
¹British Antarctic Survey, Cambridge, United Kingdom, ²LATMOS, Guyancourt, France, ³University of Manchester, Centre for Atmospheric Science, Manchester, United Kingdom

Clouds play a key role in the Antarctic radiative budget, yet numerical models cannot accurately reproduce them due to our poor understanding of aerosol-cloud interactions in the region. Current models typically underestimate cloud fractions leading to strong radiative biases, particularly at the coastal regions. Coastal Antarctic clouds in the summertime are often mixed-phase; however, the ice phase is sporadically distributed throughout the clouds, hindering modelling efforts of primary ice nucleation based solely on cloud temperature. The patchy nature of the ice phase suggests that local aerosol sources - from the sea ice, ocean, or snow-covered continent - may be influencing these clouds, and such sources are not commonly represented in regional models which only consider meteorology.

To better comprehend the importance of spatially-dependent aerosol-cloud interactions in Antarctica, we need to increase the complexity of the models we use in the region. Using the Weather Research and Forecasting model coupled with Chemistry (WRF-Chem), we investigate the effect of local aerosol sources on cloud microphysics through comparisons with in-situ observations made during the Microphysics of Antarctic Clouds (MAC) campaign. During MAC, measurements of aerosol particle and cloud properties were taken in the vicinity of the Weddell Sea, Antarctica in the austral summer of 2015, providing an invaluable dataset for model validation, investigation, and development.
From 1991 up to 2010 a lidar observatory has been active at the Antarctic station McMurdo. Since 2014 the
same lidar has been operated successfully at Dome C on the Antarctic plateau. The lidar performs optical
measurements of the stratospheric and tropospheric aerosols from about 6 km asl up to 40 km at wavelengths
of 532 and 1064 nm. The scattered signal at 532 nm is detected at two different polarizations. The observations
have been analyzed in terms of occurrences of different classes of aerosols present in the polar stratospheric
clouds. A statistical comparison of polar stratospheric clouds (PSCs) occurrence from 2006 to 2010 at McMurdo
and from 2014-2017 at Dome C, both included as a primary station in the NDACC (Network for Detection
of Atmospheric Composition Change) with the satellite borne CALIOP lidar measuring over the stations, in
order to assess possible biases arising from different classification methods deriving from the specific geometry and
sampling. Point-to-point comparison between ground based and satellite based lidar measurements is
practically impossible due to the intrinsic differences in the observation geometries and the imperfect overlap
of the observed areas. Therefore a statistical approach has been used to compare ground based and satellite
based observations. Recent results will be presented.
Free Tropospheric New Particle Formation Observed above the Andes

Federico Bianchi\textsuperscript{1} (federico.bianchi@helsinki.fi), Claudia Mohr\textsuperscript{2}
\textsuperscript{1}University of Helsinki, Helsinki, Finland, \textsuperscript{2}Stockholm University, Stockholm, Sweden

A significant fraction of atmospheric cloud condensation nuclei arises from new particle formation (NPF) where 35\% are directly formed in the free troposphere. While NPF has been observed in many places around the world, the mechanisms governing this process are still poorly understood, especially at high altitude. So far, only few studies have shown that NPF can frequently take place at high altitudes. However, none of these have identified the chemical composition of the growing clusters.

In the last few years, we have focused our studies on further characterizing NPF processes at high altitudes taking advanced instrumentation at specific locations, in order to have a better understanding of the chemical cluster composition and therefore the nucleation precursors. The equipment includes Atmospheric Pressure interface Time-Of-Flight mass spectrometers, Particle Size Magnifier and Neutral clusters and Air Ion Spectrometer. Measurements were performed at the Chacaltaya station (Andes, Bolivia), the highest in the world (5240m a.s.l.) for in situ aerosol observations.

In this study, we will present observations of NPF events that have been measured at this particular station, for the time period December 2017 - May 2018.
Relative Roles of Different Types of PSCs to Polar Ozone Depletion

Ole Kirner¹ (ole.kirner@kit.edu), Rolf Müller², Farah Khosrawi³, Roland Ruhnke³
¹Karlsruhe Institute of Technology, Steinbuch Centre for Computing, Karlsruhe, Germany, ²Research Centre Jülich, Institute of Energy and Climate Research - Stratosphere (IEK-7), Jülich, Germany, ³Karlsruhe Institute of Technology, Institute of Meteorology and Climate Research, Karlsruhe, Germany

Heterogeneous reactions on the surfaces of PSC particles and denitrification of the stratosphere are the cause for Antarctic and Arctic ozone depletion in polar spring. We investigate the impact of the different types of PSCs on this polar ozone depletion with the help of the chemistry-climate model ECHAM5/MESSy Atmospheric chemistry (EMAC).

One standard and four sensitivity EMAC simulations (nudged with ERA-Interim) have been performed from 2005 to 2016 to evaluate the contribution of liquid, NAT and ice particles to ozone depletion in different polar winters due to chlorine activation by heterogeneous chemistry on their surfaces and due to denitrification of the stratosphere.

In the first three sensitivity simulations, we changed the heterogeneous chemistry on PSC particles by switching on and off the chemistry on liquid, NAT and ice particles. One further sensitivity simulation without NAT formation (only liquid and ice particles) was performed to evaluate the contribution of NAT due to denitrification of the stratosphere.

With the help of these different EMAC simulations, we will show the significance of liquid, NAT and ice particles to polar ozone depletion caused by chlorine activation and denitrification.
Is New Particle Formation an Aerosol Source over the Southern Ocean?

Andrea Baccarini1 (andrea.baccarini@psi.ch), Silvia Henning2, Katrianne Lehtipalo1, Markus Hartmann2, Fiona Tummon3, Andrea Welti2, Aemigegger Franziska4, Conor Bolas5, Ken Carslaw6, Harris Neil7, Leighton Regayre6, Frank Stratmann2, Iris Thurnherr4, Heini Wernli5, Martin Gysel1, Urs Baltensperger1, Josef Dommen1, Julia Schmale1

1Paul Scherrer Institute, Villigen PSI, Switzerland, 2Leibniz Institute for Tropospheric Research, Leipzig, Germany, 3University of Helsinki, Helsinki, Finland, 4ETH Zurich, Institute for Atmospheric and Climate Science, Zurich, Switzerland, 5University of Cambridge, Cambridge, United Kingdom, 6University of Leeds, Leeds, United Kingdom, 7University of Cranfield, Cranfield, United Kingdom

Models estimate that about 43% of the cloud condensation nuclei (CCN) in the atmosphere are formed from condensable vapors [1] but field and laboratory experiments are required to confirm the validity of these predictions and improve their accuracy. With this contribution we will present the first comprehensive investigation of new particle formation (NPF) in the Southern Ocean.

Concentration of gaseous precursors (in particular sulfuric acid and iodic acid), chemical composition of small nucleating clusters and size distribution of ions and neutral particles at the nanometer scale were measured during the Antarctic Circumnavigation Expedition (ACE) as part of the ‘Study of Preindustrial-like-Aerosol Climate Effects’ (SPACE) project (a general overview of the campaign will be presented in another contribution).

Here we will show that, despite of the generally low temperatures and small condensational sink, NPF in the Southern Ocean rarely happen due to the small amount of condensable vapors. Our observations suggest that the few NPF events observed are sulfuric acid driven and the recently discovered iodic acid nucleation mechanism [2] is not relevant over the Southern Ocean. Finally, we will discuss the relevance of NPF in the Southern Ocean as a source of CCN (specific CCN and ice nucleating particles observations during ACE will be presented in another contribution).

In this work we analyse bacteria reaching Antarctic Peninsula/King George Is. by atmospheric transport and their deposition on surface. Air was collected using a BioSampler® flask attached to a pumping system during the summer season and fresh snow was analysed from the winter season between February 2010 and February 2011. The samples were inoculated with R2A and were incubated at different temperatures (2° C, 12° C and 28° C). Aliquots of the samples were analyzed by flow cytometry for visualization and size quantification of living and dead organisms using the fluorochromes propidium iodide (PI) and SYTO 13, respectively. Replicas of samples were filtered on Isopore membranes and the retained material was analyzed by X-ray fluorescence (XRF) and SEM + EDS to determine the elemental composition of metals of terrigenous and marine origin of inorganic aerosols attached to the bacteria. For each monthly bacteria number concentration we conducted the HYSPLIT/NOAA atmospheric dispersion model to set the trajectories of air parcels reaching Antarctica. Results indicated mostly positive cocci gram and catalase. The quantitative variability of bacteria showed strong influence of precipitation and the inter-annual melting process being the bacteria content associated with the terrigenous elements and soil temperatures. Analysis of cell viability in fresh snow seems to correlate with UV, in Antarctica, when apoptotic cells in flow cytometry were analysed.
Shipborne and Ground-based Observations of Clouds in the Southern Ocean

Peter Kuma (peter.kuma@pg.canterbury.ac.nz), Adrian McDonald, Olaf Morgenstern, Simon Parsons

University of Canterbury, School of Physical and Chemical Sciences, Christchurch, New Zealand, NIWA, Wellington, New Zealand

The Southern Ocean is characterised by sparse ground-based and in-situ atmospheric measurements. While satellite measurements provide continuous spatial and temporal coverage, they are generally not capable of observing low-level clouds and the cloud base, which are critical for accurately modelling radiative transfer. Results from general circulation models show significant biases in outgoing shortwave radiation in this region, believed to be related to deficiencies in representation of clouds, aerosols or their interaction. As part of the Cloud and Aerosol project of the New Zealand Deep South Challenge (DSC) we collected and analysed cloud measurements from multiple shipborne and ground-based deployments of several meteorological instruments: ceilometer, lidar, micro rain radar, radio soundings, aerosol sensors, sky cameras and UAV-borne sensors. With this combination of instruments we hope to advance understanding of cloud processes in this region, quantify model error compared to observations and contribute to the modelling effort of the DSC. Currently we have collected observations from a ground-based deployment on Macquarie Island and multiple voyages: Aurora Australis, R/V Tangaroa, HMNZS Wellington and R/V Nathaniel B. Palmer. By incorporating data from these and planned future deployments we intend to produce a Southern Ocean dataset of atmospheric measurements available for general use. This presentation will provide an overview of our progress and results.
This study aims to characterize the microphysical and optical properties of low-level Arctic mixed-phase clouds (MPCs) in order to improve the knowledge of these particular polar clouds. Cloud in situ measurements from four airborne campaigns (18 flights, 71 vertical profiles in MPCs) in the vicinity of the Svalbard region are combined and analyzed.

Cloud phase discrimination and representative vertical profiles of the number, size, mass and shape of ice crystals and liquid droplets are established. The results highlight that the liquid phase dominates the upper part of the MPCs. The ice phase dominates the cloud properties in the lower part and below the cloud in the precipitation region. The analysis of the ice crystal morphology highlights that riming and diffusional growth processes, including the Wegener-Bergeron-Findeisen (WBF) mechanism, are the main growth mechanisms involved in the observed MPCs.

The impact of larger-scale meteorological conditions (temperature regimes, air mass origin) on the MPC properties is also investigated. The results highlight that clean situations with low temperatures exhibit larger values of ice crystal size and IWC, whereas the situations more polluted with air mass origins from the south exhibit larger values of LWC and number of smaller droplets associated with very low values of ice crystal size and IWC.

Finally, these data lead to the determination of several parameterizations relevant for remote sensing or modeling studies.
Sakthivel Samy\textsuperscript{1} (vssamy@ncaor.gov.in), Ravichandran M\textsuperscript{2}, Jeni Victor N\textsuperscript{3}, Sathish Kumar S\textsuperscript{3}
\textsuperscript{1}National Centre for Antarctic & Ocean Research (ESSO-NCAOR), ICTD & National Polar Data Center, Vasco da Gama, India, \textsuperscript{2}National Centre for Antarctic & Ocean Research (ESSO-NCAOR), Vasco da Gama, India, \textsuperscript{3}Indian Institute of Geomagnetism, Tirunvelveli, India

High temporal resolution (1 Hz) records of temperature, wind speed and air pressure recorded at Antarctic research station Maitri (70° S, 11° E) during 2012-2016 are analysed to identify oscillations from daily to intraseasonal/extralong period timescales. The diurnal cycle dominates the hourly time series of temperature during the Antarctic summer and is almost non-existent during winter. In comparison, the hourly time series of wind speed and air pressure show a weak diurnal cycle. The dominant pattern of the intraseasonal variability of these quantities, which captures the out-of-phase of temperature and wind speed with air pressure, shows enhanced variability at timescales of, \textasciitilde 16 days respectively. The second pattern of intraseasonal variability, which captures in-phase variations of temperature, wind and air pressure, shows enhanced variability at timescales of \textasciitilde 8 days, \textasciitilde 16 days, \textasciitilde 32 days and \textasciitilde 40 days.
The surface radiation budget (SRB) has peculiar characteristics in the polar regions, due to the predominance of the infrared radiation and to the absence of solar radiation during part of the year, as well as to the meteorological conditions related to low temperature and humidity values, and to the presence of highly reflecting surfaces.

Measurements of downward shortwave (SW) and longwave (LW) irradiance were available at Thule High Arctic Atmospheric Observatory (THAAO, 76.5° N, 68.8° W, http://www.thuleatmos-it.it/) since 2009. In July 2016, additional instruments were installed during the summer campaign of the Study of the water VApour in the polar AtmosPhere (SVAAP) project: among them, downward-looking SW and LW radiometers, a RPG HATPRO microwave radiometer, an infrared pyrometer, a meteorological station, a sky imager. Measurements of SRB and of the derived cloud radiative forcing are presented and discussed as a function of simultaneous data of integrated water vapour, cloud parameters like liquid water path, cloud optical thickness and particles' effective radius (only during summertime), and under different regimes of surface albedo, typical of snow-free (from June to September) and of snow covered terrain. In summer the SRB is positive and its variability is dominated by the SW irradiance. The LW component offsets about 20% of the SW at noon in clear sky, and contributes up to 50% of the total SRB in thick cloud conditions.
Role of Katabatic Wind in Altering the Fair-weather Electric Field at Antarctica

N Jeni Victor¹ (jenivictor@gmail.com), Sakthivel Samy², M Ravichandran³, C Paneerselvam¹, Elango Paramasivan¹

¹Indian Institute of Geomagnetism, Tirunvelveli, India, ²National Centre for Antarctic & Ocean Research (ESSO-NCAOR), ICTD & National Polar Data Center, Vasco da Gama, India, ³National Centre for Antarctic and Ocean Research (ESSO-NCAOR), Vasco da Gama, India

Automatic Weather Station (AWS) and Electric Field Mill (EFM) measurements at Maitri (70° S, 11° E), Antarctica from 2013-2016 are presented in this analysis. Time series of fair weather electric field shows the signature of katabatic wind is highly dominant in the summer than winter. There are ~ 80 such events categorized, which results from the criterion like the constancy of fair weather field range/gradient pre-and post event periods. It also applies to the wind speed & direction pattern where the event is taken only when they stable for more than one hour. From the statistics analysis, the average wind speed varied nearly 10 m/s during the event periods and the average response time of electric field is 50-65 min for the wind speed change of 30-45 min with the wind direction changes less than 30 mini. The effect of katabatic wind on electric field has seasonal and Local Time (LT) dependency. We suggest that the electric field response varied at season may be due to 1. Summer has relatively more number of fair weather days than winter, hence the only dominant factor is aerosol carrying wind, Katabatic, that modulates the conductivity of near surface region, 2. The added effect of winter, snowfall and blizzard and enhanced pattern of Katabatic wind together influence the fair weather field. Local time dependence is validated with other AWS observations (IMD, Dozer point).
Atmospheric mineral dust deflated from continental surfaces is an important player in Earth climate. As it reaches inner Antarctica after long-range transport from other continents, the study of both current-days and ice-core-archived Antarctic mineral dust is very useful in recognizing its main source areas and therefore the present day and past atmospheric dust pathways. While glacial conditions, when dust concentrations are higher, have been well investigated assessing a dominant dust origin from Southern South America, a poorer knowledge is available for the Holocene and interglacials. At the LABEC-INFN accelerator, a PIXE-PIGE setup has been optimized for high efficiency particulate matter analysis. These techniques, which are high sensitive to mineral dust elements, have been used for the analysis of dust in EPICA ice core samples (Marino et al., GRL 2009) and for preliminary measurements on present day mineral dust collected at Dome C.

This research activity will be carried forward and enlarged by the recently started PNRA SIDDARTA project, whose aim is studying present-day sources and transport processes supplying mineral dust to the Antarctic plateau (by the analysis of atmospheric aerosol, surface snow and snow-pit samples collected at Dome C, as well as soil samples collected in Southern South America and Australia). Motivation, design and first results of SIDDARTA will be described together with results obtained by previous PIXE analysis of Antarctic mineral dust.
Source Apportionment of Arctic Aerosol: Results of the Ny Ålesund 2015 Campaign

Giulia Calzolai¹ (calzolai@fi.infn.it), Silvia Nava¹, Massimo Chiari¹, Franco Lucarelli², Silvia Becagli³, Laura Caiazza³, Fabio Giardi³, Mirko Severi³, Mauro Mazza³a, Rita Traversi³

¹National Institute for Nuclear Physics, Florence Division, Sesto Fiorentino, Italy, ²University of Florence and INFN-Firenze, Department of Physics and Astronomy, Sesto Fiorentino, Italy, ³University of Florence, Department of Chemistry, Sesto Fiorentino, Italy, ⁴CNR-ISAC, Bologna, Italy

Ny Ålesund is located on a western fjord of Svalbard Islands, in the northernmost point influenced by the warm West Spitsbergen Current, and thus it is an ideal site for the study of the interaction between the climate change and the atmosphere, ocean and land variations. At the Gruvebadet laboratory, samplings are ongoing since 2010 in the period March to September; in particular, in this work we will focus on the results gained by the analysis of daily PM10 samples collected during the 2015 campaign.

Daily PM10 samples were analyzed for the ionic composition by Ion Chromatography (IC) and for metals and rare earth elements (REEs) by Inductively Coupled Plasma - Atomic Emission Spectroscopy (ICP-AES). Further, for the first time, daily samples were analysed for the elemental composition by Particle Induced X-ray Emission (PIXE) analysis. PIXE is an almost unrivalled technique for the characterization of mineral dust, as it is sensitive to all the crustal elements (except O), included Si, which is usually not accurately quantifiable with other common chemical techniques.

Data on PM10 concentrations and speciation will be shown. Further, the Positive Matrix Factorization (PMF) model was applied for source apportionment and allowed the identification and the quantification of the contributions to the aerosol burden of several sources such as mineral dust, nitrate, ammonium sulfate, sea salt, biogenic emissions, anthropic emissions.
This work is the results of two experiments performed in Ny-Alesund (Svalbard) during the 2014 and 2016 spring. Two different experiments were performed to evaluate the relation between the atmospheric load of black carbon (BC) and its concentration in surface snow. One experiment focused on the daily BC concentration changes in the first 10 cm of the snow layer for a total of 80 days, the second with hourly temporal frequency for 3 consecutive days and 3 cm of snow for study the possible fluctuation of BC in surface snow due to the day and night cycle.

The atmospheric equivalent BC mass was measured by an Aethalometer, a PSAP and a mini-Aethalometer. Refractory BC concentrations in snow samples were measured with a SP2 (DMT) and the insoluble particles numbers with an Abakus system (Klotz).

Statistical modelling was considered to evaluate the relationships between the parameters and the variability of rBC variability in the snow. In both experiments a statistically significant relation was found between the dust content and rBC concentration in snow, indicating common atmospheric and depositional patterns. In the “80 days” experiment a negative relation was found between the atmospheric and the snow BC, whereas a positive relation between snow rBC content and snow conductivity. The high resolution sampling of the “3 days” experiment allowed detecting a diurnal cycle of the rBC in snow, inversely proportional to solar radiation and snow temperature.
Over the past decades, the Arctic has warmed more than any other region on Earth. However, the causes of this so-called Arctic amplification are not yet fully understood. Although model estimation of Black Carbon (BC) has been improved in the past years there is still an under or overestimation of BC in the prediction of a factor of two, which could be due to the mismatch of long-range transport due to the limited horizontal resolution. To provide better information to models, Finnish Meteorological Institute (FMI) has extended the Arctic observations to improve the capability to monitor the vertical atmospheric column in the dark period. In this work we present a new method to retrieve aerosols properties using a novel instrument that measures in dark conditions, using the moon as a source of radiation. The Lunar Photometer is an extension to the traditional Cimel sun-photometer with some significant technical modifications to optimize its performance to allow the retrieval of reduced incoming energy. Fifteen years of AOD and AE measured by collocated PFR and Cimel photometer measurements have been analyzed together with the first year of the lunar photometer measurements installed at Sodankylä station. The physical aerosol properties such as aerosol size distribution, refractive index, and the single scattering albedo analyses are also included, starting in 2013.
The Arctic is warming twice as fast as any other part of the world. The rapid climate change is associated with various feedback mechanisms which relative importance is still debated. The German project “Arctic Amplification (AC)3” aims to better quantify relevant processes and enhance the understanding of mechanisms involved with a range of field measurements and modeling. Aerosol particles affect the Arctic energy balance by direct and indirect radiative effects. This study contributes to (AC)3 by investigating sources and transport pathways of natural and anthropogenic aerosol and its radiative impact by global and Arctic-focused transport modeling. Particular focus is on black carbon (BC) which is highly absorbing at solar wavelengths and tends to warm the atmosphere. When deposited on snow/ice it lowers the surface albedo and accelerates sea ice melting.

Here, we present an evaluation study with the aerosol-climate model ECHAM6.3-HAM2.3. Using different state-of-the-art emission inventories, simulations have been performed in nudged mode with 1.8° grid spacing for the years 2006-15. The evaluation's emphasis is on the vertical layering and seasonality of Arctic aerosol using ground and airborne field data. The evaluation will reveal emission and transport-related uncertainties in aerosol radiative properties and forcing. Finally, the model results will provide an up-to-date estimate of the budget and direct radiative forcing of aerosol in the Arctic region.
Black Carbon Deposition to the Greenland Ice Sheet from Forest Fires in Canada

Jennie L. Thomas¹ (jennie.thomas@latmos.ipsl.fr), Christopher M. Polashenski²,³, Amber Soja⁴, Louis Marelle⁵, Kimberly A. Casey⁵, Hyun Deok Choi⁶, Jean-Christophe Raut⁷, Christine Wiedinmyer⁷, Louisa K. Emmons⁷, Jerome Fast⁸, Jacques Pelon⁹, Mark Flanner⁹, Jack E. Dibb¹⁰

¹LATMOS/CNRS, Paris, France, ²Dartmouth College, Thayer School of Engineering, Hanover, United States, ³Cold Regions Research and Engineering Laboratory, Fairbanks, United States, ⁴National Institute of Aerospace, Resident at NASA Langley Research Center, Hampton, United States, ⁵Center for International Climate and Environmental Research, Oslo, Norway, ⁶LATMOS, Paris, France, ⁷National Center for Atmospheric Research (NCAR), Boulder, United States, ⁸Pacific Northwest National Laboratory, Richland, United States, ⁹University of Michigan, Department of Climate and Space Sciences and Engineering, Ann Arbor, United States, ¹⁰University of New Hampshire, Earth Systems Research Center, EOS, Durham, United States

Black carbon (BC) concentrations has been observed in 22 snowpits sampled in the northwest sector of the Greenland ice sheet in April 2014. The pits contain a strong and widespread BC aerosol deposition event, which accumulated in the pits during two snow storms between 27 July and 2 August 2013. This event comprises a significant portion (57% on average across all pits) of total BC deposition measured in the snowpits (~10 month record). We link this deposition event to forest fires burning in Canada during summer 2013 using modeling and remote sensing tools. Specifically, we use high-resolution regional chemical transport modeling (WRF-Chem) combined with high-resolution fire emissions (FINNv1.5) to study aerosol emissions, transport, and deposition to Greenland snow during this event. The model captures the timing of the BC deposition event and shows that fires in Canada were the main source of deposited BC. The potential implications for understanding the influence of BC originating from fires on the optical properties of snow is discussed.
Polar lows (PLs) are intense, high-latitude maritime cyclones that bring heavy precipitation and winds above gale force. Their small horizontal scale and short life time makes them hard to predict. Therefore, improved understanding and prediction is of high importance. Satellite observations in the microwave range that have a good coverage of the Arctic region offer high potential due to theirs sensitivity to snow. Two such satellite instruments, namely Advanced Microwave Sounding Unit -B (AMSU-B) and Microwave Humidity Sounder (MHS) have been used. The investigation of PLs is done for January, 2003 to December, 2012 over which 134 cases were reported. Arctic System Reanalysis version 1 (ASRv1) is used for the analysis of atmospheric genesis conditions of PLs and compared with satellite observations. For the latter, radiative transfer simulator called PAMTRA (Passive and Active Microwave Radiative Transfer Model) has been employed. We found that AMSU-B and MHS are performing well in representing the PLs, where channels around strong water vapour line, namely 183.31 GHz, are showing strong depression in PL convective cores that At times depression can be over 40 K. Generally, simulations show good agreement with satellite observations, though not all cores of multi-low PL are resolved. Furthermore, we investigate PL cases originating in different geographical area and the amount of snowfall they bring.
Tropical Palynomorphs Detected at Central-Western Antarctic

Kamila da Matta Agostini¹ (kamila_matta@hotmail.com), Heitor Evangelista¹, Claudia Barbieri Ferreira Mendonça², Franco Nadal Junqueira Villela³, Marcelo de Araujo Carvalho³, Vania Gonçalves Esteves², Alerson Rodrigues Bezerra¹

¹Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil, ²Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil, ³Instituto Nacional de Meteorologia, São Paulo, Brazil

The regime of transport and deposition of pollen grains and spores to Antarctica may help understanding the atmospheric capability of transporting biological material intercontinentally. Snow samples were collected in Central-Western Antarctica (84ºS-079ºW), Criosfera 1 laboratory, in the years of 2013 and 2015 to investigate occurrences of palinomorphs. The collected snow was filtered in polyester blanket with 6 µm lumen and later, the palinological slides were assembled. Simultaneously, atmospheric modeling (HYSPLIT/NOAA), surface wind diagrams and data obtained in situ (wind direction, snow accumulation, air temperature and relative humidity) were used to corroborate the sources of the palynomorphs. Eleven pollen / spore grains represented the taxa: *Thelypteris* sp., *Waltheria* sp., *Pinus* sp., *Smilax* sp., *Morus alba* L, *Anadenanthera colubrina* Brenan and Campanulaceae were observed in the year of 2015 and only one grain of Poaceae in 2013. We have attributed the difference in pollen concentration to an extratropical cyclone in the coastal South Atlantic characterized as explosive that occurred near Uruguay and North / Northeast of Argentina in November 2015. Polen source region was corroborated by radiogenic Sr/Na in concomitant dust. This event, due to its high energy, was responsible for the suspension of palynomorphs, followed by transportation to the high latitudes. In the Weddell Sea, a polar cyclone assisted the entry of palynomorphs into the Antarctic continent.
An Experiment at Lat 84S to Study the Link between Cosmic Ray and Cloud Cover

André Massafferri¹ (massafferri@cbpf.br), Heitor Evangelista², Leonardo Guedes¹, Ulisses Carneiro¹, Marcos Koebcke¹, Heber Passos³
¹Centro Brasileiro de Pesquisas Físicas, COHEP, Rio de Janeiro, Brazil, ²Universidade Estadual do Rio de Janeiro, Rio de Janeiro, Brazil, ³Instituto Nacional de Pesquisas Espaciais, São Jose dos Campos, Brazil

Since Charles Wilson invented the cloud chamber in 19’s it is known that ionizing particles are capable to trigger cloud droplets. Only in 1997 the first evidence of a response of the cloud formation with respect to cosmic rays in real atmosphere has been reported, motivating many other studies, given to it potential implications to the global climate changes.

Recently the CLOUD Collaboration designed a special chamber dedicated to study the ion-aerosol mechanisms, the microphysical process to form clouds. They found that ions from galactic cosmic rays could strongly enhance the production rate of pure biogenic particles as well as oxidised biogenic vapours dominate particle growth in unpolluted environments.

In order to study the role of the cosmic ray in climate, the Criosfera 1, a remote Brazilian self-energy sustained laboratory, installed at 84°S, setup an experiment, named CREAT (Cosmic Ray Experiment at AnTartic), dedicated to monitor low energy muon flux efficiently, by means of plastic scintillators, multianode photomultiplier and FPGA technologies. The location is benefited by the high cosmic flux, absence of background radiation, human pollution and rainfall. We will present the preliminary results obtained from 2014 to 2017, analyzed using advanced statistical method to quantify their correlation with cloud of different altitudes using NASA and ERA datasets. We will also discuss the long term perspective for the CREAT project and its upgrade.
The U.S. Department of Energy (DOE) operates scientific user facilities at locations around the world, including polar regions. The Atmospheric Radiation Measurement (ARM) facility is a scientific user facility that provides researchers with strategically located atmospheric observatories. The resulting data are used to improve the understanding of how the Earth’s atmosphere works and the way those processes are represented in regional and global models. Data from these facilities are provided to the international research community through an archive that is easily accessed via the web.

The ARM program currently operates two fixed ground-based facilities in Alaska and has a third inland location that can be used for field campaigns. These facilities include:

- Barrow: to measure ocean-land-atmosphere interface conditions,
- Atqasuk: to measure land-atmosphere interface for comparison of Barrow measurements for differences between land and shore conditions,
- Oliktok (AMF-3): to measure ocean-land-atmosphere interface; use of R-2204 and W-220 for aerial atmospheric measurements.

In addition to providing full time ground-based observations, the ARM facility at Oliktok is used for operations of instrument unmanned aerial systems and tethered balloon systems. Several activities related to the Year of Polar Predication (YPP) at North Slope ARM facilities have been proposed and are under review.
The aerosol optical measurement to estimate CCN concentrations is challenging because of various aerosol characteristics. Thus, it is important to investigate the CCN-AOD relation using remote AOD data according to the regional and seasonal aerosol characteristics.

In this study, CCN-AOD relation at 500 nm is given in the Arctic region based on CCN measurement data collected during the period 2007-2013 at the Zeppelin observatory (78.91° N, 11.89° E, 474 masl). For remote sensing data, the AERONET network and MODIS AOD as well as MERRA-2 reanalysis data are analyzed. The seasonal characteristics as well as long term trends are also considered.

As a result, CCN concentration remains high during spring because of aerosol transportation from the mid-latitudes, known as Arctic Haze. Lowest CCN number densities were observed during autumn and early winter when aerosol long-range transport into the Arctic is not effective and new particle formation ceases. The results also show that the relation between AOD and CCN has a seasonally different tendency. This seasonal different CCN-AOD relation can be interpreted as many physico-chemical aerosol properties including aerosol size distribution and composition. Subsequently, CCN-AOD relation can be interpreted as many physico-chemical aerosol properties including aerosol size distribution and composition.
This work presents in situ data from aerosol measurements that took place at the Arctic Lidar Observatory for Middle Atmosphere Research, located in the Andøya island, ~300 km north of the Arctic Circle. The main goal of the measurements is the characterization of individual aerosol particles to know their morphology, size distribution, mass and chemical composition. The technique used is the collection of aerosol particles on filters for posterior analysis in the laboratory. The system is composed by an inlet, an in-line filter holder, a vacuum pump and a flow meter. The filters are weighed before and after collection for determination of the amount of particulate matter. After weighed, the filters are prepared for observation on a scanning electron microscope (SEM) or on a transmission electron microscope (TEM). Both electron microscopes allow to see the size and morphology of the individual particles. A RONTEC energy dispersive x-ray system allows to obtain the information about elemental composition of the particles. This work is supported by Fundação para a Ciência e Tecnologia (FCT) through the Portuguese Polar Program (ProPolar), Project POLARUBI.
The Atmospheric Optics Group of the University of Valladolid and the Alfred Wegener Institute (AWI) have started a joint research project which included the installation of a new generation Cimel sun-sky-lunar radiometer (CE318-T) in the Ny-Ålesund Arctic base (Svalbard, 78.9°N). This kind of instrument, in the framework of the worldwide AERosol ROBotic NETwork (AERONET), can provide aerosol properties during summer (sun) and winter (moon) time. This instrument follows all the standardized AERONET daylight observations and gives a large set of aerosol properties that can be combined with lidar and other collocated instruments using novel algorithms such as GRASP (Generalized Retrieval of Atmosphere and Surface Properties) open source code.

We present here the preliminary results of aerosol optical and microphysical observations in the French and German joint facility AWIPEV in Ny-Ålesund after several months of operation. The aerosol optical depth time series (since 1991) from a Schulz sun photometer at the AWIPEV site is compared with the first months of CIMEL database and the results highlight the necessity of re-calibration of the 1020 nm channel.

This work was supported by: project POLARMOON (CTM2015-66742-R) and IJCI-2014-19477 and PTA2014-09522-I grants of Spanish Government (MINECO), EU-H2020 under Grant Agreement Nr. 654109 [ACTRIS 2]; and RIS-ID 10745 project. Thanks to AWIPEV station crew.

Single Particle Characteristics of Biomass Burning Aerosol Transported in Arctic

Beatrice Moroni1, Kris Markowicz2, Justyna Lisok2, Christoph Ritter3, Mauro Mazzola4, Silvia Becagli5, Rita Rita5, Roberto Udisti5, David Cappelletti1 (david.cappelletti@unipg.it)
1University of Perugia, Department of Chemistry, Biology and Biotechnology, Perugia, Italy, 2University of Warsaw, Institute of Geophysics, Warsaw, Poland, 3AWI - Alfred Wegener Institute for Polar and Marine Research, Potsdam, Germany, 4CNR - ISAC - National Research Council, Italy, Bologna, Italy, 5University of Florence, Department of Chemistry, Florence, Italy

This paper reports an exceptional biomass burning (BB) advection event from Alaska registered at Ny-Ålesund from 10 to 17 July 2015 with special interest on the evolution of the particle characteristics and mixing state over time in relation to the optical properties of the aerosol. To this purpose we considered two DEKATI 12-stage aerosol samples spanning over the entire advection and analyzed them by scanning electron microscopy (SEM) techniques. Daily chemical data and hourly optical measurements were also evaluated in order to correlate individual particle characteristics with bulk aerosol properties at ground level. Results depict a complex advection event characterized by a first phase (P1) of massive input of BB organic particles (OPs), and by a second phase (P2) dominated by inorganic salts (ISs). The mixing state conditions also varied greatly, ranging from prevailing internal mixing of IS on OPs in P1 to prevailing external mixing of IS and MD particles with pre-existent OPs in P2. Optical measurements at ground level of Jul 10 are in good accordance with the particle features, but rapidly evolved likely due to a strong increase of the grain size by hygroscopic growth upon humidification. The observations reveal the influence of aging effects due to the long-range transport and to the stationing of the BB particles in the boundary layer.

JGR., 121 (2016) 14487-14512.
Pico Mountain Observatory (PIC) is a mountaintop research station located in the summit caldera of the Pico Volcano (2225 m.a.s.l.) in the Azores. During summer, this site typically lays in the free troposphere, sampling air decoupled from the boundary layer, which is different from other mountaintop observatories. PIC and the Izaña station are the only places in the North Atlantic where free tropospheric air masses can be studied over extended periods of time. Therefore, PIC, due also to its central location in the Atlantic, is an ideal place to investigate atmospheric background conditions and long-range transport effects.

We will present results of the aerosol measurements conducted at PIC since 2012. This dataset includes aerosol scattering and backscattering (by a 3-wavelength integrating nephelometer), aerosol absorption, black carbon and iron containing particles mass concentration (by a 7-wavelength aethalometer) and particle concentrations for particles bigger than 300 nm (with a 2-channel optical particle counter). In addition, several filters were collected for chemical characterization (using ion chromatography and ultrahigh resolution mass spectrometry), for microscopy and elemental analysis, and for ice nuclei analysis. During two summer seasons, we used an instrumented backpack to measure the vertical distribution (from 1225 to 2351 m.a.s.l.) of particle concentrations, in-situ optical properties, aerosol optical depth, and meteorological parameters.
The study presents a long-term climatology of cloudiness over the Norwegian and Russian parts of the Arctic Ocean. The analysis is based on routine visual surface observations that conducted at island and coastal Russian and Norwegian stations from 1930s. Total and low cloud cover and fraction of different morphological cloud types are assessed. The climatology and inter-annual variability is evaluated separately for different seas (from the Norwegian to Chukchi seas) and for open-water and solid-ice regions. In general, total cloud cover (TCC) has higher intra- and inter-annual variability over SI than over OW. A decrease of TCC in the middle of the 20th century and an increase in the last few decades is revealed at individual stations and for the Atlantic sector. Long-term positive trend of convective and negative trend of stratiform cloud forms are found. Statistically significant relationship between cloudiness and sea-ice concentration is shown.
A recent study (Grazioli et al., 2017) has shown that a significant part of precipitation in Adélie Land sublimates in the upper part of the katabatic flow. On the other hand airborne snow particles eroded from the surface also sublimate in the lower part of the katabatic layer. The question raised here is to which extent both processes influence each other, as they may influence the surface mass balance of the antarctic ice sheet margin.

A new version of MAR (Modèle Atmosphérique Régional - Gallée, 2017, in preparation) has been developed, including a new blowing snow module. The code has been rewritten and parallelized using domain decomposition and the MPI (Message Passing Interface) software.

Validation show a good agreement between the model and observations made in Adélie Land. Sensitivity tests have been performed by switching on and off the blowing snow module, in order to better understand the interaction between snow precipitation and erosion by the wind. Here we show how the interaction develops along the slopes of Adélie Land.
The aim of this research is to investigate aerosol optical and microphysical properties during spring and summer conditions in the European Arctic. In the first part of the study, we performed a model-based investigation on spring and summer AOD trends in the last 15 years with the emphasis put on the changes in the occurrence of Arctic Haze and biomass burning transport events. We confirmed the negative trend of Arctic Haze AOD and a positive one of the latter. Secondly, we estimated mean spring conditions of the aerosol optical and microphysical properties (such as scattering and absorption coefficients, single scattering albedo, Angstrom exponent, AOD, etc.) during background conditions and high concentration events of respective aerosol species. These results utilised in-situ measurements from spring campaigns conducted in 2014-2017 at Ny-Alesund, Spitsbergen under iAREA (Impact of Absorbing Aerosols in the European Arctic) project. Finally, an investigation of HYSPLIT back-trajectories during high load events was performed indicating possible source regions of particular aerosol species.
In situ and satellite-based observations reveal the existence of two types of optically thin ice cloud (TICs) in the Arctic during the polar night. The first type, TIC-1, consists of small none precipitating ice crystals and invisible to the CloudSat radar. The second type, TIC-2, is detected by CloudSat radar and CALIPSO lidar and is characterized by a low concentration of large ice crystals of sufficient size to precipitate. Energy budget diagnostics appears to be one of the most efficient ways to improve functioning physical mechanisms in atmosphere. In this study, the energy cycle equations as formulated by Nikiéma and Laprise (2013) will be used to analyse the energy budget of the atmospheric circulation in the Arctic during the polar night. To address this question, satellite-based observations (CloudSat and CALIPSO) are used to characterize the ice clouds and analyze the atmospheric conditions conducive to their formation. A reanalysis driven application of the Canadian Regional Climate Model version 5 (CRCM5) is used to perform two simulations, one with the TIC-1 conditions and the other with TIC-2 conditions. A comparative analysis will be carried out to determine the role of the thin ice cloud according to their type in the response of the energy balance. Overall, this study contributes to evaluate the relative importance of polar clouds on the atmospheric energy balance.
Urban areas in many high latitude regions have been shown to suffer from regular air quality standard violations, particularly during winter. Locally produced air pollution, in combination with cold, stagnant weather conditions and strong inversion layers, can lead to significant localized pollutant concentrations. Despite these effects, there are important knowledge gaps in our understanding of chemical and physical processes occurring under polluted conditions with limited sunlight and very low temperatures. Studies suggest wintertime aerosol in high latitude urban areas often comprises large mass concentrations of fine particulate organic carbon resulting from domestic wood burning, as well as substantial sulfate mass fractions. However, our knowledge about formation mechanisms, based on lower latitude studies, cannot explain these aerosol abundances under conditions of limited photochemistry.

We will present an overview of current knowledge regarding sources, processing and fate of wintertime air pollution in high latitude urban environments, and discuss challenges related to reconciling understanding of pollution formation and loss processes with limited observations available. A roadmap for recommended action to address knowledge gaps, being developed under the IGAC/IASC PACES (air Pollution in the Arctic: Climate, Environment and Societies) initiative will be presented, including plans for an international field experiment and new model evaluation activities.
Cloud, Aerosol, and Radiation Observations at Multiple Polar Sites

James Mather¹ (jim.mather@pnnl.gov), Kim Nitschke², Heath Powers², Maciej Ryczek², Jennifer Comstock¹
¹Pacific Northwest National Laboratory, Richland, United States, ²Los Alamos National Laboratory, Los Alamos, United States

The Atmospheric Radiation Measurement (ARM) facility is operated by the United States Department of Energy and provides extensive suites of atmospheric instrumentation for studying the interactions among clouds, aerosols, precipitation, and the surface energy budget at multiple ground-based observatories around the world (www.arm.gov). Two of these observatories are deployed for about a year at a time through a competitive proposal process. One of these deployable observatories has recently undertaken two separate missions to Antarctica and the surrounding Southern Ocean (which will have just recently been completed at the time of the Polar 2018 conference) and will soon be deployed on a third polar mission to the central Arctic Ocean as part of the Multidisciplinary Drifting Observatory for the Study of Arctic Climate (MOSAIC) initiative. ARM also operates two observatories along the North Slope of Alaska, in Barrow and Oliktok, which will be the subject of a separate presentation. The goal of this presentation is to provide an overview of the capabilities of these ARM Mobile Facilities, highlight some observations obtained from these unique deployments, and describe how scientists interested in polar measurements can engage with the ARM facility, either through analysis of previously archived data (which are available to anyone) or by proposing future field campaigns.
Aerosols affect the Arctic radiative budget directly by interfering radiation and indirectly by modifying clouds. Black carbon (BC) in snow/ice can reduce the surface albedo. The direct radiative impact of aerosols on the Arctic climate can be either warming or cooling, depending on their composition and location. Anthropogenic emissions, especially, BC and SO$_2$, have changed drastically in low/mid-latitude source regions in the past few decades. Arctic observations show that BC and sulfate aerosols had a decreasing trend in the recent decades.

We use the Community Earth System Model (CESM) equipped with a BC and sulfur source-tagging technique to quantify the source-receptor relationships and decadal trends of Arctic sulfate and BC during 1979-2014 and to identify variations in their transport pathways from lower latitudes. Emissions came from the CMIP6 datasets, which show strong regional trends in BC and SO$_2$ emissions during the simulation time period. Results show that emissions from East Asia and South Asia together have the largest contributions to Arctic sulfate/BC and their increasing trend in the upper troposphere, while the strong decrease in emissions from Europe, Russia and North America contributed significantly to the overall decreasing trend, especially, in the lower troposphere. The long-term changes in the spatial distributions of aerosols, their radiative impacts and source attributions, along with implications for the Arctic warming trend, will be discussed.
Changes in global Sea Surface Temperature (SST) gradients modulate the strength of the Southern atmospheric teleconnections, but the implications for Antarctic ice sheet (AIS) surface mass balance (SMB) are seldom investigated. Considering the Plio/Pleistocene transition as a good past analogue to future SST changes over the 21st century, idealized numerical Pliocene atmospheric and SMB simulations show that strong SST gradients induce dynamical changes that enhance or dampen the sensitivity of the AIS to teleconnections. A strong meridional SST gradient increases the influence of the Southern Annular Mode over the AIS Pacific sector. A strong zonal equatorial SST gradient strengthens the stationary Rossby wave pattern between East Australia and the Amundsen Sea, modifying the moisture fluxes pathway, which brings more precipitation over the main drainage basins of the East AIS. Similar dynamical mechanisms are simulated for projected RCP2.6 and RCP4.5 Antarctic SMB changes but compensations occur between the effect of teleconnections and the mean climate states of the simulations. Under warm climates, the SMB sensitivity to teleconnections increases, even though the atmosphere dynamics weakens and vice-versa under cold climate conditions. Although the mean climate state is a good indicator for future AIS changes, local SMB, modulated by teleconnections, might influence the retreat of key marine-based sectors.
SSW Signatures of Semidiurnal Tides and 2 Day Waves in Low Latitude MLT Region

Koushik N1 (koushiknk@gmail.com), Karanam Kishore Kumar1, Geetha Ramkumar1, Kandula V Subrahmanyam1
1Space Physics Laboratory, Vikram Sarabhai Space Centre, Indian Space Research Organisation, Thiruvananthapuram, India

Sudden Stratospheric Warming (SSW) events are found to be capable of significantly affecting the low latitude middle atmosphere. In the present study, we examine the signatures of SSW events in semidiurnal tides and quasi 2-day waves in the Mesosphere- Lower Thermosphere (MLT) region over low and equatorial latitudes using meteor wind radar observations from two stations Thumba (8.5°N, 76.5°E) and Kototabang (0.2°S. 100°E). After developing the climatology of the above parameters, behavior of equatorial and low latitude MLT region during typical polar stratospheric conditions, namely Quiet winter, Major SSW winter and Minor SSW winter, is investigated. The analysis clearly shows the amplification of semidiurnal tides during major SSW events, albeit the magnitude of enhancement varies from event to event. Interestingly, the semidiurnal tidal amplitudes are found to enhance selectively in zonal and meridional components, respectively over the low latitude and equatorial stations. Quasi 2-day wave amplitudes over both the observational sites increased in association with SSW events, with anomalously large amplitudes as high as 95 m/s during the minor SSW of January 2012. Unlike many case studies, the present study distinctively demarcates the characteristic response of semidiurnal tides and quasi 2-day waves simultaneously over low latitude and equatorial MLT region to typical polar stratospheric conditions.
Influence of ENSO, PDO and Climate Change on Tropical Andean Glaciers

Bijeesh Veettil¹ (bijeeshnair1982@gmail.com), Jefferson Simões²
¹Universidade Federal do Rio Grande do Sul / INCT da Criosfera, 970, Brazil, ²Universidade Federal do Rio Grande do Sul / INCT da Criosfera, Porto Alegre, Brazil

Since the late 1970s, tropical Andes witnessed rapid glacier shrinkage in parallel with a warming trend observed in this region. Variation in the maximum snowline during the dry season (austral winter), which can be taken as nearly equivalent to the equilibrium line in the tropical Andes, was estimated using satellite data for selected glaciers along the tropical Andes since the early 1980s. Meteorological datasets were also analysed to observe changes in precipitation, temperature, and humidity. Inner tropical glaciers, particularly those situated near the January Intertropical Convergence Zone (ITCZ), are more vulnerable to increases in temperature and these glaciers are less sensitive to variations in precipitation. In contrast, outer tropical glaciers respond to variations in precipitation very rapidly that to temperature changes, particularly when moving towards the subtropics. Glaciers in the northern tropics and dry outer tropics showed relatively slower retreat, possibly due to the occurrence of cold phases of El Niño-Southern Oscillation (ENSO) and Pacific Decadal Oscillation (PDO) together in some years. The observed anomalies in the meteorological variables slightly follow PDO patterns and annual snowline variations follow El Niño events, particularly when in phase with warm PDO.
Influence of SST in the Tropical Oceans on the Arctic Climate

Genrikh Alekseev1 (alexgv@aari.ru), Svetlana Kuzmina2, Natalia Glok1
1Arctic and Antarctic Research Institute, St. Petersburg, Russian Federation, 2Nancen Center, St. Petersburg, Russian Federation

The first objective is to assess the role of meridional atmospheric heat and moisture transport (MAHT) in the temperature variations in the Arctic. MAHT across 70N into 70-90N area was calculated using ERA/Interim reanalysis data for 1979-2016. It is found that main inflow in winter comes across 0-80E within layer between the surface and 750 hPa and explains more than 50% of variability of surface air temperature in the 70-90N area. The second objective was to assess the influence of SST anomalies in the low latitudes of Atlantic, Indian and Pacific oceans on change in the winter MAHT to the Arctic. The area and month with maximal correlation between SST and winter MAHT (up to 0.75) as well as respective lags (27-30 months) in each ocean were found. The third objective is an assessment of the influence of SST anomalies on sea ice cover in the Arctic. Series of water temperature at the section in the Barents Sea, sea ice extent and surface air temperature in the Arctic were used additionally. It is found intimate link between change of Atlantic SST in low latitudes and sea ice extent in the Arctic with correlation coefficients up to 0.90 and delays up to 3 years. A mechanism of the influence of SST anomalies in low latitudes on winter MAHT, sea ice and air temperature is proposed. It includes the interactions of atmospheric (Hadley and Ferrel circulations, NAO) and oceanic (Gulf Stream, the North Atlantic and the Norwegian currents) circulation patterns.
One of the most visible and iconic aspects of recent climate change is the dramatic loss of Arctic sea-ice. Without efforts to slow manmade global warming, an ice-free Arctic would likely occur in summer by the middle of this century. The precise timing of an ice-free Arctic will depend however, on both the magnitude of future human-induced global warming and upon the magnitude and phasing of internal climate variability. This talk will present results from a large initial condition ensemble of global climate model simulations. Each ensemble member has a different realization of internal variability superimposed on the underlying externally forced response. Ensemble members that transition more quickly from present-day to ice-free conditions tend to be those that over the same time period are transitioning from negative to neutral/positive conditions of the Inter-decadal Pacific Oscillation (IPO). The phase of the IPO can shift the projected timing of first ice-free conditions by 5-10 years. Ensemble members that depict the IPO- phase in the 10-year period ending 2016 tend to transition toward IPO+ in the following decades, which accelerates the loss of ice and leads to an earlier projection of ice-free conditions. If the real world IPO continues to transition towards it’s positive phase, away from IPO- in the recent past, this may hasten the emergence of ice-free summers in the Arctic.
Understanding the Interactions between Polar, Midlatitude and Tropical Regions

Irina Rudeva¹² (irina.rudeva@unimelb.edu.au), Ian Simmonds¹
¹University of Melbourne, Melbourne, Australia, ²P.P. Shirshov Institute of Oceanology, Moscow, Russian Federation

Many studies document Southern Hemisphere tropical and midlatitude influences on the Antarctic sea ice, and, vice versa, Antarctic sea ice influence on the midlatitudes and tropics. Analogous types of associations have been documented for NH polar and midlatitude/tropical regions. In this study potential teleconnection patterns are identified using a range of techniques, including ray tracing (e.g. Karoly 1983, Shaman et al. 2012) and wave activity flux (WAF, Takaya and Nakamura 2001). These approaches allow one to diagnose a path of wave packets that propagate from a specific region, that can be interpreted in terms of 'waveguides'. A suit of low-frequency and stationary ray tracing experiments will be conducted with an ensemble of rays starting within Arctic/Antarctic sea ice regions and, then, midlatitude/tropics to identify 'hot spots' within them.

Particular attention will focus on the refraction of rays and to what extent the stationary and low-frequency waves can 'escape' the sea ice zone regions, hence, be able to influence climate in lower latitudes.
Black Carbon Deposition to Antarctica: Low Latitude Hydroclimate Teleconnections

Monica Arienzo\textsuperscript{1} (marienzo@dri.edu), Joe McConnell\textsuperscript{1}, Nathan Chellman\textsuperscript{1}, Kelly Gleason\textsuperscript{1}, Sepp Kipfstuhl\textsuperscript{2}

\textsuperscript{1}Desert Research Institute, Reno, United States, \textsuperscript{2}Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Meeresforschung, Bremerhaven, Germany

Black carbon (BC) and other biomass-burning emissions increasingly are recognized as major components of climate forcing. BC aerosols impact climate directly by changing Earth’s radiation budget and indirectly by reducing albedo when deposited on bright surfaces such as snow and ice. Yet quantification and predictive climate modeling have been hampered by limited understanding of the drivers of regional-scale biomass burning and few long-term burning records.

In this work, we will compare the Antarctic BC results from an array of eastern Antarctic ice cores to low-latitude paleoclimate proxies to investigate a potential link between low latitude climate, biomass burning, and BC emissions. We will present high-resolution records of BC concentration and BC particle mass distributions (a proxy for BC particle sizes) from these ice cores focusing on the last 2,000 years of BC deposition. For BC concentration and particle mass determinations, ice cores were analyzed using the Desert Research Institute continuous flow analysis method, allowing for seasonal resolution of BC measurements. Results will be compared between ice cores, to previously published BC modeling results, and to low latitude hydroclimate records from the BC source areas to determine potential teleconnections between the low and high latitudes.
The Ellsworth Mountains are located at the intersection between the western border of the West Antarctic Ice Sheet and the Ronne Ice Shelf (RFIS), at the base of the Antarctic Peninsula (AP). Several firn cores retrieved from this region in 2014 and 2015, were analyzed for stable water isotopes and glacio-chemical content. The dating of the cores shows that the accumulation in this region is relatively high for inland regions but low for coastal areas, with annual accumulation ranging between 200 and 400 kg m$^{-2}$ y$^{-1}$. A clear decrease of the accumulation is observed from the ice shelf border inland, with a clear orographic effect of the mountains. This indicates that moisture masses approached the region from the Weddell Sea (and not from the Bellingshausen-Amundsen Sea). Annual accumulation values show a strong decrease from the 1970’s to present, with the annual mean falling by a 50%. This is the opposite of observations made on the west coast of the AP, where accumulation has doubled during the last century. In this work we will integrate circulation model and re-analysis datasets to explain the strong decrease of accumulation during recent decades and its link to changing oceanic conditions, with special focus on sea ice variability and the environmental forcing of the accumulation variability. Finally, we will compare our results to CMIP5 to better calibrate our observations and to generate future predictions, which are important to determine the stability of the RFIS.
Sea ice is an important player in the global climate system owing to its properties:
1) it acts as an insulator between ocean and atmosphere,
2) it is an efficient reflector of incoming shortwave radiation and
3) phase changes related to freezing and melting processes alter the vertical stability characteristics of the water column and therefore ocean circulation.

Of the Arctic Ocean, the Barents-Kara Seas have experienced the largest loss in sea ice cover since the start of the observational period in 1979. For the atmospheric flow, areas of sea ice loss/reduction mean a change in the lower boundary condition. Areas of sea ice loss are characterized by increased latent and sensible heat fluxes from the ocean to the atmosphere, elevated near-surface air temperature and reduced vertical stability. Re-analysis data have revealed November sea ice anomalies to have a significant impact on later winter sea level pressure, surface air temperature, and precipitation anomalies over the Euro-Atlantic sector (García-Serano et al. 2015). The proposed coupled response with the stratospheric polar vortex could explain the delayed late-winter tropospheric response in the North Atlantic Oscillation seen in observational and modeling data. This study aims at investigating this aspect further by initializing a seasonal prediction system with reduced sea ice cover in the B/K Seas in autumn to study the timing and character of the atmospheric response in the following winter season.
Arctic Warming and the Amazon Rainforest Precipitation

Enoil de Souza Junior¹², Eder Bayer Mayer³, Jefferson Cardia Simões²

¹University of Manitoba, Winnipeg, Canada, ²Universidade Federal do Rio Grande do Sul / INCT da Criosfera, Porto Alegre, Brazil, ³Universidade Federal do Rio Grande, Rio Grande, Brazil

The current atmospheric warming of the Arctic may weaken the Azores high pressure centre and, consequently, weaken the northeast trade winds, may reduce precipitation in part of the Amazon region. From this hypothesis, we explore possible teleconnections between the variability in the extent of Arctic sea ice and the volume of precipitation in low latitudes. Using NCEP reanalysis data for precipitation in the Amazon and NSIDC data for the extent of sea ice over the period 1979-2015, a linear regression analysis shows a positive correlation around r = 0.4. When we selected a point in the Amazon region called P1 (r = 0.45), where we extracted a time series for the volume of precipitation to compare with the Arctic sea ice variability, a linear scatter plot shows r-square = 0.2. The work also shows the behaviour of the pressure fields that highlight the teleconnections described here.
This work examines the South Pacific Ocean climate variability as recorded by two proxies (MSA and δ¹⁸O) from an ice core collected in the Pine Island Glacier at the Mount Johns site (79°55′S, 94°23′W; 2100 m a.s.l.). The two proxies show a positive trend in the period 1979-2008 [MSA (+0.210 µg L⁻¹ a⁻¹), and δ¹⁸O (+0.054‰ a⁻¹)]. At the same time, the Southern Hemisphere annular mode index (SAM) showed a positive trend in summer (+0.078 a⁻¹) and in autumn (+0.050 a⁻¹), indicating a more intense cyclogenesis in the Southern Ocean, displacement of the storm tracks towards the south, the deepening of the Amundsen Sea Low and the decrease in the sea ice extent, contributing to a greater advection of oceanic air masses into the interior of the Western Antarctica ice sheet, these are the probable causes for the positive trends of the two proxies. In winter and spring, the SAM does not show the same tendency (-0.004 a⁻¹) and (+0.004 a⁻¹), favouring the displacement of the polar jet stream and the storm tracks to the north, increasing the south flow from the Antarctic Plateau to the Mount Johns region. We also discuss the influence of the ENSO phenomenon on the environmental variability of the Mount Johns region.
Influence of Tropical SST on Antarctic Sea Ice in the Global Warming

Genrikh Alekseev\textsuperscript{1}, Nanalia Glok\textsuperscript{1} (glok.natasha@mail.ru), Anastasia Vyazilova\textsuperscript{1}, Nikolai Ivanov\textsuperscript{1}, Alexander Smirnov\textsuperscript{1}

\textsuperscript{1}Arctic and Antarctic Research Institute, St. Petersburg, Russian Federation

The sea ice cover in the Antarctic did not show a downward trend for the observed global warming while global climate models show a decrease. The aim of our study is to explain this climatic phenomenon on base of the idea of joint dynamics of ocean structures in the Southern Ocean - the Antarctic circumpolar current (ACC), the Antarctic polar front (APF) and the edge of the maximumal extent of sea ice while the locations of these structures are changed under the influence of SST anomalies in low latitudes. We used ERA/Interim, HadISST data and sea ice data base for 1979-2016. The dependence between SST anomalies in the low latitudes of the Northern Hemisphere and the position of the Antarctic polar front, maximum sea ice extent is found. The obtained results reflect the opposite trends in the change of sea ice extent in the Arctic and in the Antarctic under the influence of SST anomalies in common region of the North Atlantic. This influence is spread by means of the shift of atmospheric circulation modes (intertropical convection zone (ITCZ), the Hadley circulation (HC)) to the north with a positive SST anomaly and vice versa for negative anomaly with the corresponding displacements of the zonal modes in the atmospheric circulation in the Southern hemisphere (AAO, SAM) and zonal ocean modes (ACC, APF) in the Southern Ocean, followed by the boundary of sea ice extent.
During the last two decades, when surface air temperature (SAT) in the Arctic increased faster than globally, several abnormally severe winters occurred in northern continents. The "warm Arctic/cold continents" pattern of SAT anomalies in these winters has often been attributed to the Arctic sea ice loss. Here, using monthly mean fields from the ERA-Interim reanalysis, we investigate a spectacular event of this type observed in autumn 2016. Anomaly fields for each month in 2016 were constructed by removing local, 1979-2016 means from the raw data. In October 2016, negative SAT anomalies reached about 6°C over Eurasia (mainly in the Asian sector). They were accompanied by a weaker "cold spot" in North America and positive SAT anomalies exceeding 8°C in the Arctic. This SAT anomaly pattern was driven dynamically by an abnormal atmospheric circulation, as indicated by a wavenumber-2 pattern of sea level pressure anomalies with major centres of action over Scandinavia and North Pacific. In October 2016, temperature advection by northerly wind anomalies over Asia exceeded by far (4 times) the corresponding standard deviation in the 1979-2016 period. The distribution, magnitude and timing of the anomalies of sea ice concentration, sea surface temperature and surface heat flux from September to December indicate that the atmospheric circulation anomaly in autumn 2016 was rather triggered by anomalous air-sea interactions in the North Pacific than by Arctic sea ice anomalies.
Antarctic Surface Temperature Variability and its Relation to ENSO

Gabriel Retamales-Muñoz\textsuperscript{1}, Claudio Duran-Alarcon\textsuperscript{2}, Cristian Mattar\textsuperscript{1} (cmattar@uchile.cl)
\textsuperscript{1}Universidad de Chile, Laboratory for Analysis of the Biosphere (LAB), Santiago, Chile, \textsuperscript{2}Université Grenoble Alpes, Institut des Géosciences de l’Environnement (IGE), Grenoble, France

The variability of Antarctic tropospheric circulation is dominated by the Antarctic Oscillation (AO) and influenced by El Niño-Southern Oscillation (ENSO), due to the low-high latitude atmospheric teleconnections. Previous works have evidenced the impact of the warming/cooling phases of ENSO (El Niño/La Niña) on the distribution of precipitations, sea ice and near-surface temperature mainly in west Antarctica. Under a climate change scenario, the frequency of extreme El Niño episodes is expected to increase in response to a projected eastern equatorial Pacific warming. Therefore, the aim of this work is to assess the role of ENSO on the Antarctica Land Surface Temperature (LST) during the last century until the present in the framework of a project of the Chilean Antarctic Institute (INACH). LST is retrieved using data from MODerate resolution Imaging Spectroradiometer (MODIS), ERA-Interim and ERA 20\textsuperscript{th} Century reanalysis and in-situ weather stations. Non-parametric test were used to estimate the trend of LST and the correlation in different spatiotemporal scales to the Oceanic Niño Index (ONI). Preliminary results showed a cooling trend (-0.324 K/decade; p>0.05) over the Peninsula and the eastern part of the Antarctic zone in the period of years 2001-2016. We also explore the seasonal variation of these trends and the relationship to ONI. The cooling and warming evidence contributes to better understand the surface temperature of antarctic climate system.
ENSO and SAM Influence in Southern Brazil Precipitation Anomalies

Pedro Valente1,2, Francisco Aquino1,2, Pedro Reis1,2, Jefferson Simões1,2 (jefferson.simoes@ufrgs.br)
1Universidade Federal do Rio Grande do Sul / INCT da Criosfera, Geography, Porto Alegre, Brazil, 2Centro Polar e Climatico, Instituto de Geociências, Porto Alegre, Brazil

We used precipitation data from the University of Delaware reanalyzeres, zonal and meridional wind, geopotential height (925, 500 and 200 hPa), OLR anomalies (ERA-Interim), Niño (CPC/NOAA) and SAM (Marshall) index to examine the influence of the El Niño-Southern Oscillation (ENSO), the Southern Annular Module (SAM) and atmospheric circulation in the Southern Brazil (SB) spring and summer precipitation anomalies (1970-2000 period). Previous studies indicated positive (negative) precipitation anomalies during El Niños (La Niñas), but these anomalies vary with the ENSO intensity and its interaction with the SAM, by altering the atmospheric circulation pattern between Tropics and Antarctica. In summer, positive precipitation anomalies in El Niño exceed 150 mm, with weak (strong) SAM (Niño), negative anomalies below 50 mm with neutral (moderate) SAM (Niño). Negative anomalies below 100 mm occur with neutral (strong) SAM (Niño). In spring, in El Niño years, positive (negative) anomalies of geopotential height are observed in the SB and negative (positive) anomalies in the subtropical jet. In La Niña years, the subtropical jet is strengthened (weakening of the subpolar jet) and there is a negative (positive) geopotential anomaly in the SB region and in Bellingshausen Sea (Weddell). We identified that the positive precipitation anomalies are more frequent during La Niñas, despite the highest occurrence in El Niños.
The High Frequency Variability of Antarctic Sea Ice and Transient Systems

Camila Carpenedo¹ (camila.carpenedo@ufu.br), Nathalie Boiaski², Tércio Ambrizzi³

¹UFU, Geography, Uberlândia, Brazil, ²UFSM, Physics, Santa Maria, Brazil, ³USP, Atmospheric Science, São Paulo, Brazil

There is a great potential for Antarctic sea ice to affect atmospheric circulation, because its extent located in a very sensitive region, to the south of the Southern Hemisphere baroclinic zone of the. Thus, the objective of this study is to evaluate the propagation of transient systems over South America (SA) associated with the high frequency of Antarctic sea ice variability. We employed the NSIDC Antarctic sea ice dataset for the Bellingshausen-Amundsen Seas (BAS) and Weddell Sea (WS) sectors and the ECMWF ERA-Interim global atmospheric reanalysis. The anomalies without linear tendency were filtered for the 2-10 day period, generating a daily high frequency anomaly dataset. The quartile analysis defined the extreme high frequency sea ice anomalies. In the austral winter (JJA), extreme sea ice retraction (expansion) events for the BAS sector were associated with the extratropical (tropical-extratropical) high frequency wave train. Consequently, there are air temperature anomalies at 2 meters over the SA extratropical (tropical-extratropical) latitudes, with the warming/cooling associated with low / high anomalous surface air pressure. On the other hand, the high frequency wave train associated with extreme sea ice retraction (expansion) events in the WS sector does not affect SA, but suggest heating/cooling event modulation over Australia.
The Kongsfjorden, an Arctic fjord is experiencing warming due to increased input of Atlantic water masses. High-throughput sequencing was performed to examine bacterial diversity from the outer and inner zone of the fjord in summer and fall. A total of 11,999 operational taxonomic units (OTUs) were assigned into 19 known phyla and 5 genera incertae sedis. Significant variation ($p = 0.001$, $n = 4$) was observed between the bacterial community structure of outer and inner fjord while variation between summer and fall was minimum. *Proteobacteria* was the most abundant phylum (55.9-61.0%) in summer and fall. The most dominant alphaproteobacterial member of this phylum (OTU 263 *Pelagibacteriaceae*) contributed maximum to the observed dissimilarity between the outer and inner fjord community. Characterised by relatively fresher and warmer water, glacial meltwater input could be a major source of predominance of *Flavobacteriaceae*, *Psychrobacter*, *Sphingomonadales* and *Loktanella* in the inner fjord in summer. Thus, the significant variation in the bacterioplankton community composition of outer and inner fjord indicates strong and localized influence of glacial melt water in shaping the community structure.
The Diversity of Ice Algal Communities on the Greenland Ice Sheet

Stefanie Lutz¹ (stlutz@gfz-potsdam.de), Jenine McCutcheon², James B. McQuaid², Liane G. Benning¹²³
¹GFZ German Research Centre for Geosciences, Potsdam, Germany, ²School of Earth & Environment, University of Leeds, Leeds, United Kingdom, ³Free University of Berlin, Department of Earth Sciences, Berlin, Germany

The Greenland Ice Sheet (GrIS) is an important component of Earth’s cryosphere. Due to the extensive area over which surface melting occurs, which can be up to 100% during extreme melt events, it can be regarded as the largest supraglacial ecosystem on Earth. Ice algae are the dominant primary producers on bare ice surfaces throughout the course of a melt season. Ice-algal-derived pigments cause a darkening of the ice surface, which in turn decreases albedo and increases melt rates. Their role and importance in changing melt rates has only recently been recognized, yet we know little about their community compositions and functions. Here we present the first high-throughput sequencing analysis of ice algal communities along a 100 km transect across the ‘dark zone’ of the GrIS combined with subsequent oligotyping of the most abundant taxa. Our data reveal an extremely low algal diversity with Ancylonema nordenskiöldii and a Mesotaenium species being by far the dominant taxa in all sites. We show that an OTU-based approach is not sufficient for the evaluation of the low ice algal diversity on the GrIS. Oligotyping revealed hidden diversity that could not be detected by conventional clustering of OTUs. Oligotypes of the dominant taxa exhibit a site-specific distribution, which may be linked to different stages in the melt season. Our results document for the first time the unknown distribution patterns of ice algal communities that play a crucial role in the GrIS ecosystem.
Particle-associated and Free-living Bacterial Communities in Kongsfjorden

Anand Jain, Femi Anna Thomas, Rupesh Kumar Sinha, Archana Singh, Kottekkatu Padinchati Krishnan

1National Centre for Antarctic and Ocean Research (ESSO-NCAOR), Cryobiology, Vasco da Gama, India

Particle-associated bacteria are likely to play an increasing role in coastal biogeochemistry and carbon fluxes as a result of increased particle transport to coastal Arctic waters. However, few studies have characterized particle associated (PA) and free-living (FL) bacterial communities in coastal Arctic ecosystem. In the present study V3-16S rRNA amplicon sequencing was used for analyzing difference between free-living (FL, < 1.2 to 0.2 mm) and particle-associated (PA, >1.2 mm) bacterial community, and their spatial variation between inner fjord (IF) and outer fjord (OF) of Kongsfjorden. A total of 4,454,142 high quality V3-16S rRNA sequences obtained clustered into 32,058 OTUs which are distributed among 24 known bacterial phyla. There was a clear spatial variation among FL bacterial community, while PA community remained similar at both sampling locations. In addition, FL bacterial community differs from that of PA community and had relatively higher abundance (>4 fold) of Alteromonas and Pseudoalteromonas, while PA community was relatively more enriched with Balneatrix, Ulvibacter, Formosa, Candidatus Planktomarina, Sulfitobacter, Loktanella, members of SAR116 and Acidimicrobiales. However, certain bacterial taxa Polaribacter and SAR11 co-occurred in both FL and PA fractions with varied proportions in IF and OF. Our results suggest co-occurrence of both PA and FL specialist as well as generalist bacterial groups in Kongsfjorden.

Bacterial Diversity in Rocks over 14 Localities of Victoria Land, Antarctica

Claudia Coleine1 (coleine@unitus.it), Fabiana Canini1, Laura Selbmann1, Jason E. Stajich2, Silvano Onofri1, Laura Zucconi1

1University of Tuscia, Department of Ecological and Biological Sciences, Viterbo, Italy, 2University of California, Department of Microbiology and Plant Pathology and Institute of Integrative Genome Biology, Riverside, United States

The endolithic microbial communities represent a borderline adaptation to extreme environmental stressors and are the predominant life form in the ice-free regions of Victoria Land, Antarctica. In the last decades, many studies focused on prokaryotic component in soils, while our understanding and knowledge on distribution and structure of bacteria in endolithic communities are still limited. In this study, we investigated the diversity of bacteria in cryptoendolithic communities growing within sandstone in Victoria Land, Antarctica. Rock samples were collected from 14 different sites, ranging from 1000 to 3300 m a.s.l. of altitude and over a latitude of about 3°. V4 region of 16S rDNA was sequenced through meta-barcoding approach on Illumina platform. Our results showed that Actinobacteria and Alphaproteobacteria are predominant among all samples as 'core' group component of the bacterial taxa characterizing these communities. The general belief that such extreme environments harbor a relatively low species diversity was confirmed by the diversity indices values. In addition, the detection of a higher number of unclassified bacterial phylotypes respect to many other environments (about 20% of relative abundance) suggests that Antarctic rocks host a pool of novel taxa.
Investigation of glacial habitats became a priority due to the impact of climate changes on the dynamics of Polar and alpine glaciers. Our study focused on cave ice microbiome unraveled the diversity of total and active bacterial communities from the 13,000 years old ice chronosequence of Scarisoara Ice Cave, Romania. Vertical ice coring of the perennial ice block was carried out, reaching a record depth of 25.3 m. Radiocarbon dating of the ice core indicated a linear chronosequence up to 13,000 years B.P.

16 melted ice samples from every 1,000 years interval were filtered and used for total DNA and RNA extraction and geochemical analyses. Chemical parameters revealed large variations for the last 5 centuries followed by a stable period, and significant changes in the 5000 years B.P. ice layer. Bacterial diversity based on 16S rRNA gene MiSeq Illumina sequencing of both gDNA and cDNA is currently underway. Correlation with the chemistry of the ice substrate will unravel the microbial resilience, highlighting the active community composition in this habitat for the last 13,000 years. Total and viable microbial content of each sample was quantified by qPCR and LIVE/DEAD staining, indicating a correlation with age and organic content of the ice.

This report of the oldest cave ice chronosequence could contribute to identifying biomarkers of climate and environmental changes.

Acknowledgments: This work was supported by the UEFISCDI H2020 ERANET-LAC ELAC2014/DCC0178 joint project.
Microbial communities are often described by the diversity of 16S and 18S rRNA gene amplicons. The cost of amplicon sequencing has dropped considerably in recent years, making analyses of hundreds or thousands of samples a reality for even single investigator projects. Although this approach continues to provide enormous insight into microbial ecology, it can be difficult to interpret the metabolic processes underlying diversity without a priori knowledge of the observed taxa. To more easily connect 16S and 18S rRNA gene data with likely microbial metabolisms we developed paprica, an open source pipeline for metabolic inference. Rather than cluster reads into operational taxonomic units (OTUs), paprica assigns reads to their best location on a phylogenetic reference tree constructed from all completed genomes in Genbank. This allows for an easy analysis of samples through phylogenetic structure, and by associating environmental reads to the metabolism found at that location on the tree, metabolic structure. Paprica was initially developed for the analysis of marine samples from the western Antarctic Peninsula, but we have applied it to Antarctic marine and lake samples. Here we will provide an update on the paprica methodology, and highlight both the strengths and limitations of our approach.
The Pasvik river is one of the largest river in the Northern Fennoscandia. Its water conditions are representative of Eastern European rivers. The river collects snowmelt, and it is typically a freshwater environment at its inner zone and brackish at its outer zone. Sediment samples were collected from 9 stations during two seasonal surveys (May and July 2014). Physical-chemical parameters were monitored at sampling time. Samples were analyzed for viable heterotrophic bacteria, total prokaryotic abundance, microbial enzymatic activity rates, and phylogenetic composition of bacterial community. Microbial enzymatic activities generally increased in July, but showed spatial and temporal variability. In May, leucin aminopeptidase showed the highest values at outer stations (9.37 mmol/g/h). The bacterial community resulted highly variable among the sampling stations with the predominance of the Proteobacteria, followed by the Actinobacteria and CF group of Bacteroidetes. In July, an increased abundance of the Acidobacteria was observed at St.1 (from 4.7 to 22.1%). This study highlights both seasonal (May and July) and spatial differences within the microbial community that inhabit sediments along the Pasvik river. This finding is probably strictly dependent on freeze-thaw cycles of the water body, with consequent organic inputs to sediments in July. The microbial community appears to be adapted to fluctuating conditions modulated by seasonality.
Are they Really Poles Apart? Aerial Connection between High Latitude Ecosystems

David Velazquez¹ (david.velazquez@uam.es), Pablo Almela¹, Sergi Gonzalez², Francisco Vasallo³, Eugenio Rico⁴, Ana Justel⁵, Antonio Quesada¹

¹Universidad Autonoma de Madrid, Biology, Madrid, Spain, ²Agencia Española de Meteorologia, Barcelona, Spain, ³Agencia Española de Meteorología, Rota, Spain, ⁴Universidad Autonoma de Madrid, Ecology, Madrid, Spain, ⁵Universidad Autonoma de Madrid, Mathematics, Madrid, Spain

Extreme cold is a defining feature of High Arctic, Antarctic and Alpine sites which are separated by large distances and climatic barriers. Microbial environments are major features across those cryoenvironments. However, little is known about the biogeography and communalities of cold-dwelling microbes along the Cryosphere.

Recently attention has been focused on the rapid changes observed in polar regions. Summer warming in the Arctic has been observed to accelerate, peaking in the snow-free season and soil evapotranspiration. This alteration would potentially strength airborne microbial transportation at a planetary scale. In this context, Antarctica would become an ideal site for examining global scale microbial dispersal given that it is isolated from neighbour lands over 20 million years and it hosts habitats that are selective for the settlement and thriving of certain communities.

Generation times of bacteria in cloud-water mirror those in Arctic freshwater ecosystems and point out to atmosphere as a tributary site that may potentially act as bridge among the whole Cryosphere. Here, we test geographical isolation as an effective barrier to microbial transport by computing long distance trajectories from both Polar Regions and across different atmospheric layers. We study the 16S rRNA gene of different freshwater communities to evaluate the global affinities of low-temperature ecotypes throughout the Cryosphere.
Members of the Bangiales (Rhodophyta) are distributed worldwide from tropic to Antarctic and Arctic waters. Three species of the Bangiales, Bangia sp. (as B. atropurpurea), Pyropia endiviifolia (as Porphyra endiviifolium) and Wildemania plocamiestris (as Porphyra plocamiestris), have been reported in the Antarctic. Morphological and molecular data were investigated for the Bangiales from the Antarctic and its adjacent waters. Molecular data from over 150 taxa of the Bangiales worldwide including previously published sequences, indicated that the genera Bangia, Dione, Porphyra, Pyropia, Wildemania and other related genera be recognized in the Bangiales as in the previous molecular study. The Bangia sp. from the Antarctic was strongly allied to B. sp. from Atlantic Canada, interestingly. Pyropia endiviifolia is olive green in color and it allied to a clade with at least three Pyropia species from Falkland Islands, Navarino Island, Rio Seco and Punta Arenas, Chile. Wildemania plocamiestris growing on other macroalgae in sub-tidal zone grouped into the genus Wildemania with the species having one or two cell layers in molecular data. The diversity, taxonomic issues, phylogenetic relationships, distribution and the divergence times of the Antarctic members of the Bangiales will be discussed.
Global warming and climate change have been manifested in the decrease of Arctic sea ice extent and thickness. The thinner sea-ice regime has significant implications for Arctic primary productivity and biogeochemistry. It is therefore necessary to improve our understanding of microbial dynamics that ultimately drive productivity and the strength of the biological carbon pump in order to better predict future trends in Arctic biogeochemistry. In this study we present a comprehensive analysis of the biogeographic patterns of Arctic prokaryote and eukaryotic protist diversity and distribution along two oceanographic transects in late July 2016 crossing fjord, shelf and oceanic domains along the western (Kongsfjorden) and northern (Rijpfjorden) coast of Svalbard. A total of 11 stations were sampled at three depths (surface, chlorophyll maximum and above the seafloor) and amplification of 16S rRNA and 18S rRNA genes was performed and sequenced in Illumina MiSeq with a sequence depth of about 100 thousand read-pairs. The prokaryotic and eukaryotic protist data set comprises highly complex and diverse microbial communities with a marked biogeographic pattern. Strong links were identified between bacterioplankton and phytoplankton/picophytoplankton distribution driven by environmental and biogeochemical factors that will help to unravel the role of microbial pathways in supporting Arctic Ocean primary productivity and system integrity.
Highest Cyanobacteria Diversity on Granite Substrates in Sør Rondane Mountains

Valentina Savaglia1 (valentina.savaglia@uliege.be), Zorigto Namsarev1,2, Marie-José Mano1, Annick Wilmotte1

1University of Liège, InBioS-Centre for Protein Engineering, Liège, Belgium, 2NRC “Kurchatov Institute”, Moscow, Russian Federation

In the Sør Rondane Mountains (Dronning Maud Land, East Antarctica), cyanobacteria are mainly present in sheltered spots in rocky areas, supporting the importance of micro-topographic and climatic conditions. Biofilms, crusts and gravels on granite and gneiss substrates were sampled in 2009-2010 near the Belgian Princess Elisabeth Station and their morphological (126 samples) and molecular diversity (26 samples) was assessed. Furthermore, strains were isolated. A DNA extraction protocol was designed for the taxa with large polysaccharidic sheaths. Based on microscopy, crusts were the richest samples followed by gravels. The most diverse communities were found on the granites. Based on DGGE of 16S rRNA gene, 28 OTUs shared at least 97.5% of 16S rRNA similarity. OTUs’ richness varied between 1 and 5 per sample. A comparison of morphological and DGGE analyses showed that for most samples, the number of morphotypes was higher than the number of OTUs. However, both methods were congruent in defining the richest sites. The most frequently observed OTU was affiliated to *Phormidium/Microcoleus* sp. No OTU was common to all the 10 sites. The higher diversity on granite substrates (mainly big boulders) could be explained by higher stability of the underlaying rock and its ability to keep water on the surface, thus creating favorable conditions for development of organisms. Further insights will be given by the analysis of more samples with High-Throughput amplicon sequencing.
Snow covers >90% of glacial surfaces at the start of the summer and is a biologically active and dynamic habitat for microorganisms (Hodson et al., 2008) rather than merely a repository of deposited material. With a warming cryosphere, snow packs are getting wetter and less persistent globally but we are yet to understand the distribution of microbes and nutrients within different layers of a snowpack and how this supports the concept of the snowpack as an ecosystem. We therefore hypothesized that with the thermal evolution of a snowpack, greater heterogeneity will be expected in terms of microbial cell numbers, viability, species richness and nutrients within different layers. To test our hypothesis, we sampled seven different sites over four months from spring to summer on the Svalbard ice cap, Foxfonna. Snowpack communities were studied for microbial abundance, pigment inventories and nutrient chemistry. Our results demonstrate snow ecology is driven not only by meltwater evolution but by geochemical and physical changes within the snowpack as the melt season progresses. We also present microbial community analyses showing how the structure of microbial populations within snow and ice change during the transition from spring to summer. Our results highlight the importance of integrating snowpack physical and geochemical conditions to appreciate the dynamic response of resident microbes to seasonal melting in the High Arctic.
Compare and Contrast the Arctic and Antarctic Atmospheric CH₄-oxidizing Bacteria

Maggie Lau¹ (maglau@princeton.edu), Collin R. Edwards¹, Calvin Rusley¹, Tullis C. Onstott¹
¹Princeton University, Department of Geosciences, Princeton, United States

Annually thawed near-surface cryosols that occur in the Arctic and Antarctic exhibit atmospheric CH₄ (atmCH₄) consumption. AtmCH₄ is believed to be utilized by aerobic CH₄-oxidizing bacteria (MOB) that have high affinity for atmCH₄ (atmMOB). By deep sequencing of soil metagenomes and binning, we constructed 90%-complete genomes of Upland Soil Cluster (USC) alpha from Axel Heiberg Island, Nunavut, Canadian high Arctic, and USCgamma from Taylor Dry Valley, Victoria Land, Antarctica. This study aims to compare and contrast the genomes and metabolic potential of these two genotypes that occur in the acidic Arctic and alkaline Antarctic cryosols. USCalpha and USCgamma both possess the high-affinity form of methane monooxygenase, and enzymes for complete CH₄ oxidation. The atmMOB genomes do not code for soluble methane monooxygenase. No genes for nitrogen fixation were detected but nitrate reductase. The ribulose monophosphate (RUMP) pathway for assimilation of formaldehyde typically found in gamma-proteobacterial methanotrophs is not detected in the USCgamma genome. Notably, both atmMOB genomes indicate the potential to use acetate, and store and consume glycogen, suggesting that they may be facultative methanotrophs. This genetic information provides insight into their adaption to the changing climate and their respective roles in the carbon cycle of the polar terrestrial ecosystems.

Distribution of Picoeukaryotes in Summer and Autumn of the Southern Chukchi Sea

Fang Zhang¹ (zhangfang@pric.org.cn), Jianfeng He¹, Shunan Cao¹
¹Polar Research Institute of China, Shanghai, China

Picoeukaryotes dominate the photosynthetic biomass and will thrive with increasing temperature in the polar marine ecosystems. The study of picoeukaryotes in the Chukchi Sea are rare. This work relates the community distribution and composition of the picoeukaryotes to different water masses and physicochemical parameters in the southern Chukchi Sea in both the middle summer (July) and early autumn (September) of 2012. Chrysophyceae, Mamiellophyceae and Dinophyceae were the main microbial classes in July, with relative abundance > 0.5%. Mamiellophyceae, Chrysophyceae, Trebouxiophyceae, Mediophyceae and Dinophyceae were the main microbial classes in September. *Nannochloris* and *Bathycoccus* were indicators to the Alaskan Coastal Water. *Cryptococcus*, *Prasinoderma* and *Bolidomonas* were indicators to the Bering Sea Water. The prevalence of *Poterioochromonas malhamensis*, a nano-Chrysophyceae and a bloom disordered the distribution of the picoeukaryotes in July. The abundance, biodiversity and structure of the picoeukaryotes community low related to the physicochemical parameters. *Micromonas* predominated in September, when all the community parameters of the picoeukaryotes high correlated to the physicochemical parameters. An upwelling were detected (67.7°N, 168.9 °W) and greatly influenced the distribution of picoeukaryotes and supplied nutrients to the regrowth or the *P. malhamensis* and diatoms.
Glacial forefields are extremely sensitive to temperature changes and considered ideal places to explore how microbial communities will respond to climate-driven environmental changes. Our knowledge of how the bacterial community activities and structure were influenced by changing environment due to glacier retreat is still very limited. Here, a series of soil samples with ice and without ice coverage along the glacial retreat path were sampled in the forehead of Larsemann Hill of East Antarctica ice sheet. By employing the MiSeq sequencing methods, and combining geochemical data analysis, the bacterial diversity including the abundant and rare group were studied and compared among samples. Our results show that abundant bacterial communities were more sensitive to changing conditions in the early stages of deglaciation than rare community members. Moreover, among the environmental parameters tested, which included total organic carbon, pH, and moisture of the soils, ice thickness was the most influential factor affecting the community structure of abundant bacteria. These results show the different effects of abundant and rare bacteria on community shifts and highlight ice thickness as the primary factor affecting the bacterial community in the early stages of deglaciation. The response of microbial community to climate change can be predicted with more certainty in this polar region.
Cold Adaptation Strategy of the Antarctic Cyanobacterium *P. priestleyi* ULC007

Benoit Durieu¹ (benoit.durieu@uliege.be), Denis Baurain², Annick Wilmotte¹, Yannick Lara¹,³,⁴

¹University of Liège, InBioS-Centre for Protein Engineering, Department of Life Sciences, Liège, Belgium, ²University of Liège, Eukaryotic Phylogenomics, Department of Life Sciences, Liège, Belgium, ³University of Liège, UR-Geology-Palaeo-Biogeology-Botany-Palynology, Liège, Belgium, ⁴Gembloux AgroBioTech-University of Liège, Microbial Processes and Interactions, Liège, Belgium

In Antarctica, Cyanobacteria are key primary producers and play a major role in the colonization of deglaciated habitats. Cyanobacterial mats are widespread in aquatic biotopes and often dominate the total phototrophic biomass. In order to gain further insights on the mechanisms underlying the ecological success of Antarctic cyanobacteria, we studied the gene repertoire of *Phormidesmis priestleyi* ULC0007, a filamentous cyanobacterium isolated from shallow freshwater lake microbial mats in the Larsemann Hills. Here, we investigate the occurrence of genes involved in the cold stress response as a proxy to the adaptation to environmental conditions in Antarctica. We compare a selection of 42 PEGs (protein encoding genes) linked to cold adaptation in 72 cyanobacterial genomes. Polar strains have the highest number of copies of genes coding for fructose aldolase, chaperone Hsp, and universal stress protein and a high number of fatty acid desaturase and genes involved in exopolysaccharide (EPS) biosynthesis. To provide a better overview of the genetic mechanisms of adaptation to cold, we investigated the gene functional categories based on the RAST subsystems technology. Polar strains have the most occurrences for subsystems “Choline and Betain Biosynthesis”, “DNA repair”, “EPS biosynthesis” and “Heat shock DnaK gene cluster”. Our results underline the importance of these functions in the adaptation mechanisms of cyanobacteria to the polar environment.
Dispersant Impacts on Arctic Microbial Community Dynamics and Oil Biodegradation

Saskia Rughöft¹ (saskia.rughoeft@uni-tuebingen.de), Christian Hallmann²,³, Andreas Kappler¹, Sara Kleindienst¹
¹Eberhard-Karls-University Tübingen, Centre for Applied Geoscience (ZAG), Tübingen, Germany, ²Max-Planck-Institute for Biogeochemistry, Jena, Germany, ³University of Bremen, MARUM, Bremen, Germany

As a response strategy to oil spills in the marine environment, chemical dispersants are frequently applied to reduce oil slicks and oil delivery to shorelines. However, the impact of chemical dispersants on native microbial communities and, more specifically, oil degrading bacteria remains unclear. Particularly pristine, more extreme environments like the Arctic Ocean are largely unexplored in this regard, even though pollution risks are increasing with rising interests in Arctic oil exploration and transportation routes. Here, we assessed the impact of the chemical dispersant Corexit 9500A on Arctic microbial seawater communities and their oil biodegradation potential. For this, oil spill conditions were simulated in laboratory microcosms at 1.5 °C and 15 °C with Arctic seawater from 150 m depth, amended with oil only (± nutrients), oil-dispersant mixtures, or only dispersant. Dissolved organic carbon (DOC) concentrations, bacterial productivity data, and cell counts suggested active oil and dispersant degraders. Marine oil snow formation and DOC degradation was enhanced in oil microcosms compared to oil-dispersant setups. Additionally, ¹⁴C-naphthalene oxidation rates suggested that the native microbial community might not be equipped for rapid biodegradation of aromatic hydrocarbons. Analyses of microbial community composition and hydrocarbon quantifications will help to further elucidate the impacts of oil and dispersants in Arctic pelagic ecosystems.
Nitrifiers Still Alive in Antarctic Soils under Moss Vegetation

Kentaro Hayashi1 (kentaroh@affrc.go.jp), Yukiko Tanabe2,3, Nobuhide Fujitake4, Morimaru Kida4, Masahito Hayatsu1, Sakae Kudoh2,3

1Institute for Agro-Environmental Sciences, NARO, Division of Biogeochemical Cycles, Tsukuba, Japan, 2National Institute of Polar Research, Tachikawa, Japan, 3SOKENDAI (The Graduate University of Advanced Studies), Tachikawa, Japan, 4Kobe University, Kobe, Japan

Nitrogen (N) as a macronutrient is cycled also in Antarctic terrestrial ecosystems, in which microbes are a main driver. In the N cycle, nitrification is the only source of nitrate other than atmospheric deposition of perhaps very small contribution in Antarctica. Nitrification is a two-step process, ammonia oxidation and subsequent nitrite oxidation. We measured ammonia oxidation potentials (AOP) of soils collected at two sites (69°14.5′S, 39°44.7′E, 52 m ASL and 69°14.4′S, 39°45.1′E, 114 m ASL) in Yukidori-zawa, Langhovde, East Dronning Maud Land, and at one site (66°46.3′S, 50°35.3′E, 121 m ASL) near Mt. Riiser-Larsen, West Enderby Land, East Antarctica. Soils were collected for each layer, i.e., moss layer, mineral surface soil with accumulated organic matter (A layer), and subsoil (B layer(s)). Fresh soils were used to determine their AOP values at around 10 °C by means of aerobic static incubation adding a substrate solution. Responses of AOP to a combination of incubation temperatures (10 and 20 °C) and substrate concentrations (8 steps from 0.1 to 4 mM ammonium) were also measured for the soil with the highest AOP (A layer of the site 2 in Yukidori-zawa). In all the sites, the A layers had relatively high AOP values. A unique response to the substrate concentrations was also found, it will be shown at the conference in combination with the relationships of AOP to key soil properties and characteristics of nitrifiers, i.e., ammonia oxidizing bacteria and archaea.
Dimethylsulfiniopropionate (DMSP) is mainly produced by marine phytoplankton serving as an osmolyte, antioxidant, predator deterrent, and cryoprotectant. It is also a carbon and sulfur source for marine bacteria. Bacteria may metabolize DMSP via the demethylation pathway involving DMSP demethylase (dmdA) gene and the cleavage pathway involving several different DMSP lyase genes. Most of DMSP released into seawater is degraded by bacteria via demethylation. A total of thirty bacterial strains were isolated from Arctic Kongsfjorden seawater using low-nutrient medium containing 1mM DMSP. Analysis of 16S rRNA gene sequences showed that, except for strains BSw22112 and BSw22131 respectively belonging to the genera Pseudomonas and Glaciecola, all bacteria fell into the genus Pseudoalteromonas. dmdA genes were detected in three Arctic strains Pseudoalteromonas sp. BSw22112, Pseudomonas sp. BSw22131 and Glaciecola sp. BSw22132 within the Gammaproteobacteria, as well as one Antarctic marine alphaproteobacterial Roseicitreum antarcticum ZS2-28. Their dmdA genes showed significant similarities (97.7-98.3%) to that of Ruegeria pomeroyi DSS-3, a well-known roseobacterium possessing both pathways for metabolism of DMSP. Among the four tested strains, only Pseudomonas sp. BSw22131 was able to grow in M9 medium supplemented with DMSP as sole carbon source. Results in this study support a hypothesis of lateral gene transfer for dmdA among taxonomically heterogenous bacterioplankton.
Mycobryosphere: Fungi Associated with Bipolar Mosses Present in Antarctica

Camila Rodrigues¹, Mariana Ferreira¹, Vivian Gonçalves¹, Micheline Carvalho-Silva², Paulo Câmara³, Carlos Rosa¹, Luiz Rosa¹ (lhrosa@icb.ufmg.br)
¹Federal University of Minas Gerais, Microbiology, Belo Horizonte, Brazil, ²Federal University of the Vales of Jequitinhonha and Mucuri, Unaí, Brazil, ³University of Brasília, Botany, Brasília, Brazil

Mosses are a major component of the vegetation in ice-free regions of Antarctica. The aim of the study was to examine the diversity of epiphytic and endophytic fungi, as well as those present in the rhizoids of Polytrichastrum alpinum and Polytrichum juniperinum collected in Antarctica. Five gametophytes were collected at King George Island, which were subjected to surface sterilization and inoculated onto Sabouraud agar (SBA) for isolation of fungi. After the different isolation process, 217 fungi isolates were recovered and 19 taxa were identified by molecular biology methods. Thelebolus sp., Pseudogymnoascus sp., and Tumularia sp. were the most abundant taxa recovered. Pseudogymnoascus sp., Glarea sp., Chalara pseudoaffinis, Gyoerffyella entomobryoides, Helotiales sp., Leotiomyctidae sp., Microdochium phragmitis, Phaeosphaeria sp., and Pochonia sp. were isolated only from P. alpinum. Cladosporium sp., Exophiala sp., Fusicladium sp., Leptosphaeria sp. and Oleoguttula sp. were isolated only from P. juniperinum. Our results suggest that bipolar mosses shelter rich and diverse fungal communities, including taxa phylogenetically near to symbionts, decomposer, and phytopathogenic fungi.
The Southern Ocean (SO) is a major site for sequestration of anthropogenic carbon dioxide (CO₂). The epipelagic regions are where key processes of photosynthetic CO₂ fixation are performed by both pro- and micro-eukaryotes. The effects of climate change on physical oceanography of the SO may have a globally significant impact on the efficiency of the biogeochemical cycling, but the extent of this is unclear, because the basic biogeography of these organisms are still quite limited to select locations of the SO. We sampled epipelagic seawater at multiple transects along the Indian, Australian and Pacific regions of the SO (71°E-170°W) and mapped both pro- and eukaryotic community composition using high resolution 16S and 18S rRNA tag sequencing. This is aligned with corresponding physical/biogeochemical observations to investigate potential triggers of observed community shifts. Across all transects, samples are dominated by the Pelagibacteraceae (SAR11) family with shifts in different Pelagibacteraceae oligotypes observed from low to high latitude samples. Spatial/longitudinal distance were not observed to drive community differences between samples at similar latitudes or surface water zones. Statistical analysis show temperature to be the major driving force for community selection. These findings contribute to filling critical knowledge gaps on how changes in SO physical oceanography under forcasted global change scenarios might alter CO₂ uptake and the biological pump.
We highlight the findings of several years of research in Astrobiology and Planetary Sciences using concepts and methods of polar eco-physiological research, combining field research with planetary simulations in the lab and in space. The studies were carried out to gain insights into the interactions between extremophilic microorganisms (archaea, bacteria and eukarya) and changing environment which are achieving conditions as they were observed on another terrestrial planet such as Mars. Furthermore, the experiments which will be presented were performed to check the responses of the organisms to new simulated planetary and space conditions. They are the basis for classifying a planet from an experimentally point of view as to be habitable or not to be able to support any kind of life forms. The second eco-physiologically relevant investigation enterprise in the presented work focuses on key-molecules which play a specific active or protective role in physiological processes such as e.g. chlorophyll, carotene and methane besides others. These molecules are characterized by Raman spectroscopy and wavelength modulation spectroscopy and checked if they can be detected as specific bio-traces or biosignatures in a polar and Mars-like environment, what might support future exploration missions to other planets with the final goal to search for life.
Diversity and Antifreeze Activity of Fungi in Snow of Antarctic Peninsula

Graciéle de Menezes¹, Bárbara Porto¹, Jefferson Simões², Carlos Rosa¹, Luiz Rosa¹ (lhrosa@icb.ufmg.br)
¹Federal University of Minas Gerais, Microbiology, Belo Horizonte, Brazil, ²Federal University of Rio Grande do Sul, Polar and Climate Center, Porto Alegre, Brazil

The present study focused the characterization of the fungal community present in the seasonal snow of Antarctic Peninsula. Approximately 10 kg of snow from the uppermost 1.5 m layer was collected in the Deception, King George, Snow and Robert islands as well as in two sites of Peninsular region (Hope Bay and Arctowiski Peninsula) and melted at 20 °C over a period of about 12 h. This process resulted in 10 L of water and a total of 1.5 L of melted snow was filtered through of 0.45 µm membrane with 47 mm diameter in duplicate. The membranes were placed on the media Sabouraud agar, minimum medium and incubated at 10 °C for 60 d. Two hundred thirty-four fungi isolates were obtained and identified by molecular biology methods in taxa belonging to 24 genera of the Ascomycota, Zygomycota and Basidiomycota phyla. The genus Penicillium, Phenolipheria and Leucosporodium were the most abundant. A new, blue and endemic species, Antarctomyces pellizariae, was described. Fungal diversity of snow was high represented by cosmopolitan cold-adapted and endemic species. In addition, all fungi were submitted to deep freeze conditions and 82 isolates were able to survive at -74 °C after 30 days. The detection of the antifreeze capabilities of these fungi suggests that they have adaptive strategies to survive in the snow and can represent sources of compounds to biotechnological applications.
Mycosphere of Antarctic Plants *Deschampsia antarctica* and *Colobanthus quitensis*

Lívia Costa¹, Camila Rodrigues², Carlos Rosa³, Luiz Rosa¹ (lhrosa@icb.ufmg.br)

¹Federal University of Minas Gerais, Microbiology, Belo Horizonte, Brazil

The aims of our study were to characterize the endophytic and epiphytic fungi, as well as those present in the rhizome of the two Antarctic angiosperms *Colobanthus quitensis* and *Deschampsia antarctica*. Plants were collected in the King George, Penguin, Elephant, Halfmoon Islands, as well as the Continental Peninsula. After the different isolation processes, 309 fungal isolates were recovery from *D. antarctica* and 89 from *C. quitensis* as endophytic and epiphytic of their leaves and roots. All fungi obtained were identified by molecular biology methods in 23 taxa from the 12 different orders. *Penicillium* was the most abundant genera associated with *D. antarctica* and *Vishniacozyma* with *C. quitensis*. *Antarctomyces, Pseudogymnoascus, Vishniacozyma, Microdochium*, and *Penicillium* occurred in both plants. Our results indicate that the Antarctic angiosperms shelter rich fungal communities in/on their tissues and represent a hotspot microhabitat of fungal diversity in different regions of Antarctic Peninsula.
Winter Survival of Freshwater Diatoms in the High Arctic

Eva Hejduková1 (hejdukova.eve@gmail.com), Linda Nedbalová1,2, Josef Elster2,3
1Charles University, Faculty of Science, Prague, Czech Republic, 2Academy of Sciences of the Czech Republic, Institute of Botany, Třeboň, Czech Republic, 3University of South Bohemia in České Budějovice, Faculty of Science, Centre for Polar Ecology, České Budějovice, Czech Republic

Natural conditions in Polar Regions are characterized by many extremes and could seem unfavourable for life. Despite this fact, diatoms (Bacillariophyceae) apparently adapted well and belong to very important primary producers in a wide range of habitats in both Arctic and Antarctic environments. However, it remains unknown, which strategy enables them to survive long polar winters. For microorganisms, dormancy is a strategy to overcome unfriendly conditions, but morphologically distinct resting stages are rarely observed in diatoms. The aim of this project is the study of annual cycle of polar freshwater diatoms to reveal their overwintering strategy. We hypothesize that only a small amount of cells survive winter season and that diatoms do not form any morphologically different stages for survival. Morphology and viability of diatom cells is studied in natural samples collected during one year. For the multiple sampling four study sites (streams, shallow wetland, and seepage with high abundance of diatoms) were established during summer season 2017 in the Arctic (Central Spitsbergen, close to Longyearbyen). The viability of cells is evaluated five times following key events for survival (summer vegetative season, autumn freezing, winter, spring melting, summer season) using a multiparameter fluorescent staining (SYTOX Green, CTC and DAPI combination) combined with light microscopy.
Phenotypic Traits of Prokaryotic Cells Variability in the Southern Ocean

Rosabruna La Ferla¹ (rosabruna.laferla@iamc.cnr.it), Giovanna Maimone¹, Monique Mancuso¹, Giuseppe Arena², Filippo Azzaro¹, Maurizio Azzaro¹

¹National Research Council, Institute for Coastal Marine Environment, Messina, Italy, ²University of Messina, Department of Chemical, Biological, Pharmaceutical and Environmental Sciences, Messina, Italy

The Terra Nova Bay (Ross Sea, Antarctica) is a microbiological laboratory owing to its high environmental variability that affects plankton dynamics. Previous studies on plankton communities mainly focused on phytoplankton biomass and production processes. Studies of the succession the heterotrophic populations have relatively been neglected also if a sudden variability of the micro- nano- and picoplankton size fractions biomass with the ice melting has been highlighted. In this context the prokaryotic cell morphometry and morphology assume a key role to quantify the carbon budget.

In the frame of CEFA “Coastal Ecosystem Functioning in a changing Antarctic ocean” project (31st PNRA expedition), in a fixed station of Terra Nova Bay (Michaud Pier - MP, repeatedly sampled) and along the roundtrips from New Zealand to the bay (NZ-TNB) seawater samples were collected.

The prokaryotic cell abundances, phenotypic variability (cell morphometry and morphology) and biomass were determined by image analysis. Moreover, the nutrient concentrations (NO₃+NO₂, NH₄ and PO₄) were detected. The aim of the study is to assess the relationships among the phenotypic variability and the nutrient pools. ANOVA showed a significant variability of cell morphometry among MP and NZ-TNB (P< 0,05). Different significative correlations between the prokaryotic abundance, cell volumes, biomass and cell morphotypes vs. nutrient concentrations were computed in MP and NZ-TNB.
Bacteria in the Atlantic Southern Ocean

Jodi Pieterse¹, Ethel Phiri², James Lloyd², Susanne Fietz³ (sfietz@sun.ac.za)
¹Stellenbosch University, Conservation Ecology, Stellenbosch, South Africa, ²Stellenbosch University, Institute of Plant Biotechnology, Stellenbosch, South Africa, ³Stellenbosch University, Earth Sciences, Stellenbosch, South Africa

Bacteria play a key role in the Southern Ocean ecosystem functioning, including in the carbon, nitrate and iron cycles. We present a study aimed at identifying and cultivate bacteria from the subtropical, subantarctic and antarctic zones of the Atlantic Southern Ocean. We further interrogated the roles the observed bacteria play in the marine polar ecosystem. Metagenomic samples were collected from surface waters across the three zones in summer 2015, and summer and winter 2017. Microbial plates for cultivation and experiments were added in 2017. Results are discussed with regards to the functional characteristics of the observed and/or cultivated bacteria. For example, five genera were identified and cultivated in austral summer 2017: Halomonas, Pseudoalteromonas and Salinibacterium from the sub-tropics, Citricoccus and Pseudoalteromonas from the subantarctic, and Pseudoalteromonas, Salinibacterium and Vibrio from the Antarctic zone. Their functional roles in the ecosystem differ; for example, Citricoccus is a potential producer of siderophores, essential in the iron availability for phytoplankton, whereas Halomonas might play a role in the nitrogen cycle, but might also be involved in the degradation of hydrocarbons. In addition to the in-situ, transect biodiversity data we will present the impact of iron enrichment on shifts in the prokaryotic communities in the three zones.
LPS Structure from the Cold-adapted *Shewanella* sp. HM13 Grown at 4°C and 18°C

Angela Casillo¹ (angela.casillo@unina.it), Chen Chen², Jun Kawamoto², Kohei Kamasaka², Tatsuo Kurihara³, Maria Michela Corsaro¹

¹Università degli Studi di Napoli Federico II, Naples, Italy, ²Kyoto University, Institute for Chemical Research, kyoto, Japan

Lipopolysaccharides (LPS) are the main component of the outer membrane of Gram-negative bacteria. Due to their external location, it is reasonable to think that LPS are involved into the life adaptation at low temperature. The LPS is composed of three different domains: an O-specific polysaccharide and a core oligosaccharide, which in turn is covalently linked to the third domain, the lipid A.¹ It has been reported that unsaturated fatty acids belonging to both phospholipids and lipid A moiety are responsible of the membrane fluidity enhancement when bacteria thrive at low temperature.² Up to now, only few LPS structures from cold-adapted bacteria have been characterized, and an interesting common feature is the production of rough-LPS.³ The characterization of other LPS structures from cold-adapted bacteria can shed light about the interaction between the cell and the environment.

In this communication, the molecular characterization of LPSs from the fish intestinal bacterium *Shewanella* sp. HM13 is reported. In particular, the LPS structures obtained from *Shewanella* sp. HM13 grown at 4°C and 18°C are analyzed and compared.

²De Maayer et al., *EMBO reports* 2014 15(5): 508-517.
The Ross Sea continental shelf is a unique region of the Antarctic, both with regard to its physics and its ecology and it is considered a “natural laboratory” for investigating the potential effects of climate change. It is noteworthy that sea ice distributions has significantly changed with years in the Ross Sea, inducing unpredicted cascade effects on trophic dynamics and carbon and nutrient drawdown.

With the aims to identify signs and patterns of microbial responses to current climate change, the variability of the microbial respiration rates in the Ross Sea was assessed by comparing the data of two cruises carried out in late-spring and early summer (ROSSMIZE 1994-95 and P-ROSE 2016-17) twenty-two years later.

In particular, estimates of microbial community respiration and carbon dioxide production rates by ETS assay were performed.

A high variability of respiratory rates was detected on both time and space scales in the Ross Sea. The distribution of plankton respiration and organic matter degradation was put in relation with the different ice cover of the investigated areas. Comparing the two expeditions could help to better understand the carbon flux transfer efficiency and carbon export variability on a large time scale.
The Ross Sea, one of the most productive seas of the South Ocean, includes polynyas, marginal ice zones, coastal areas and open sea that contribute differently to biological processes. To identifying responses of plankton compartment to climate change, an oceanographic PNRA campaign (P-ROSE Project) was here carried out in January-February 2017. Two polynyas occurred, a small near the Terra Nova Bay (TNB) and a larger one between the Ross Ice Shelf and Cape Adare. The variability of extracellular enzymatic activity (a proxy of organic matter degradation) in relation to environmental conditions (temperature, salinity and total phytoplankton biomass) was studied along longitudinal and latitudinal transects. Hydrolysis rates of aminopeptidase (LAP), beta-glucosidase (GLU) and alkaline phosphatase (AP) and -for the first time in this area- the corrispective free enzymes (dissolved in waters) were determined. Results showed decreasing trends in the TNB from coastal to off-shore stations and from surface to depth for LAP, that were related positively to temperature (T) and negatively to salinity (S) and depth (p< 0.01%). High values in the N-S transect of offshore stations were observed, probably due to fresh organic matter. LAP were positively correlated with T and negatively with S and depth (p< 0.01%). GLU was positively correlated with AP and LAP (p< 0.05%). Free enzymes ranging from 17 to 99% on total showed variability among stations and high percentages for free-GLU at DCM.
Genomic Comparative Analysis of Bacteria Associated to Antarctic Sponges

Mario Moreno¹ (mario.moreno@mayor.cl), Mariela Guajardo¹, Nicole Trefault²
¹Universidad Mayor, Doctoral Program in Integrative Genomics, Santiago, Chile; ²Universidad Mayor, Center for Genomics and Bioinformatics, Faculty of Sciences, Santiago, Chile

Sponge microbiome is composed of a wide range of microbial communities which display a key role in different aspects of the sponge biology and in biogeochemical cycling of key elements for ecosystem functioning. Here, we studied the metabolic potential of seven bacterial strains isolated from two Antarctic sponges, with emphasis on nutrient cycling and symbiotic lifestyle, using whole-genome Illumina sequencing and genomic comparative analysis using the RAST server. Bacteria isolated were assigned to the genera Pseudoalteromonas (E16.1, E19.1, 19.4), Nesterenkonia (E16.7, E16.10), Sporosarcina (E16.8), and Cellullophaga (E16.2). Genomic completeness was estimated as higher as 98% for all genomes. Bacterial strains isolated display metabolic potential to perform: nitrite reduction (Nitrite reductase, nir; Pseudoalteromonas and Nesterenkonia genera) and phosphorous cycle (i.e. Polyphosphate kinase, ppk gene; all genera). Interestingly, Cellullophaga has genomic elements associated with CRISPR systems. Genomic comparative of sponge-associated Nesterenkonia and Cellullophaga against free-lifestyle strains showed that associated bacterias have higher genome size and uniques functions related to virulence, phages. Overall, genomic features in bacterial isolated from Antarctic sponges shown a metabolic potential related to nutrient cycling and display signatures related to symbiotic lifestyle, extending previous results from tropic and temperate environments to polar systems.
Extremophiles are found in all three domains of life, however, extremophiles from different domains utilize varying mechanisms for dealing with harsh environmental conditions. We used next-generation sequencing to investigate differences in inter-domain responses to extreme conditions along a high elevation salinity gradient in the McMurdo Dry Valleys, Antarctica. The soil salinity for the 25 samples collected along the gradient ranged from 50 to 8355 µS cm⁻¹. Richness varied widely between domains along the transect with a total of 354 bacterial, 2 archaean, 56 fungal, and 69 non-fungal eukaryotic OTUs. Richness for all domains declined significantly (P ≤ 0.01) with increasing conductivity, however, the strength of the relationship varied (R² of 0.83 for bacterial to 0.25 for fungal OTUs). Ordination (PCoA) revealed significant (ANOSIM R = 0.97) groupings of low/high conductivity bacterial OTUs, while OTUs from other domains were not significantly clustered. Beta-diversity analyses found significant patterns for bacteria only, including evidence of a nested structure indicating species loss as opposed to replacement. A PICRUSt analysis, which predicts metagenome functional content, indicated the high conductivity bacterial OTU cluster had an over representation of genes responsible for coping with osmotic stress. These results suggest that while increased salinity acts as a stressor for organisms across all three domains, within-domain responses also vary considerably.
ACBC - Antarctic Circumnavigation Bacterial Collection: Highway to Knowledge

Marion Fourquez¹ (marion.fourquez@gmail.com), Amandine Laffite¹, Christel Hassler¹
¹University of Geneva, F.-A. Forel for Environmental and Aquatic Sciences Marine and Lake Biogeochemistry, Genève, Switzerland

A freely accessible culture collection of polar bacteria will be available shortly (2019). We collected natural bacterial communities during the Antarctic Circumnavigation Expedition (ACE) from Dec. 2016 to Mar. 2017 for isolation and identification purposes. The expedition has travelled for 33,565 km all around Antarctica, allowing us to bring back unprecedented live samples from the Southern Ocean. Water samples were collected at 15 different sites at the surface, 15, 100 and 1000m depth. Two additional samples were collected: one in the Ross Sea at 3800m to get the signature of the Antarctic Bottom Water, and another one at 700m at on seabed underneath the Mertz glacier. Bacteria colonies were first grown in nutrient rich (Marine Agar) and poor (R2A) media at 4°C directly on board the R/V Akademik Treshnikov. Each colonies were subsequently isolated a first time at sea, followed by additional isolation steps in our home lab (Geneva, Switzerland) until we get pure cultures. A total of 314 isolates were recovered, documented and archived at -80°C. Using 16S rRNA Sanger sequencing, we have so far characterized the bacterial diversity of 186 of these isolates. One of the project’s overarching goals was to identify the key microbial players across the Southern Ocean and to stimulate research on bacteria inhabiting this extremely harsh region of our world. The outcome of this project resonates with a better understanding of the functioning and diversity of the Southern Ocean.
Metabolic Response of Sea-ice Diatoms to Shifting Temperature and Salinity

Hannah M. Dawson¹ (hmdawson@uw.edu), Angela K. Boysen¹, Katherine R. Heal¹, Laura T. Carlson¹, Anitra E. Ingalls¹, Jodi N. Young¹
¹University of Washington, Oceanography, Seattle, United States

In polar oceans, sea-ice algae are important primary producers during the spring and winter months. However, we have a limited understanding of how they are physiologically adapted to the large variations in temperature and salinity associated with seasonal cycling of sea ice. Here, we use a mass spectrometry-based targeted metabolomics approach to evaluate the response of sea-ice algae to changing temperature and salinity. Axenic cultures of the Antarctic sea-ice diatom, *Nitzschia lecointei* were grown at salinities of 32 and 41 and at -1 and +4°C. Under the culture conditions tested, growth, cell size and photosynthetic efficiency were unaffected despite large differences in intracellular metabolites among treatments. Temperature had a greater affect than salinity on metabolite composition, influencing cryo- and osmoprotectants, antioxidants as well as other metabolites. Compatibles solutes, including N-rich glycine betaine and proline, along with S-rich dimethylsulfoniopropionate (DMSP) were among the most abundant metabolites detected. Surprisingly, these compounds displayed different responses to temperature and salinity. We will compare laboratory results to environmental samples of first-year sea ice with a dominant *Nitzschia* community that we collected from Utqiagvik, AK. Changes in metabolite composition in response to environmental change could have implications for biogeochemical cycling and ecosystem dynamics in sea ice over the season.
Growth Performance of Psychrotolerant Cyanobacteria from Svalbard Archipelago

Zoya Khan¹, Azmir Hamidi¹, Wan Muznah Wan Omar¹ (wmuznah@usm.my), Peter Convey², Faradina Merican¹
¹Universiti Sains Malaysia, School of Biological Sciences, Penang, Malaysia, ²British Antarctic Survey, Cambridge, United Kingdom

A filamentous benthic cyanobacteria, strain USMAC16, was isolated from High Arctic Svalbard archipelago, Norway, and was identified to species level using polyphasic approach that combine morphological and molecular characterization (16S rRNA gene sequence). Cell dimensions, and apical cell shape are consistent with the *Pseudanabaena* genus description. The molecular characterization of USMAC16 gave 100% similarity with *Pseudanabaena catenata* SAG 1464-1, originally reported from Germany. Strain USMAC16 was cultured under a range of temperature (4±2°C, 15±2°C and 25±2°C), and photoperiod (24 hours light, 16 hours light, 12 hours light and 24 hours dark) conditions in liquid media, and harvested at exponential phase to examine growth and biochemical composition. The highest growth rate (0.538day⁻¹) and chlorophyll a (306.7 mg/L) concentration was recorded at 15±2°C under 24L:0D and 16L:08D light durations, respectively. Highest carbohydrate (216.6 µg/L) and protein (2.67 µg/L) was observed at 25°C in the absence of light. This analysis provides baseline data documenting the variations in biochemical compositions of *P. catenata* in response to changing temperature regimes and this indicates that the strain was psychrotolerant as it is an organism from a cold environment that can adapt to culture temperatures of > 15°C.
The microalga *Stichococcus bacillaris* isolated from Signy Island soil was found to be resistant to cycloheximide (CHX), a eukaryotic protein synthesis inhibitor produced by *Streptomyces griseus*. The strain was first obtained from a mixed assemblage of several green algae species. When introduced to media containing 100µg/ml CHX, only *S. bacillaris* survived and continued to grow after three weeks of incubation. An initial lag of growth in the first two weeks of incubation indicates that *S. bacillaris* attained the tolerance by adaptation. Morphological comparison between cell cultures grown with and without CHX indicated no measurable change in their phenotypic characteristics. Species identification was confirmed by sequencing 18S rDNA. Subsequently, a series of experiments conducted using different CHX concentrations confirmed the ability of *S. bacillaris* to tolerate up to 400µg/ml CHX concentration. Ongoing research is addressing the mechanism by which *S. bacillaris* achieves resistance, and whether this phenomenon is widespread in the species or specific to this Antarctic strain.
The Secret Life of Bacteria: Ecological Function in Cryoconite Hole Environments

Ewa A Poniecka¹ (ponieckaea@cardiff.ac.uk), Elizabeth A Bagshaw¹, Henrik Sass¹, Christopher J Williamson², Alexandre M Anesio², Martyn Tranter²
¹Cardiff University, School of Earth and Ocean Sciences, Cardiff, United Kingdom, ²University of Bristol, Bristol Glaciology Centre, Bristol, United Kingdom

Polar regions serve as a natural laboratory to study simplified microbial and biogeochemical processes in habitable niches. An example of such niches are cryoconite holes, regarded as hotspots of microbial processes on glacier surfaces. Data on how microorganisms, especially anaerobic ones, function in cryoconite holes are, however, scarce.

We applied a range of microbiological tests to understand the physiological capabilities of the most abundant cultivable microorganisms from cryoconite holes worldwide (Greenland, Svalbard, Antarctica). Oxic and anoxic conditions were applied to mimic microniches within the habitat. The growth of bacteria was assessed under a range of treatments: freeze-thaw cycles, temperature gradients, and varying organic carbon substrates.

Our study demonstrates that heterotrophs of cryoconite holes are adapted to fast-changing environmental conditions by ability to survive multiple freeze-thaw cycles and changing oxygen conditions, and scavenging a wide range of organic substrates. The elevated growth of anaerobic part of the community in the lowest temperatures indicates they might be key players in winter conditions or in early melt season, when the oxygen is potentially depleted and accumulated dead cells provide a source of organic matter for scavenging. Consequently, anaerobic heterotrophs are likely crucial for the reactivation of the community after the polar night.
The Nutrient Limitation of Soil Microbial Community in High Arctic Forefield

Petra Lulakova¹ (petrica@centrum.cz), Petra Vinosova², Petr Capek³, Jacob Yde⁴, Marek Stibal², Hana Santruckova¹

¹University of South Bohemia, Faculty of Science, Ceske Budejovice, Czech Republic, ²Charles University in Prague, Faculty of Science, Department of Ecology, Prague, Czech Republic, ³Pacific Northwest National Laboratory, Environmental Molecular Sciences Laboratory, Richland, United States, ⁴Western Norway University of Applied Sciences, Faculty of Engineering and Science, Sogndal, Norway

Although the soil succession has been studied intensively in the forefields of retreating glaciers, little is known about the physicochemical constraints of microbial functioning which determines the rate of initial soil development. Knowing these constraints may improve our understanding of factors limiting microbial growth during the soil succession. Commonly measured soil characteristics such as moisture and pH have been shown to change along the soil age and to shape microbial community structure and activity during the succession. However, the extent of microbial nutrient limitation, which is more difficult to estimate, remains unclear. It has been suggested that nutrient limitation has even stronger effect on the rate of microbial succession than climate, especially at very harsh conditions.

We assume that nutrient limitation of soil microbial community is especially pronounced on the bare forefields of the High Arctic regions, where the plant cover establish much longer. In order to estimate nutrient limitation of the microbial activity on the bare forefields in Svalbard, we set up an incubation experiment where we added organic carbon (C), inorganic nitrogen (N) and phosphorus (P) separately or in different combinations and measured the changes in microbial respiration rate and microbial biomass. The effect of nutrient addition on the microbial activity and growth is discussed in respect to microbial community structure and available nutrients at in-situ conditions.
Life on Earth appeared with UV resistant anaerobic organisms. Then, cyanobacterial prokaryotes have flourished oxygenic life on earth. In spite of global change biology, they are still the most successful organisms. Adaptive evolution create contemporary cyanobacteria, very tolerant to extreme circumstances. Foremost, UV radiation as the most lethal factor increase mutation rate. Also, prime necessities of life such as liquid water supply would play a key role on habitability on survivability of resistant life forms. A molecular dynamics approach can be used in order to obtain insights water/ice interface over continued cycles of freezing and thawing. Adventures in protein world revealed many positive biosignatures of antifreeze, ice-binding and ice structure proteins at Polar Regions. Although, working mechanisms has a long way to go, this study review these themes and psychrophilic adaptation process. It will make possible to understand the thermal hysteresis structures and function to potential biologic niches in more detail.
Bacterial taxa when stimulated by water additions will break dormancy, grow, and become dominant members of the community, contributing significant pulses of CO$_2$. Pulses are associated with high levels of bacterial productivity in soils. (Aanderud et al. 2011) I have examined the bacteria taxa that resuscitate and become metabolically active following two forms of water stress (soil drying-rewetting and freeze-thaw cycles) and have captured and measured the CO$_2$ emanating from those soils. Specifically, I used target metagenomics, which uses a specific gene pool within bacteria that is associated with a function of an ecological process, in this case active (16S mRNA communities) bacteria and all bacteria (16S rRNA communities) during drying-rewetting and freeze-thaw cycles. I have measured an array of community dynamics as dry soils were rewetted and as frozen soils thaw multiple times in three cold desert soils. I am searching for continuity or predictability in the bacteria rapidly responding in ecosystems to understand if there are coherent or universal patterns of the bacteria within these stresses in cold desert ecosystems. I have examined three cold deserts which include the Great Basin Desert, UT, The Junggar Desert, China, and the McMurdo Dry Valleys, Antarctica. Overall I am looking to; Identify whether bacterial response to water stress is universal or only localized and if bacterial adaptations are the same within similar but geographically isolated systems.
Detection of Lipase Gene from *Sphingobacterium sp.* Isolated from Polar Region

Rashidah Abdul Rahim\(^1\) (rashidahrahim@gmail.com)  
\(^1\)Universiti Sains Malaysia, School of Biological Sciences, Penang, Malaysia

In past few decades, microbial enzymes have been favorable demands among industrial fields due to their high specificity and stability of being active under mild conditions. Known as a versatile enzyme beneficial to many biotechnological approaches, lipases have received massive interest worldwide. A psychrophilic microorganism isolated from polar soil sample tested positive as a lipase producer was studied. DNA extraction was conducted by modified CTAB method and 16S rRNA sequencing result revealed its identity to be in close resemblance with *Sphingobacterium* sp. (97% identity). The bacterium was found to be psychrotolerant with the growth temperature ranging from 4°C to 25°C ±2°C. Halo zone formation in qualitative (primary) screening using sensitive and specific plate assay detected the presence of lipase produced by the bacterium. To date, not many studies on lipases from *Sphingobacterium sp.* was done, and lipase structure from this bacterium has not been solved yet for better understand of its enzymatic activity. In the study on detection of lipase gene by PCR method using specific designed primers, two different lipase sequences from *Sphingobacterium sp.* which are SGNH subfamily hydrolase (lisophospholipase) (553bp) and alpha/beta hydrolase (esterase/lipase) (845bp) were detected. The lipase genes will be cloned, expressed and purified for further structure-function study of the enzyme.
Isotopic-related Warming Effects on the Northern Antarctic Peninsula Ecosystem

Elisa Seyboth1,2 (elisaseyboth@gmail.com), Silvina Botta3, Carlos Rafael Borges Mendes4, Javier Negrete5, Luciano Dalla Rosa3, Eduardo Resende Secchi3

1Universidade Federal do Rio Grande, Instituto de Oceanografia, Laboratório de Ecologia e Conservação da Megafauna Marinha, Rio Grande, Brazil, 2Universidade Federal do Rio Grande, Programa de Pós-Graduação em Oceanografia Biológica, Rio Grande, Brazil, 3Universidade Federal do Rio Grande, Instituto de Oceanografia, Laboratório de Ecologia e Conservação da Megafauna Marinha, Rio Grande, Brazil, 4Universidade Federal do Rio Grande, Instituto de Oceanografia, Laboratório de Fitoplâncton e Microorganismos Marinhos, Rio Grande, Brazil, 5Instituto Antártico Argentino, Departamento de Biología de Predadores Tope, Buenos Aires, Argentina

An isotopic approach was used to investigate whether the temporal and spatial patterns of energy transfer along the food web is similar in areas under different effects of warming around the Northern Antarctic Peninsula (NAP). Samples were obtained from 2013 to 2016 in Bransfield and Gerlache Straits and in Powell Basin. Mean values of δ13C and δ15N were, respectively, -26.3‰ (± 2.9) and 0.9‰ (± 1.7) for POM - particulate organic matter (n=65), -25.6‰ (± 0.9) and 5.3‰ (± 1.1) for krill (n=29), -24.1‰ (± 2) and 8.9‰ (± 1.5) for humpback whales - Megaptera novaengliae (n=67), -24.6‰ (± 1.2) and 8.2‰ (± 0.7) for fin whales - Balaenoptera physalus (n=23) and -24.4‰ (± 1.6) and 8.7‰ (± 1) for Antarctic minke whales - Balaenoptera bonaerensis (n=16). The isoscapes generated for baseline at the NAP ecosystem provided knowledge on how the δ13C and δ15N values of POM varied spatially and temporally in the region. POM samples in which diatoms and cryptophytes were predominant significantly differed in the δ13C values and the contribution of these groups to the total phytoplankton biomass was positively and negatively correlated with the POM δ13C values, respectively. The differences observed are considered representative of contrasting environmental conditions. The present study provides new insights for the stable isotope values in the Antarctic ecosystem and may help to foresee the consequences of physico-chemical changes in water properties to the biota due to global warming.
Forecasting assemblage-level responses to climate change is a great challenge for global ecology. Marine data are limited because they largely come from experiments using small numbers of species, mesocosms whose interior conditions are unnatural, and long-term correlation studies based on historical collections. We describe the first experiment to warm benthic assemblages to ecologically relevant levels in situ. Heated settlement panels were deployed near Rothera Station on Adelaide Island, Antarctica, with three test conditions: ambient and 1°C and 2°C above ambient (predicted sea temperature increases in the next 50 and 100 years, respectively). There were massive impacts on the marine assemblage, with near doubling of growth rates. Growth increases far exceeded those expected from biological temperature relationships established more than 100 years ago by Arrhenius, and demonstrated to accurately describe temperature effects on biological systems since then. The growth increases resulted in a single “r-strategist” pioneer species (the bryozoan *Fenestrulina rugula*) dominating seabed spatial cover and drove a reduction in overall diversity and evenness. In contrast, a 2°C rise produced divergent responses across species, resulting in higher assemblage variability. This divergence in response at 2°C warming probably indicates some, but not all, species were warmed to temperatures near their long-term physiological limits and their capacities to resist warming were compromised.
Rising human activity in Antarctica, combined with the recent changes to the polar climate mean that establishing the risk of non-native terrestrial species to vulnerable, biodiversity and nutrient-poor ecosystems is urgent. Yet the impact on Antarctic ecosystem function from existing introduced species remains unclear. Of the five known non-native invertebrate species in terrestrial Antarctica, the flightless midge *Eretmoptera murphyi* may currently present the highest risk to local indigenous communities and is an excellent case study to establish these impacts, as the only higher invertebrate in the terrestrial ecosystem of Signy Island. Introduced to Signy in the 1960s from sub-Antarctic South Georgia, *E. murphyi* has established successfully, with an estimated mean biomass 2-5 times greater than the entire native arthropod communities in the areas it has colonised. As a detritivore and with no competitors or predators, *E. murphyi* may have a major impact on nutrient cycling which will, in turn, affect peat decomposition and soil structure, thereby having wider impacts on all levels of biodiversity. This study seeks to identify whether and how much the midge is impacting the local ecosystem through *in situ* measurements of key nutrient levels, invertebrate community assemblage, substrate microbial loads and vegetation diversity, and will be combined with a revision of the species' current distribution range and abundance on Signy to establish the scope of its impact.
Vertical Profiles and Feeding Strategies of Copepods in Prydz Bay, Antarctica

Guang Yang¹ (yangguang@qdio.ac.cn), Chaolun Li¹, Yanqing Wang¹
¹Institute of Oceanology, Chinese Academy of Sciences, Qingdao, China

The vertical profiles of zooplankton community structures and feeding strategies and trophic niches of dominant copepod species were investigated using fatty acids and stable isotopic biomarkers based on samples collected from various water strata of Prydz Bay, Antarctica during austral summer of 2013. Four zooplankton communities belonging to distinct water strata were identified. The four groups differed more in animal abundance than in species composition. A few species (Metridia gerlachei, Rhincalanus gigas, Alacia spp.) showed significant diel vertical migration based on quadratic regression analysis. Sampling depth was the strongest differentiating factor between samples. These results suggest that depth-related differences in the environmental characteristics of water masses, such as temperature and salinity, may have the greatest effect upon community structure. Copepods showed species-specific and depth-related differences in fatty acid biomarkers and stable isotopic values. Intra-population variability and higher δ¹⁵N values in M. gerlachei and Paraeuchaeta antarctica dwelled in the mesopelagic and bathypelagic zone indicated the flexible feeding strategies of these copepods responding to the changing food availability. The species-specific and depth-related feeding strategies of copepods based on biomarkers in this study could enable them to utilize different ecological niches and minimize inter- and intra-specific completion in the Prydz Bay ecosystem.
Benthic marine invertebrates are diverse in Antarctica, but little is known about their parasitic counterparts. *Asterophila*, a genus of eulimid gastropod, is endoparasitic in asteroid sea stars. There are four known members in this genus, one of which has been described from the Antarctica Peninsula and forms part of a putative radiation of species in this region. In order to further explore this radiation, 61 *Asterophila* specimens were collected from 38 hosts in Antarctica. Five genes were used for phylogenetic reconstruction and species delimitation and a test of host-parasite co-evolution was conducted by employing global congruence and event-based reconciliation analyses. The resulting *Asterophila* phylogeny shows high support for nine species-level entities in Antarctica, suggesting undocumented diversity in this group. These nine putative species show varying degrees of host specificity and species with more extensive sampling show higher host diversity. Significant global congruence between host and parasite phylogenies was detected, suggesting these groups are co-evolving, but the majority of links were explained by host switching rather than strict co-speciation. Investigating co-phylogenetic patterns provides insight into whether host and parasite lineages are evolving in synchrony, which may have important implications for biodiversity conservation. In all, these results advance our understanding of diversity and the processes driving this diversity in Antarctica.
The Effect of Low Temperature on Photosynthetic Processes in an Antarctic Lichen

Michaela Marečková¹ (mareckova.mm@gmail.com), Miloš Barták¹
¹Masaryk University, Faculty of Science, Department of Experimental Biology, Brno, Czech Republic

Physiological responses of autotrophic constituents of Antarctic vegetation oasis have met a great importance in respect to recent climate variability in the region of Antarctic Peninsula. In our study, we investigated the effects of low temperature and short-term photoinhibition at high and low thallus temperature, respectively, on the fast chlorophyll fluorescence transient (OJIP) and OJIP-derived photosynthetic parameters in foliose lichen Dermatocarpon polyphyllizum. The lichen thalli were collected at James Ross Island, Antarctica. In a laboratory, the samples were exposed to a gradually decreasing temperature (22, 18, 14, 12, 10, 7, 4, 0 and -5°C). The initial phase of the transient (O-J) caused by the reduction of the primary quinone acceptor (QA) was found temperature-dependent. The K-step was apparent for the samples measured at the temperature above 12°C, but not below 10°C in light-adapted lichen thalli. In photoinhibited samples, we used OJIPs, OJIP-derived parameters, and evaluated the effect of photoinhibition on samples with scraped and intact upper cortex of a lichen at 18°C (measured temperature optimum of D. polyphyllizum) and 4°C. In conclusion, OJIP is an useful tool to investigate temperature-dependent changes in photosystem II as well as the effect of photoinhibition and consequent recovery of photosynthesis in chlorolichen photobionts. The method thus might be used in thermal resistance studies. We thank to CzechPolar2 and ECOPOLARIS for funding.
Winter Physiological Suppression in Antarctic Krill is Not Observed Everywhere

Kim Bernard¹ (kbernard@coas.oregonstate.edu), Anthony Cossio², Jennifer Walsh², Christian Reiss²
¹Oregon State University, College of Earth, Ocean, and Atmospheric Sciences, Corvallis, United States, ²National Oceanic and Atmospheric Administration, Antarctic Ecosystem Research Division, La Jolla, United States

With a combined biomass greater than almost any other animal on Earth, Antarctic krill (Euphausia superba) supports vast numbers of top predators, contributes to biogeochemical cycling, and is the subject of a growing fishery. Overwinter survival is one of the key factors contributing to the success of the Antarctic krill population but it is one of the least understood aspects of the species’ life cycle. Physiological suppression is an important strategy used by krill to survive in regions where winter food resources are low, such as the Lazarev Sea. However, it has been shown that in other regions, such as the Bransfield Strait in the northern Antarctic Peninsula (AP), krill continue to feed during the winter, suggesting minimal physiological suppression. We measured winter respiration rates of krill in the northern AP, an important, but rapidly warming, overwintering region for these organisms. Our measured respiration rates were higher than those reported for other regions. Our results highlight the importance of the northern AP for overwintering krill. Elevated respiration rates, however, correspond to greater minimum energy demands and we will discuss potential food resources available to krill overwintering in this region. Finally, we suggest that the elevated winter respiration rates in the northern AP are indicative of life history plasticity with important implications for the timing of reproductive development.
There is a dearth of knowledge about biodiversity levels found in shallow environment in the Southern Ocean, a situation opposite to that found in other oceans. These habitats are however exposed to fast-paced changes in key environmental parameters. Shallow marine fauna has been facing past climatic events, but at time frames of different orders of magnitudes. Its response to current change is (re-)shaping the function and structure of ecosystems. On top of understanding these aspects, the ongoing RECTO/vERSO projects have identified plasticities (trophic, dispersive) and connectivities as key research areas to characterize the response of Southern Ocean ecosystems to Global Change.

The Belgica120 expedition is an attempt to delineate the impact of contrasted glacial regimes on the structure of shallow benthic communities by

- mapping marine habitats and quantifying the physiological sensitivity of selected taxa
- assessing the levels of biodiversity in an underexplored area of the West Antarctic Peninsula (WAP)
- using genomics to unravel past and present connectivity of key species
- modelling trophic networks in fast-changing environmental conditions
- testing the concept of using an agile platform for Antarctic marine biology work

In this presentation, we will give an overview of the Belgica120 experience, present initial results as well as discuss new perspectives for future research on Southern Ocean biodiversity.
Greenland is one of the Arctic regions that might be severely affected by climate change. The trend towards a rise in temperature could cause changes in soil microbial diversity. Despite the high ecological interest in Polar Regions, little is known about the structure and diversity of the terrestrial microbial communities in ice-free areas in West Greenland, compared to other Arctic regions. In the frame of the International Network for Terrestrial Research and Monitoring in the Arctic (INTERACT), the Effects of Climate change On Microbial Community of Soil in Greenland (COMICS-G) project aimed

i) to characterize and compare the soil prokaryotic and eukaryotic diversity along a vegetation transect (NERO line transect, established in July 2007 for monitoring future changes of boundaries between vegetation zones and in the species composition of the plant communities, including heat, bedrock, snow patch and nude soil) in the Kobbefjord field Station, West Greenland and

ii) to clarify how the biodiversity of these communities would respond to climate change. To this scope, meta-barcoding approach, targeting the ITS region and V4 region of 16S for fungi and bacteria respectively, is being performed on Illumina Miseq. The results will give important clues to figure out the potential effects of environmental changes predicted for the Arctic regions.
Due to spatial scarcity and lack of long instrumental climatic records as well as missing written sources from the Arctic, studies focusing on proxy archives and environmental reconstructions are important evidence of eoclimatic variations in (sub)-polar regions. We introduce here one such highly valuable proxy archive, the long-lived, circumpolar, and relatively abundant tundra shrub *Juniperus communis*. Although it has shown good potential for environmental reconstructions (e.g. summer temperature, or ice-sheet melt) it is still a chronically understudied species, not only in terms of its ecology but also with respect to its wide geographical distribution. As environmental reconstructions are becoming integral parts of climate and environmental change research the demand for reliable and complex proxy data rises. Therefore, we are currently building the circumpolar wood anatomy juniper network to satisfy this need. So far, seven locations - mainly along the Northern Atlantic coast - have been sampled. Nonetheless, field campaigns covering Asia and N. America are still missing. Here, we invite the polar scientific community to contribute to our juniper network with the benefits of co-authorship and network access for each data contributor. We have developed a sampling procedure to guarantee the comparability of the obtained collections. Sampling per site takes approx. two person days, only basic equipment is needed and samples are easy to transport.
Primary Photosynthesis in Antarctic Lichen at Subzero Temperature: A Lab Study

Josef Hájek¹ (jhajek@sci.muni.cz), Miloš Barták¹, Jana Morkusová¹, Marie Forbelská²
¹Masaryk University, Faculty of Science, Laboratory of Photosynthetic Processes, Section of Plant Physiology and Anatomy, Institute of Experimental Biology, Brno, Czech Republic, ²Masaryk University, Faculty of Science, Department of Mathematics and Statistics, Brno, Czech Republic

Antarctic lichens in wet state may witness freezing and thawing cycles during austral summer. It is well established that the lichens are capable to perform photosynthesis at subzero temperature. In our study, we focused on the decline of photosynthesis due to gradual freezing. To evaluate the temperature dependence of primary photochemical processes of photosynthesis, we exposed hydrated thalli of Usnea antarctica (collected at James Ross Island) to linear cooling from +20 to -50°C at a constant rate of 2°C/min. Simultaneously, two chlorophyll fluorescence parameters (FV/FM: potential yield of photosynthetic processes in photosystem II, \( \varphi_{\text{PSII}} \): effective quantum yield of PSII) were measured by a modulated fluorometer. The two parameters showed a S-curve decline with temperature decrease. The decline started at -5 (FV/FM) and +5°C (\( \varphi_{\text{PSII}} \)), respectively. U. antarctica exhibited the first sign of FV/FM decline at -12°C. The critical temperature (CT) related to full inhibition of the photosynthetic processes in PSII (FV/FM), was found at -20°C. For individual samples, CT for FV/FM was typically lower than for \( \varphi_{\text{PSII}} \). Analysis of S-curves was done in order to find a parameter evaluating lichen resistance to subzero temperature. The method of linear cooling combined with simultaneous measurements of chlorophyll fluorescence parameters proved to be an efficient tool in the estimation of lichen sensitivity/resistance to freezing. Acknowledgements: CzechPolar infrastructure, ECOPOLARIS.
Genetic Patterns at Fine Spatial Scales: Complex Findings in a Complex Landscape

Daniela Monsanto¹ (dmonsanto119@gmail.com), Arsalan Emami-Khoyi³, Peter Teske¹, Ian Meiklejohn², Bettine van Vuuren¹

¹University of Johannesburg, Department of Zoology, Johannesburg, South Africa, ²Rhodes University, Department of Geography, Grahamstown, South Africa

Landscape genetics describes spatial genetic patterns, and overlays these onto a habitat matrix. Observed patterns can then be interpreted from the viewpoint of the individual organism, and how different organisms move and interact within their habitat. Using Cryptopygus antarcticus travei from sub-Antarctic Marion Island as a model organism, we explored spatial genetic structure across a 350 m transect, and interpreted our results in light of the factors driving small-scale evolution within the group. Our results for 390 individuals from 22 sampling sites revealed the presence of two genetic lineages whose contact zone broadly coincides with a ridge in the landscape. The contact zone does not manifest as a clean break, but rather a complex pattern of clustering, with sampling sites on either side of the ridge showing alternating lineage membership. Individuals within each site were not admixed but, uniformly belonged to the same lineage, and the level of inbreeding was consistent with what is expected for sexually reproducing organisms. High genetic diversity reflects a large effective population size, consistent with the high census population size reported for the species. Taken together, our results argue against asexual reproduction as an explanation for the complex spatial pattern. A more plausible explanation might involve the occurrence of divergent micro-habitat preferences and/or a fitness vacuum driven by local adaptations.
Lipid Carbon Turnover Reveals Stage-specific Differences in Antarctic Copepods

Wilhelm Hagen¹ (whagen@uni-bremen.de), Martin Graeve², Lauris Boissonot², Barbara Niehoff²
¹University of Bremen/BreMarE, Marine Zoology, Bremen, Germany, ²Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

Lipid turnover dynamics of two herbivorous Antarctic copepod species with different types of lipid depots (wax esters, triacylglycerols) were investigated by compound-specific isotope analysis to elucidate biochemical pathways and energetic adaptations. The dominant *Calanoides acutus* and *Calanus propinquus* were collected in the Antarctic Weddell Sea in late December and fed with ¹³C labeled diatoms for 9 days. ¹³C incorporation was monitored by isotope ratio mass spectrometry. Total lipid (TL) mass and fatty acid/alcohol compositions did not change significantly during the experiment. However, lipid carbon turnover was intense especially in the copepodid V (CV) specimens of *C. acutus*, which exchanged 80% TL, whereas lipid turnover rates of female *C. propinquus* and *C. acutus* were lower. Structural fatty acids (FA) were exchanged with similar rates in all copepod groups and twice as high for 16:0 and 20:5(n-3) as for 18:0 and 22:6(n-3). Long-chain monounsaturated FAs (MUFA) are largely stored as energy reserves. 20:1(n-9) and 22:1(n-11) showed highest turnover rates in *C. acutus* CVs, only 20:1(n-9) was exchanged in *C. acutus* females and there was no MUFA turnover in *C. propinquus* females. Fatty alcohols also exhibited much higher exchange rates in *C. acutus* CVs than in the females. These differences emphasize the more intense biochemical activities in growing CV stages, whereas in females metabolic processes are less pronounced and probably more related to egg production.
Ecosystem Research at the Canadian High Arctic Research Station (CHARS)

Ian Hogg¹ (ian.hogg@polar.gc.ca), Ioan (Johann) Wagner¹, Donald McLennan¹, Jean-François Lamarre¹, Stephanie Coulombe¹

¹Polar Knowledge Canada, Canadian High Arctic Research Station, Cambridge Bay, Canada

Polar Knowledge Canada (POLAR) was established to provide a world-class research station in the Canadian Arctic anchoring a strong research presence that serves Canada and the world. A strong component of this is to advance knowledge of the Arctic and to improve the quality of life for people living in the north. The Canadian High Arctic Research Station (CHARS) at Cambridge Bay in the central Canadian Arctic is now nearing completion and will provide a range of laboratory and office facilities in the 7,500 m² Main Research Building. From a regional biodiversity perspective, the station is located near four major bioclimatic zones and provides access to a range of freshwater, terrestrial and marine habitats. Available data suggest an abundance of previously unknown and/or cryptic species in the Arctic. This, combined with the area around CHARS being relatively little studied, make the CHARS location a highly interesting region for ecological and cryosphere studies. A nearby “Experimental and Reference Area” (ERA), will be the focus of intensive research efforts over the next two years in an effort to provide an accurate assessment of ecosystems within the ERA. This would benefit strongly from international collaborators. POLAR is strongly committed to developing productive research partnerships with national and international scientists and opportunities exist for international researchers to visit and use the facilities.
The seasonal advance and retreat of sea ice around the northern Antarctic Peninsula can have a significant impact on phytoplankton, mainly due to alterations in the availability of ice-free areas, micro-nutrient inputs by meltwater and variations in water column structure. The aim of this work was to evaluate the effect of sea ice conditions on phytoplankton biomass and community composition in an area off the northern Antarctic Peninsula. Two contrasting conditions were studied: a strong environmental gradient around the sea ice edge, with a marked meltwater signal (summer 2013) and the same area with little indication of meltwater and no detectable sea ice conditions (summer 2014). There was a clear distinction between the phytoplankton communities under sea ice influence, where mainly cryptophytes were associated with shallow mixed layers and high water column stability in 2013 and an important presence of diatoms in 2014, associated with deeper mixed layers, lower silicic acid concentrations and higher magnitudes of both salinity and temperature, under very little sea ice influence. Gymnodinioid dinoflagellates were an important component in both years, apparently occupying sites/conditions less favourable to cryptophytes. These results support previous suggestions that climate factors leading to shortening of the sea ice season in the region do have an important impact particularly in shaping the dominance of the main phytoplankton functional groups in the region.
Ecological niche models are now commonly used to characterize the relationship between species occurrences and environmental conditions. Amongst these models, the correlative approach (species distribution models, SDMs) has been widely applied to modeling the distribution of various organisms at different spatial scales. However, this approach has received some criticisms because it assumes that species distribution is at the equilibrium with the environment. This constitutes a serious limitation to modeling dynamic predictions such as future range shifts due to climate change. SDMs are unable to integrate the full range of processes involved in physiological responses of species to environmental changes. In order to consider these biological processes in modeling procedures, we generated mechanistic models based on the Dynamic Energy Budget (DEB) theory, capturing metabolic processes of an organism during its entire life cycle using temperature and food availability. This approach allows getting an enhanced assessment of fitness components such as survival, development, growth and reproduction.

We modeled the distribution of the echinoid *Sterechinus neumayeri*, a common species in benthic communities from Antarctic shallow areas. We used an integrative approach based on both correlative and mechanistic models to predict species range shift with predicted environmental changes, a crucial issue for biodiversity conservation and management.
Estimating Adaptive Capacities of *Salpa thompsoni* Facing Southern Ocean Warming

Wiebke Wessels¹ (wiebke.wessels1@uni-oldenburg.de), Katharina Michael¹, Gabriele Sales², Chiara Romualdi², Bettina Meyer¹,³

¹Carl-von-Ossietzky University of Oldenburg, Institute for Chemistry and Biology of the Marine Environment, Oldenburg, Germany, ²University of Padova, Department of Biology, Padova, Italy, ³Alfred Wegener Institute, Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

The polar regions and the western Atlantic sector of the Southern Ocean in particular are among the fastest warming areas on the planet. Long-term data sets indicating a decline in krill abundance in the northern part of the Western Antarctic Peninsula (WAP) and an increase of salp populations as well as a shift in food quality and quantity, highlight the unique characteristic of the WAP region to observe the ecosystem response to climate change. Krill and salps are among the most important grazers, playing a crucial role in the WAP ecosystem. Thermal limits on physiological processes in krill and salp life cycles on different levels of the organism are yet unknown, limiting the accuracy of predictions on how these two species might respond to climate change. To assess the natural plasticity of Antarctic salp, *Salpa thompsoni*, between seasons, winter and summer samples were subjected to high throughput sequencing as well as additional cellular analyses. The *de novo* generated transcriptomes of *S. thompsoni* and its Mediterranean relative, *S. fusiformis*, were compared to detect regional adaptive strategies. First results on metabolic and reproductive activity in *S. thompsoni* in response to seasonal differences will be presented. The unique life cycle, changing between solitary and aggregate stage and therefore facilitating fast reproduction under favourable conditions, might be the baseline for potential adaptive capacity of *S. thompsoni*. 
A First Approach to the Leaf Hydraulic Properties of Deschampsia antarctica

Patricia L. Sáez\(^1\) (patrisaezd@gmail.com), Lohengrin Cavieres\(^2\), Constanza Ramírez\(^2\), Betsy Rivera\(^2\), Valentina Vallejos\(^2\), Yessenia Aguayo\(^2\), Domingo Sancho-Knapik\(^3\), José Peguero-Pina\(^3\), Eustaquio Gil-Pelegrin\(^4\), Jeroni Galmes\(^5\), Leon A. Bravo\(^6\)

\(^1\)Universidad de Concepción, Silvicultura, Concepción, Chile, \(^2\)Universidad de Concepción, Concepción, Chile, \(^3\)Universidad de Concepción, Zaragoza, Spain, \(^4\)CITA, Aragon, Zaragoza, Spain, \(^5\)Universidad de Islas Baleares, Palma de Mallorca, Spain, \(^6\)Universidad de la Frontera, Temuco, Chile

Increase temperature produces changes in photosynthetic limitations of Deschampsia antarctica, promoting higher rates of net photosynthesis. This photosynthetic response is related to change in leaf traits, specifically associated to the CO\(_2\) mesophyll conductance (\(g_{\text{m}}\)). Considering that the CO\(_2\) and water vapor share, partially, diffusion pathways in the leaf mesophyll, we ask if change in \(g_{\text{m}}\) under warmer condition are accompanied by changes in the leaf hydraulic properties of \(D. \text{antarctica}\). Given that currently there are no studies about the hydraulic characteristics of Antarctic vascular species, both under field or laboratory conditions, our first goal was tune-up methodologies to measure the leaf hydraulic conductance (\(K_{\text{leaf}}\)) and the whole hydraulic conductance (\(g_{\text{plants}}\)). The increase in net photosynthesis triggered at higher growth temperatures were accompanied by increases in both \(K_{\text{leaf}}\) and \(g_{\text{plants}}\). These changes were also associated to adjustment in the leaf traits as leaf density and leaf mass area production, and also with changes at vascular leaf level. Despite these adjustments could be positive for the growth of \(D. \text{antarctica}\) under warmer growth conditions, plants could be more susceptible to damage during sudden freezing events, which could increase, as a result of regional climate change.

Acknowledgments: INACH RT 13_16.
Under Ice Flagellates Bloom in Coastal Area of the Ross Sea (Antarctica)

Maria Saggiomo¹ (m.saggio@szn.it), Francesco Bolinesi², Laura Escalera³, Francesca Margiotta³, Vincenzo Saggiomo³, Olga Mangoni⁴

In early spring 2016 water samples, under annual fast ice from 0-100 m, were collected in a coastal area in Terra Nova Bay (Ross Sea) from December to January (2015-2016). We investigated temporal distribution of temperature, chlorophyll a, particulate organic carbon and phytoplankton composition. Several new and unusual events were observed in the under-ice phytoplankton community of the Ross Sea. A massive under ice bloom dominated by flagellates, < 10 µm of length, was recorded. This group was numerically similar and/or dominant compared to diatoms in this study. Flagellates blooms showed a high temporal variability in species composition: i) the chrysophyte *Ochromonas* spp., generally found in Antarctic lakes, was observed for the first time in the sea; ii) the parmales *Pentalamina corona*, known for the Antarctic pelagic environments, was found for the first time under the ice with unusually high concentrations and iii) the haptophyte *Phaeocystis antarctica*, was reported for the first time in the under ice system in high concentrations. These events could be related to a peculiar seasonal progression in the ice melting process in the 2015-2016 period or may indicate an environmental change. The ecological role of this flagellates under the pack ice should be studied in detail.
Morphological Differentiation Reflect Ecological and Genetic Background in *Usnea*

Shunan Cao¹ (caoshunan@pric.org.cn), Fang Zhang¹, Hongyuan Zheng¹, Chuanpeng Liu², Fang Peng³, Qiming Zhou²

¹Polar Research Institute of China, Shanghai, China, ²Harbin Institute of Technology, School of Life Science and Technology, Harbin, China, ³Wuhan University, College of Life Science, Wuhan, China

King George Island is the second largest ice-free area of the South Shetland Islands, and the fruticose lichen *Usnea aurantiaco-atra* is the most dominant and widespread flora around King George Island. It had been observed that the individuals of *U. aurantiaco-atra* with different phenotypes could grow on various substance. A comprehensive analysis combining morphological and phylogenetic traits reveals that the phenotypic differentiation of *U. aurantiaco-atra* (erect growth on stones or with prostrate growth with mosses) provides an effective approach to adapt to different micro-environments, and those individuals with complicated morphological traits grow on different substances (e.g., stone, wood, even other lichen such as *Umbilicaria antarctica*) could share the same genotypes (they have the same ITS rDNA sequences of both mycobiont and photobiont). Moreover, haploid disequilibrium testing indicates that there is no significant genetic difference for the two growth forms (erect and prostrate) when fungal and algal ITS rDNA were treated as two alleles of one lichen individual. The two growth forms of *U. aurantiaco-atra* appear to reflect different stages of lichen-moss community succession, and a mode is proposed for demonstrating the occurrence of this succession. Also, the current study implies that lichen is a mini-ecosystem more than a dual symbiotic association of fungus and alga.
Introduction of the Journal *Advances in Polar Science* and Call for Papers

Jing Huang$^1$ (huangjing@pric.org.cn), Xiaoliang Ling$^1$, Beichen Zhang$^1$

$^1$Polar Research Institute of China, Shanghai, China

*Advances in Polar Science* (APS) has been published since 1990 as a peer-reviewed English-language journal dedicated to the presentation of multi-disciplinary achievements in Arctic and Antarctic expeditions and research (until 2011 it was known as the Chinese Journal of Polar Science [English Edition]). In 2015, we made APS more truly international, with two new Co-Editors-in Chief, Dr. Huigen Yang and Prof. Ian Allison, and a new expert team of disciplinary Editors from China and many other nations involved in polar research (http://www.aps-polar.org/home/editorialboard). Our broad goals for the journal in the near future are to improve the quality of contributions and to attract more involvement and contributions from outside China. Specific objectives will include using APS as a platform to raise international awareness of Chinese polar research and to facilitate collaboration between China and other nations in polar science, and to build both inter-disciplinary and bi-polar links within our research community. APS is a true open-access, quarterly scientific journal. Articles published in APS are free of charge with generous funding from PRIC. For more details, please see the attached introduction file or visit the APS's websites: www.aps-polar.org
The Results of Camera and Satellite Transmitter Deployment in Vernadsky Area

We report the results of the work on establishing of camera network and penguin tags deployment in penguin colonies in the area around Vernadsky Station as a part of the CCAMLR/CEMP Projects. The projects have been initiated by scientists from USA, Argentina and Poland, and supported by the CEMP Fund. The data of the project will allow analysing the climate changes and krill fishery influence on the Antarctic Peninsula ecosystem. Ukraine is responsible for support and providing the cameras and satellite transmitter deployment in gentoo and Adelie penguin colonies at the Galindez, Petermann, and Yalour Islands. The pictures of gentoo colonies at the Galindez and Petermann Islands, and Adelie colonies at Yalour Island have been processed according protocol and methods provided and coordinated by US scientists. Information on copulation, egg lay, maximum number of eggs, hatch, maximum number of chicks, date of cheque, and the maximum number of adults have been obtained and analysed during breeding season 2016/2017 from the photos of the all nine cameras. The results of visual observations coincided with camera photos are discussed. ARGOS satellite tags have been installed successfully at fifteen adult gentoo penguins in Galindez Island colony and some of tags are still transmitting in the end of October 2017.

The work is supported by CEMP Fund of the CCAMLR, by National Antarctic Scientific Center of Ukraine and Taras Shevchenko National University of Kyiv, project 16BF051-02.
The polar cod (*Boreogadus saida*) and the Antarctic silverfish (*Pleuragramma antarctica*) are pelagic fish endemic of the Arctic and Antarctica, respectively. Shaped for life in icy waters, both the polar cod and the Antarctic silverfish are nowadays abundant in the pertaining polar marine ecosystem, playing a central role as link between top predators and lower trophic levels. Although phylogenetically distant, during their independent evolutionary histories in polar regions, these two polar fish has been subjected to similar ecological drivers, eventually leading to a comparable suite of, biological and ecological adaptations.

Both species are zooplanktivorous, known to primarily feed on copepods, euphausiids and amphipods. Intraspecific regional differences in diet, reflecting prey availability, have been recorded for both the cod and the silverfish, supporting the hypothesis of them being opportunistic feeders. In the light of the ongoing climate change how each of the species might cope with changes in the prey availability is of particular relevance with strong implications for the polar food web.

Here we apply an ecomorphological approach to characterize the feeding modes of the polar fishes, aiming at better understand their feeding adaptation, and their potential trophic flexibility. The morphofunctional bases of the feeding mechanisms are assessed through morphometric analysis of mouth structures, jaws, buccal cavity, muscles of the head and gill rakers.
Five Millennia of Environmental Dynamics from an Ice Core in the Mongolian Altai

Sandra Brügger¹ (sandra.bruegger@ips.unibe.ch), Erika Gobet², Michael Sigl³, Dimitri Osmont³, Tatjana Papina⁴, Natalia Rudaya⁵, Margit Schwikowski³, Willy Tinner²

The Central Asian forest-steppe ecotones are highly vulnerable to environmental shifts such as drought and overgrazing. Knowledge about past vegetation and fire responses to environmental change may contribute to a better understanding of future ecosystem dynamics. However, paleo records are scarce in the region. Our novel high-alpine ice record from Tsambagarav glacier (4130m asl) in the Mongolian Altai provides unique paleoenvironmental information at the landscape scale with an exceptional temporal resolution and a sound chronology covering the past 5500 years. We use pollen as proxies for vegetation composition and structure, microscopic charcoal as a proxy for fire activity, and spheroidal carbonaceous particles (SCPs) to infer fossil fuel combustion.

We present the first microcharcoal-inferred fire history record from Mongolia which can be directly linked to past vegetation dynamics. Reconstructed mid to late Holocene forests collapsed and fire increased, likely in response to climate change. Our results underscore the vulnerability of relict forest ecosystems in the Mongolian Altai and imply that in these steppic areas, moisture is more important than temperature for tree growth. We conclude that Central Asian forest ecosystems including the Russian Altai are highly vulnerable and may collapse rapidly in the future, if global warming will be associated to moisture declines as anticipated by regional climate models.
Diversity Structure of Rotifer Communities in Deglaciation Areas of Svalbard

Tomotake Wada¹ (wada.tomotake@nipr.ac.jp), Nataliia Iakovenko²,³,⁴, Miloslav Devetter⁵,⁶,⁷, Karel Janko⁷,⁸,⁹, Sakae Kudoh¹,¹⁰, Masaki Uchida¹,¹⁰

¹SOKENDAI, Tokyo, Japan, ²Schmalhausen Institute of Zoology NAS of Ukraine, Invertebrate Fauna and Systematics, Kyiv, Ukraine, ³University of Ostrava, Biology and Ecology, Ostrava, Czech Republic, ⁴Institute of Animal Physiology and Genetics, Laboratory of Fish Genetics, Liběchov, Czech Republic, ⁵Institute of Soil Biology AS CR, České Budějovice, Czech Republic, ⁶Biological Centre AS CR, České Budějovice, Czech Republic, ⁷Centre for Polar Ecology, České Budějovice, Czech Republic, ⁸Institute of Animal Physiology and Genetics, Liběchov, Czech Republic, ⁹University of Ostrava, Ostrava, Czech Republic, ¹⁰National Institute for Polar Research, Tokyo, Japan

Glacial retreat occurs worldwide due to global climate change. Svalbard glaciers are ones of the most retreating in the world (Norwak & Hondson 2014). Their exposed forelands create new niches for terrestrial microbial organisms, in particular for microscopic invertebrates that influence further changes of the rock substrates. This study aims at understanding the diversity patterns, in particular, gradients of diversity and abundance in deglaciation areas, of a key group of soil microfauna, rotifers (Rotifera).

Soil and moss were collected in Adolfsbukta (Nordenskiöldbreen, NB), and the vicinity of Ny-Ålesund (Austre Brøggerbreen, ABB), both at a single point and along the transects, 0 to circa 500 m from the glaciers. Rotifers were extracted using the method of Freckman & Virginia (1993), counted and identified to species. Eighteen rotifer species were found in NB and 12 in ABB, respectively, with Adineta gracilis, Ceratotrecha cornigera, C. velata, Habrotricha cf aspera, Macrotachela cf concinna, M. insolita being the most common and abundant species. Abundance varied from 0 ind/g (near the glacier) to 50-75 ind/g of soil (more than 200 m from the glacier), however no strict diversity and abundance gradients were observed, with a higher number of species and individuals occurring under moss patches. Therefore, deglaciation areas in Svalbard provide new niches for microinvertebrate communities that might cause further changes in structure and composition of the exposed soils.
Soil characteristics allow the understanding of the factors that drive vegetation development and dynamics in Maritime Antarctica, being extremely sensitive to between environmental changes. We investigated the relation between soil attributes with landscape features and plant community. We analyzed soil attributes in ten different plant communities following a toposequence, near Henryk Arctowski Polish Station, Admiralty Bay, Antarctica Maritime. Results indicate that coastal phanerogamic communities presented greater phosphorus and organic matter contents due to ornithogenic influence. In these areas, soil shows low levels of sodium and low pH at the bottom of the toposequence. Fruticose lichen communities were observed at high altitudes, characterized by higher exchangeable sodium and calcium contents, as well as lower amounts of phosphorus and organic matter. Mosses carpets are mainly found on wet soils, with low diversity of species, coupled with little soil organic matter accumulation. Bare soil as reference, presented very low organic matter content, high pH and sodium saturation. We observed that organic matter only accumulates at the bottom of the toposequence, under phanerogamic community. Lichens communities are found at higher positions of the landscape under very of higher diversity shallow and skeletic soils, indicating a strong dependence of vegetation establishment to physical conditions, especially moisture.
Similarity of Trends of Scrubs Expansion in Arctic and High Mountains in Russia

Elena Belonovskaya¹, Arkadiy Tishkov¹ (tishkov@biodat.ru)
¹Institute of Geography, RAS, Biogeography, Moscow, Russian Federation

In the beginning of the XXI century in tundra and high mountains growth of plant productivity and vegetative index (NDVI) was revealed (Walker et. al. 2012; Bhatt et. al. 2013; Belonovskaya et al., 2016; Tishkov et al., 2016; Shiyatov 2009; Vinogradova et al., 2015). The main cause of this process is synergism of climatic and anthropogenic impact changes. Growing season’s increasing, active temperature sum’s raising and soil melting depth’s deepening result scrub vegetation of Betula, Salix, Duschekia, Pinus, Juniperus, Rhododendron, etc. genera’s spreading in Russian tundra (Kola Peninsula, lower Pechora-river, Yakutia) and in the high mountains (Khibini, Urals, Eastern Siberia, Caucasus). Similar process is noticed for Alaska and Canadian Arctic (Duschekia, Salix and Betula) (Tape et al., 2006). The trend of scrub vegetation invasion was recognized in global scale for various treeless biomes. In high mountain regions scrub area’s enlargement is caused by climatic changes as well by abandoning of alpine pastures. In Arctic and high mountains widening of scrub vegetation initiates development of landscape diversity, increasing of snow accumulation and therefore development of continuous scrub cover, organic matter accumulation and changes of soil thermal regime. Thus this process may have the cyclic character because according the “cascading effect” it induces “inverse relationships”: reaction of all landscape components and as a result scrub degradation in the future.
First described around 100 years ago, *Halirytus magellanicus* is a non-biting midge native and probably endemic to southern South America. The species has received no specific research attention since its discovery, and little is known about its habitat, life cycle and other biological characteristics. Recently, it has been relocated in Navarino Island, southern Chile, providing the opportunity to document the species' biology, and compare with other, better studied, Antarctic and sub-Antarctic relatives. We completed a spatial point-pattern analysis to characterise its habitat at several bays on Navarino Island, and ecophysiological experiments addressing its adaptive features in terms of tolerance to desiccation, salinity, temperature variation and salinity+temperature interaction. The species is active for most of the year and has a multivoltine life cycle, in contrast with its assumed closest relatives, the Antarctic/sub-Antarctic endemics *Belgica antarctica* and *Eretmoptera murphyi*. Primary habitat requirements for the larvae include filamentous algae and thin sand, which appear to be necessary to secure larvae and pupae from being washed away during the tidal cycle. While the larvae can withstand wide variation in salinity and temperature, as may be expected during intertidal exposure, they are vulnerable to desiccation stress, especially at higher temperatures. These features permit the species to inhabit a wide range of intertidal microhabitats.
Exploration of the flora of the Canadian Arctic has been ongoing for almost two hundred years, yet substantial gaps remain in our floristic understanding of this large, rapidly changing and difficult-to-access region. Detailed information on the diversity and distribution of Arctic plants and lichens at local, regional and global levels is urgently needed to understand the potential impacts of climate change on Arctic flora. Since 2008 we have been conducting floristic surveys in botanically-understudied regions of the Canadian Arctic; lichen exploration began in 2016. The comprehensive baseline data of our >8000 new collections, all housed permanently in the National Herbarium of Canada at the Canadian Museum of Nature, and other herbaria in Canada and internationally, adds important baseline knowledge to our understanding of Arctic plant and lichen biodiversity. Our collections include first records for specific areas (e.g., territories, parks, islands), major and minor range extensions, second or third collections of poorly-known species at the northern or southern edges of their ranges, new discoveries of rare species, and they fill in gaps in the known distributions of Arctic species. We are working on a new Arctic Flora of Canada and Alaska, which aims to bring together all available information on the diversity and distribution of vascular plants in this region, including keys, descriptions, nomenclature, distribution maps, images and more.
A Spatially Explicit Food Web Model to Evaluate Change on the Kerguelen Plateau

Roshni Subramaniam1,2,3 (roshni.subramaniam@utas.edu.au), Jessica Melbourne-Thomas2,3, Stuart Corney2, Kerrie Swadling1, Patrice Pruvost4, Matt Pinkerton5
1Institute for Marine and Antarctic Studies, University of Tasmania, Hobart, Australia, 2Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia, 3Australian Antarctic Division, Hobart, Australia, 4Muséum National d'Histoire Naturelle, Département Milieux et Peuplements Aquatiques, Paris, France, 5National Institute for Water and Atmospheric Research, Wellington, New Zealand

The Kerguelen Plateau is a highly productive area. Seabirds and seals breed on the islands, parts of the plateau support nurseries and larval development for fish species, and iron enrichment from the shelf produces phytoplankton blooms that attract a wide range of species to forage in the area. The plateau also supports valuable fisheries for Patagonian toothfish and icefish. The area is changing, with increasing temperatures, and movement of oceanographic frontal systems that interact with the plateau. Climate model projections suggest that these changes are likely to lead to increases in primary productivity. We have developed the first balanced Ecopath with Ecosim model for the Kerguelen Plateau using published information on species biomass and diet. We present this model with an added spatial component (Ecospace) that allows us to examine spatial variation of the food web across the plateau. We present results from a set of spatially explicit scenarios to examine the combined effects of changes in primary productivity and fisheries for the Kerguelen Plateau and evaluate the impacts of these changes throughout the food web.
Abundances and Activities of Prokaryotic Community in Water of an Arctic River

Marco Graziano¹ (margraziano@unime.it), Maria Papale¹, Antonella Conte¹, Gabriella Caruso², Alessandro Ciro Rappazzo², Angelina Lo Giudice², Stefano Amalfitano³, Giovanna Maimone², Carmen Rizzo¹, Serena Savoca¹, Emilio De Domenico¹, Rosabruna La Ferla², Maurizio Azzaro²

¹University of Messina, Department of Chemical, Biological, Pharmaceutical and Environmental Sciences, Messina, Italy, ²IAMC-CNR Messina, Messina, Italy, ³Water Research Institute (IRSA), National Research Council, Roma, Italy

The spatial and temporal distribution of microbial biomass and metabolic rates were investigated in water samples collected along the Pasvik River (Arctic Norway) from 9 stations during two sampling campaigns (May and July 2014). Water samples were analyzed for physico-chemical parameters, viable bacterial abundance (VCs), prokaryotic abundance (PA), microbial enzymatic and respiratory activity. All data were statistically analyzed. VCs were generally homogeneous in May and July. PA showing enhanced abundance in July and higher values in the outer than in inner stations. Microbial respiration was higher in July than in May. Pearson's correlation coefficients showed that physical and chemical parameters affected both the PA and functionality. Respiration was significantly related to Temperature, suggesting its stimulation on the oxidation process. ANOSIM analysis showed seasonal significant differences (R=0.231, p=0.002), with temperature accounting for 11.4% of total variability. Psychrophilic microorganisms of the Pasvik river appear to be quite plastic to acclimate to seasonal changes of the cold habitat in which they live, modifying their abundance and metabolism, although further research is needed for a deepen knowledge of this Arctic ecosystem.
Dwarf Brooder versus Giant Broadcaster: Unrecognized Species in a Brittle Star

Quentin Jossart\textsuperscript{1,2} (qjossart@gmail.com), Chester Sands\textsuperscript{2}, Mary A. Sewell\textsuperscript{1}
\textsuperscript{1}University of Auckland, Auckland, New Zealand, \textsuperscript{2}British Antarctic Survey, Cambridge, United Kingdom

Characterizing a species reproductive mode (brooder, broadcaster) is key to understand the evolution and resilience of SO organisms as reproductive mode affects connectivity and demographic patterns. Distinct reproductive modes might sometimes suggest unrecognized speciation that can be confirmed through genetic or morphological investigations. This is the case for the brittle star Astrotoma agassizii where divergent genetic clades were associated with a brooding (Patagonia) and a broadcasting reproductive mode (Ross Sea). Here we investigated the genetic diversity and reproductive mode of A. agassizii from individuals collected in South Georgia (SG) and around Antarctica (208 samples). Two CO1 clades were found, one restricted to SG (clade 1) and another shared between SG and Antarctica (clade 2). Size investigations revealed a dimorphism at SG: only small individuals (disc diameter < 2.5cm) were found in clade 1 while all the largest specimens (up to 6cm) were found in clade 2. Moreover, five specimens of clade 1 were brooding, whereas clade 2 included seven Antarctic specimens exhibiting broadcasting. These results suggest that there are different species in SG: a large broadcaster (shared with Antarctica) and a smaller brooder (specific to SG). This SG clade is also separate from the two Patagonian clades described in other studies. Species integrity and distribution will be tested by exome capture analysis (hundreds of nuclear loci) and by the addition of more locations.
Corals as a Model to Measure Change in Polar Oceans

Narissa Bax¹ (baxn@utas.edu.au), Laura Robinson², David Barnes³, Chester Sands³, Rachel Downey⁴, Christoph Held⁵, Camille Moreau⁶, Bernabe Moreno⁷, Maria Paulsen⁸

¹University of Tasmania, Hobart, Australia, ²University of Bristol, Bristol, United Kingdom, ³British Antarctic Survey, Cambridge, United Kingdom, ⁴Australian National University, Canberra, Australia, ⁵Alfred Wegener Institute, Bremerhaven, Germany, ⁶Universite Libre de Bruxelles, Brussels, Belgium, ⁷Universidad Cientifica del Sur, Lima, Peru, ⁸University of Bergen, Bergen, Norway

Initial research by the Antarctic Seabed Carbon Capture Change (ASCCC: www.asccc.co.uk) project indicates that Arctic and Antarctic seabeds are absorbing and storing more carbon as the climate warms. Understanding the oceanic carbonate system across space and time is a key objective of the ASCCC multidisciplinary team. This study uses stylasterid corals, which are key global habitat constructors, as a model taxa to conduct a systematic study of how, where and why the changing chemistry of the ocean has the potential to affect calcification (the ability to grow skeletons). Stylasterid corals may have the capacity to calcify and survive the predicted acidification of the Polar regions (where pH change linked to anthropogenic CO2 is strongest). Unlike other coral groups, stylasterids can either be composed of aragonite (more soluble), calcite (less soluble), and in some species both. If stylasterids are able to manipulate their skeletal composition in response to oceanic change, then they may acclimate to anthropogenic activities, such as predicted ocean warming and acidification, which would be a significant advance in our understanding of ocean life adaptation to current and predicted environmental change.
The freshwater genus *Aulacoseira* (Thwaites 1848: 167) was established in 1848 (Round *et al.* 1990). In the Antarctic Region, only one species was recorded so far (*A. principissa* Van de Vijver (2012: 35)), widespread on all sub-Antarctic islands such as Iles Crozet, South Georgia or Heard Island (Van de Vijver 2012). Doing a qualitative analysis in a corer with 50cm sampled at the Glubokoe Deepe Lake, Fildes Peninsula, King George Island, west coast of the Antarctic Peninsula, 34 taxa were found and identified, of which only 19 were considered as frequent. Among these 19 taxa the most abundant species along all layers was the centric diatom *Aulacoseira glubokoyensis*, a new species discovered throughout this study. This data was related with environmental variables, and showed a decrease in relative abundance and cell size in the period of higher ozone variation. According with VICENT & SOY, 1993, UV-B radiation can lead to harmful effects in all organisms living in aquatic environments, and some physiological adaptation to this new condition may take generations to occur, which could explain the decline in the relative abundance of *Aulacoseira glubokoyensis* during some phases and consecutive increase, showing a possible adaptation. As it is a new species further studies about the ecology and correlation with environmental factors are still underway.
Trophic Ecology of Antarctic Deep-sea Echinoderms of the Weddell Sea

Sergio Rossi¹,² (sergio.rossi@unisalento.it), Francyne Elias-Piera³,⁴
¹Università del Salento, DISTeBA, Lecce, Italy, ²Universitat Autònoma de Barcelona, ICTA, Cerdanyola del Vallés, Spain, ³Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of

In the Southern Ocean, the trophic ecology of deep-sea communities is probably one of the most neglected. In the present study, the food sources and energy mobilization of three different deep-sea echinoderms living in the Weddell Sea (around 1500 m depth) were investigated with indirect tools (i.e. stable isotopes, biochemical balance and free fatty acids contents). The stalked crinoid Dumetocrinus antarcticus, the holothurian Rhipidothuria racovitzai, and the ophiuroid Ophiura carinifera were sampled in spring during a Polarstern cruise. We found that stable isotopes were in line of previous results of other species (δ¹³C ranging from -24.3‰ to -26.5‰; δ¹⁵N ranging from 6.8‰ to 7.9‰), showing similarities in the food sources used by the three echinoderms. The capability to store energy by these three organisms is conspicuous and different [e.g. from 18 to 45% of the organic matter (OM) are lipids]. The capability to mobilize energy in the form of carbohydrates and free fatty acids among species was also very different (e.g. biomolecules ranging from 9 to 22 µg Carbohydrates mgOM-1 and from 4 to 39 µg free fatty acids mgOM-1). The fatty acid markers and the Saturated, Mono Unsaturated and Poly Unsaturated Fatty Acid proportion were also very different depending on the species. It is suggested that even if the food sources are similar for the three echinoderms, the strategies to manage the energy inputs in these deep-sea organisms in polar environments may be quite different.
Sea Ice Duration and Ice Scour Influence Macroalgae at Potter Cove, Antarctica

Isla 25 de Mayo/King George Island is one of the best studied areas, particularly Potter Cove. At Carlini station we recorded the (1) duration of sea ice cover, (2) iceberg scouring (using experimental markers on the seabed at 5 and 10m) and (3) biological responses, in terms of macroalgal % cover, since 2014. Although links between sea ice duration, ice scour and benthos structure have been established, only one other locality (Rothera, Adelaide Island) makes similar measures. We found much variability in sea ice duration, just 46, 64 and 20 days respectively in 2014, 2016 and 2017 compared with 118 days in 2015. Correspondingly more markers were hit (i.e. higher ice scour frequency) in 2014 and 2016 (53±14 and 75±10, respectively) than in 2015 (41±9). The macroalgal % cover was significantly lower (34±8) in 2016 compared to 2014 and 2015 (78% ±4 and 57% ±14, respectively). These preliminary results suggest that a lower macroalgal % cover could be related with higher ice scouring due to reduced sea ice duration among abiotic and biotic factors controlling macroalgal cover.

Maintaining these studies long term should tease out natural short term variability in time and space from benthic ecosystem responses to regional climate-forced physical changes. Collaboration between UK, Argentina and Germany has established matched protocols, enabling us to quantify how life on Antarctica’s seabed is responding to profound sea ice losses.
Wind & Tide Affect Antarctic Krill Aggregations in a Biological Hotspot

Kim Bernard1 (kbernard@coas.oregonstate.edu), Megan Cimino2, William Fraser3, Joshua Kohut4, Matthew Oliver5, Donna Patterson-Fraser3, Oscar Schofield4, Hank Statscewich6, Deborah Steinberg7, Peter Winsor6
1Oregon State University, College of Earth, Ocean, and Atmospheric Sciences, Corvallis, United States, 2Scripps Institution of Oceanography, University of California, San Diego, La Jolla, United States, 3Polar Oceans Research Group, Sheridan, United States, 4Rutgers University, New Brunswick, United States, 5University of Delaware, Newark, United States, 6University of Alaska - Fairbanks, Fairbanks, United States, 7Virginia Institute of Marine Science, Gloucester Point, United States

Antarctic krill, *Euphausia superba*, is an abundant and ecologically important zooplankton species in the Southern Ocean. Biological hotspots, with elevated krill biomass, exist around Antarctica, often as a result of the concentrating effect of bathymetry and ocean currents. Such areas are key foraging grounds for numerous top predators. A hotspot of krill biomass exists off southern Anvers Island, Western Antarctic Peninsula, and supports a population of Adélie penguins that feed almost exclusively on it. We investigated the variability in krill aggregations in the nearshore waters of this hotspot over four consecutive summers, identifying environmental factors that were responsible. We identified three distinct krill aggregation types (Large-Dense, Small-Close & Small-Sparse aggregations) and found that the relative proportion of each type varied significantly between survey days. Large-Dense aggregations were more frequent when westerly winds dominated and when the local mixed tide was in the diurnal regime. Small-Close aggregations were also more frequent during diurnal tides. Conversely, Small-Sparse aggregations were more prevalent when the mixed tide was in the semi-diurnal phase. We suggest that, under certain conditions, the biological hotspot in the nearshore waters off southern Anvers Island, functions as a zone of accumulation, concentrating krill biomass. Our findings provide important information on the dynamics of Antarctic krill at the local scale.
Permafrost Peatlands and Climate Change: Response on Hydrological Variations

Olga Ogneva¹ (ogonlogin@gmail.com), George Matyshak², Matvey Tarkhov²
¹Lomonosov Moscow State University, Soil Science, Moscow, Russian Federation

Nowadays permafrost peatlands (PP) of the forest-tundra transition zone are subjected to annual temperature increase which leads to permafrost thawing and evolution of PP landscapes. In present study two predictable scenarios of PP landscapes evolution were tested: i) flooding of PP and ii) drying with following forest invasion in case of good drainage. The aim of the study was to estimate how organic carbon (OC) of PP will respond to these scenarios. Peat samples were collected in northwest Siberia in the zone of discontinuous permafrost (N65°19', E72°53'). To simulate flooding peat samples were incubated under laboratory conditions (25°C) during 1 week at a range of WHC - from 15 to 100% and then basal respiration was measured. To simulate drying peat samples were dried completely (25°C) and later rewetted to 60% of WHC, CO₂ effluxe was measured after the rewetting and during 30 days, to reveal fast response of OC to changed moisture conditions.

PP show resilience to flooding and the water content changes as a whole. CO₂ efflux from peat ranged from 6.0 to 6.8 mkg C-CO₂ g⁻¹ h⁻¹ with max for 35 and min for 55% of WHC. For the dried samples CO₂ effluxes increased up to 2.5 times in the first four days after rewetting and reached values of 16.3 C-CO₂ g⁻¹ h⁻¹, whereas declined afterwards and reached the 5.5 C-CO₂ g⁻¹ h⁻¹ at the end of experiment.

Thus, drying promotes rapid decomposition of OC, whereas flooded wouldn’t have the determinative effect on peat mineralization.
Understanding how changes in environmental conditions affect prey and their predators is fundamental for interpreting variability in natural marine ecosystems. We used the Antarctic fur seals (Arctocephalus gazella), a top predator of cephalopods, to evaluate their potential as an indicator of change in prey availability and local/regional environmental conditions. We used Antarctic fur seal scats (i.e. faeces) to assess the cephalopod component of their diet from 2009 to 2013 and relate the stable isotopic signature of lower beaks ($\delta^{13}C$ and $\delta^{15}N$) to oceanographic conditions around South Georgia. Our results showed that Antarctic fur seals are capable of feeding on a wide variety of ecologically different squid species, with S. circumantarctica being the most frequent and with the highest number of lower beaks in the scats collected. Isotopic data revealed that S. circumantarctica is an Antarctic water species, predominantly inhabiting an offshore/oceanic habitat, with low trophic level in relation to other species of Antarctic squids. From an ecological view, we demonstrated that in years of abnormal environmental conditions associated with low Antarctic krill Euphausia superba density, S. circumantarctica exhibited a higher trophic level as well a clear predominance for more offshore areas and, occurred more frequently in the diet of Antarctic fur seals.
Gigantism among Southern Ocean organisms is a very common feature, due to the cold and oxygen-rich water. The Giant Antarctic Octopus (*Megaleledone setebos*), is known to inhabit the Southern Ocean, reaching sizes up to 90cm and 14500g. In our study, we report the largest specimen ever found with 115cm and 18300g, caught in January of 2017 at Dumont D’Urville Sea. This species have an important role in the food web being present in the diet of the valuable Antarctic toothfish (*Dissostichus mawsoni*) and other charismatic top predators. Yet, nothing is known about its ecology. To answer some questions, we used beaks found in the diet of *D. mawsoni* and measured the content of δ¹³C and δ¹⁵N along the beak to reveal habitat and trophic shifts along the life. Our results show that the values of δ¹³C are relative stable along the life, suggesting that this species doesn’t migrate, however the small increase of δ¹³C content may suggest a little movement towards offshore. In terms of δ¹⁵N values, an increase of values along the beak suggest an increase of the trophic position along the life. Also, a correlation between δ¹³C and δ¹⁵N values suggest that the movement towards offshore and the increase in the trophic chain are related. Being a benthic species, the results might suggest that the octopus tend to descend the slope along the life, going to deeper waters and changing the type of diet along the life, being also available in bigger sizes to the deep-sea predators.
In connection to the threats connected with current climate changes, there is a growing interest in unravelling species diversity patterns across a range of Antarctic terrestrial and freshwater habitats. There is growing evidence that polar lakes represent valuable centres of biodiversity as well as sensitive indicators of environmental changes. A recent limnological survey described six lake types on the Ulu Peninsula (James Ross Island) that were classified according to their geomorphological position, stability, physico-chemical characteristics and biota. The lakes form a valuable set of ecosystems in the transitional zone between the maritime and continental Antarctica and therefore play an important role in the comparison with other freshwater sites. The aim of our study was to characterize the taxonomic composition of benthic autotrophic assemblages in the lakes and to assess the key factors that influence their composition. The sampling revealed high diversity of microbial assemblages that was primarily determined by lake type and associated differences in water chemistry. Massive autotrophic mats were observed mainly in the littoral zone of relatively old stable shallow lakes, whereas the mats were absent from the young lakes. However, a large variability was also observed within lakes belonging to one type suggesting the possible importance of priority effect in determination of community structure in environments with minor differences in environmental conditions.
Air temperature is increasing and will keep rising, more rapidly in the Arctic than in other regions. As a consequence, soil warming is expected, which will accelerate permafrost thawing and soil organic matter mineralization. This acceleration will enhance in turn the nutrient availability for plants. The projected changes might affect plant diversity, traits and strategies, altering ecosystem functioning and vegetation-climate interactions.

Here, we explore experimentally the effects of increased permafrost thawing depth and shallow nutrient availability on plant traits, resource acquisition and growth strategy of tundra shrubs. We measured seventeen plant traits related to resource acquisition, light interception and growth in four shrub species in a thawing and fertilization experiment in a Siberian tundra ecosystem. Shallow nutrient addition caused shrubs to shift from resource conservation to more rapid resource acquisition and faster growth. These strategy responses might enhance shrub vulnerability to pests and climate extremes, which are projected to become more frequent.

Our findings suggest that plant traits of tundra shrubs respond in a coordinated way to environmental changes. Taking this coordinated response into account will contribute to more realistic dynamic global vegetation models and robust predictions of shifts in vegetation, ecosystem functioning and vegetation-climate feedbacks.
The polar areas are being affected hard by the climate change. By altering the characteristics of the marine ecosystem in both poles. In case of the sedimentary communities, which have been very little studied mostly in relation to the importance of the biological factors (i.e. consumption, competition and bioturbation) on the dynamic, structure and diversity of the communities.

The increase in climate change has led to an increased in the storms, and therefore a greater action of waves on sessile organisms such as seaweeds. Which are detached, and afterwards stranding in the intertidal or staying at the bottom. These deposits of algae could attract predators, provide protection, perhaps to be a nursery, or this maybe physically disturbed the organisms that live in the soft sediment. This could trigger a change in the structure and dynamics of the community.

During 2017 work was done in the Arctic. There, samples were taken from soft bottom communities (intermarenal and subtidal) characterizing the community through species richness, individual number, Shannon index and Evenness, as well as biomass. At the same time, field experiments are carried out to determine the effect of detached algae and the exclusion of predators on population dynamics. These activities will be repeated in Antarctica during the 2018 campaign.

Experiments and sampling will determine the degree of incidence of detached algae and the presence of predators in these communities.

*Pseudogymnoascus* fungi, commonly isolated from polar soils, have been shown to secrete high levels of extracellular hydrolase enzymes (EHE), suggesting a role as important decomposers. *Pseudogymnoascus* has been shown to yield varying levels of enzymatic activity across different temperatures, but not much is known about their initial response to heat stress and how this modulates EHE production. We sought to measure the expression of known molecular markers of stress response following heat challenge. Three possible orthologs of *Saccharomyces cerevisiae* HSP70 genes (SSA1, SSA2, SSA3 and SSA4) and one possible ortholog of HSP90 (HSP82 and HSC82) were identified among available *Pseudogymnoascus* spp. protein predictions. Primers for quantitative real-time PCR were designed to amplify these identified orthologs (named HSP70A, HSP70B, HSP70C, HSP90) as well as nine putative reference genes. Two Arctic and two Antarctic strains were cultured at 15°C (ideal temperature) for 5 days then transferred to 25°C (heat challenge temperature) for 2 hours. Similar degrees of gene expression changes were observed in all four polar isolates. Expression of HSP70A, HSP70B and HSP90 was induced following heat challenge, suggesting thermal stress response was elicited. HSP70B and HSP90 showed greater upregulation and thus may be good candidates to serve as molecular markers for heat stress in *Pseudogymnoascus*. This study will be expanded to include temperate strains and time-course experiments.
Photosynthetic Activity of Marine Phytoplankton in the Antarctic Peninsula

Sazlina Salleh¹ (sazlina@usm.my), Hilal Zainudin², Firdaus Abdul Mutalib², Mahadi Mohammad²³, Wee Cheah⁴, Nur Aqilah Muhamad Darif¹²
¹Universiti Sains Malaysia, Center for Policy Research and International Studies (CenPRIS), Penang, Malaysia, ²Universiti Sains Malaysia, Center for Marine and Coastal Studies (CEMACS), Minden, Malaysia, ³Universiti Sains Malaysia, School of Biological Sciences, Minden, Malaysia, ⁴University of Malaya, Institute of Ocean and Earth Sciences, Kuala Lumpur, Malaysia

The photosynthetic activities of coastal marine microalgal community in the Antarctic Peninsula were investigated during the Malaysia Antarctic Scientific Expedition 2016 conducted from 13th January to 14th February 2016. A total of 7 stations were investigated along a southbound transect from King George Island (62°S 58°W) to Darboux Island, Graham Coast (65°S 64°W). Sea water temperature varied from 10.5°C to -1.2°C during the sampling. Microalgae communities were dominated by diatoms within the genus of Odontella, Proboscia, Eucampia, Chaetoceros, Coscinodiscus and Thalassiosira during the study. The ratio of variable to maximum fluorescence, a measure of maximum quantum yield of photosystem II (Fv/Fm) was recorded at Darboux Island with a value of 0.291, whereas the minimum Fv/Fm of 0.053 was measured at Trinity Island. Statistical analysis shows that although temperature, pH and light intensity, and nutrients (ammonia, orthophosphate, nitrite and nitrate) were significantly different (p< 0.05) among the sampling stations, photosynthetic activities of coastal marine microalgae in the Antarctic Peninsula were mainly driven by nutrients (mainly phosphate and nitrogen).
Predicting Diatom Diversity in the McMurdo Dry Valleys with Metacommunity Models

Eric R. Sokol¹ (sokole@gmail.com), Tyler Kohler², Diane McKnight³, Mark Salvatore⁴
¹Battelle Ecology, Inc., National Ecological Observatory Network (NEON), Boulder, United States, ²Charles University in Prague, Department of Ecology, Prague, Czech Republic, ³University of Colorado Boulder, INSTAAR, Boulder, United States, ⁴Northern Arizona University, Department of Physics & Astronomy, Flagstaff, United States

Diatoms represent a diverse group of primary producers that reside in microbial mats in aquatic habitats in the McMurdo Dry Valleys. Recent work has shown that different factors control diatom biodiversity in stream and pond ecosystems. Glacier-fed streams provide intermittent habitats where flow permanence can vary widely depending on the geomorphology of the catchment and factors controlling glacier melt. Alternatively, ponds provide insulated and persistent habitats for microbial mats and their resident diatoms. As such, diatom community composition is predicted by flow permanence in streams, whereas variation in diatom biodiversity among ponds appears to be better explained by dispersal dynamics and colonization history. Numerical models provide a tool to test alternative hypotheses about the underlying processes that shape observed biodiversity patterns, and make informed predictions about biodiversity in future climate scenarios. Here we present advances in a metacommunity simulation package for R (MCSim) and demonstrate how it can be used to test alternative community assembly hypotheses to explain freshwater diatom biodiversity data that was collected by the McMurdo Dry Valleys Long Term Ecological Research (MCM-LTER) program. Further, we demonstrate how parameterized simulations can be used to predict biodiversity metrics, such as beta-diversity (among-pond or among-stream variation in community composition), in altered climate scenarios.
Glaciomarine fjords exhibit substantially different ecosystem forcing than adjacent continental shelves and can be highly sensitive to climate warming. Extensive research indicates that subpolar Arctic fjords are heavily influenced by glacial meltwater/sediment inputs, resulting in high turbidity and seafloor burial rates, yielding macrofaunal communities with low abundance and diversity. In contrast, poorly-studied sub-polar fjords along the Western Antarctic Peninsula (WAP) sustain weak meltwater influences, resulting in low turbidity and seafloor burial rates. Thus, benthic communities in WAP fjords may not currently be limited by turbidity and burial disturbance, and have the potential to harbor abundant and diverse macrobenthic communities. Here we characterize the benthic macrofaunal community of Andvord Bay, a subpolar fjord along the warming WAP. We compare down-fjord changes in macrobenthic abundance, diversity and functional-group structure to a variety of potential ecological drivers including sediment burial rate, sediment Chl-a concentration (an indicator of labile detritus availability), and sediment-community respiration (an indicator of seafloor detrital carbon flux). Benthic abundance is high in mid-fjord, and is most strongly correlated with carbon flux and food availability, while burial disturbance may occur only within 1-kilometer of actively flowing tidewater glaciers. These patterns are likely to change as warming increases meltwater/sediment inputs.
One of plants mechanisms for stress tolerance is the functional symbiosis such as endophytism, which is defined as the mutual association of a plant with a microorganism, which lives inside the tissues of the plant without causing any symptom of disease. On the other hand, Antarctica is known as one of the most stressful environment, due to its extreme aridity and subzero temperature, however, despite the adverse conditions it is possible to find two vascular plant species: Deschampsia antarctica and Colobanthus quitensis. The presence of C. quitensis in Antarctica stands out above D. antartica, due to the fact that it has not been possible to establish a characteristic to survive such extreme conditions. In this investigation, we compared the production of total soluble sugars, proline and oxidative stress in individuals of C. quitensis with endophytic fungi (E+) and without endophytic fungi (E-) under optimal irrigation (H+) and drought stress conditions (H-), concluding that the presence of endophytes plays an important role in the mechanism of tolerance to stress, since in individuals E+, there is a higher production of sugars and less damage by oxidative stress. Besides, this pattern was observed in three sampling sites along a latitudinal gradient from -53° to -67° latitude (South of SouthAmérica, Polish Base Arctowski and Lagotellerie in Antarctica), being individuals from more stressful sites more dependent on the presence of endophytes to tolerate drought stress.
Transcriptome of the *Branchinecta gaini*: Unraveling the Thermal Stress Response

Marcelo Gonzalez¹ (mgonzalez@inach.cl), Alejandro Font¹, Cesar Cardenas¹, Magdalena Osorio¹, Jean-Yves Toullec², Erwan Corre²

¹Instituto Antartico Chileno, Punta Arenas, Chile, ²Station Biologique de Roscoff, Roscoff, France

The Antarctic fairy shrimps crustacean *Branchinecta gaini* (Branchiopoda, Anostraca) inhabits freshwater lakes and pools in Antarctica, one of the most hostile environments on earth. In Maritime Antarctica occurs in several freshwater lakes in Fildes Peninsula (King George Island, South Shetland Islands). This crustacean showed a great physiological flexibility to support highly fluctuating environments. Despite their adaptations for cope a high environmental variability, transcriptome studies have not yet been performed on this crustacean. RNA samples were extracted from a pool of adults individuals and the sequencing was performed using the Illumina platform HiSeq2500. Over 48 million total reads were assembled into 43,847 contigs. 16,503 annotated genes were obtained and they represent 36.68 % of total transcriptome. A total of 57 GO terms in three ontologies was obtained. *B. gaini* expressed several heat shock proteins like as Hsp90, Grp94, Hsp70, Hsp40 and proteins related to ubiquitin mediated proteolysis. These data sets are the first transcriptome resource for this Antarctic Brachiopoda and constitute the first step toward further studies linked to stress response, phylogenetics or molecular mechanics to stress response.
Soil development and nutrient cycling are the main drivers of greenhouse gas production in terrestrial ecosystems of Antarctica. Vegetation cover, biological influence, temperature and soil moisture strongly affect this dynamic. Thus, the objective of this work was to evaluate the potential of greenhouse gases production in lab of the main terrestrial ecosystems in a toposequence in King George Island, Maritime Antarctica, under different temperatures (-2, 4, 6 and 22ºC). Greater N₂O emissions were observed in Deschampsia - Prasiola communities, under ornithogenic influence, reaching 22.58 ngN/g_soil/day at 6ºC. Higher CH₄ emissions were observed in Moss Carpets and Fanerogamic Communities, showing greater variations at 6ºC (2.67 ngC/g_soil/day). Lichen community presented low potential of emission in elevated positions of the landscape, with similar behavior of bare soil. We observed elevated CO₂ emissions in Fruticosus Lichens community at 22ºC (22.08 ugC/g_soil/day), followed by Fanerogamic Communities. Biological activity and increasing temperatures enhances the potential of greenhouse gases emissions, especially in communities with ornithogenic influence and vegetation coverage.
Increase Temperature Favors the CO$_2$ Assimilation of Antarctic Vascular Species

Patricia L. Sáez$^1$ (patrisaezd@gmail.com), Lohengrin Cavieres$^1$, Constanza Ramírez$^1$, Jeroni Galmes$^2$, Leon A. Bravo$^3$

$^1$Universidad de Concepción, Concepcion, Chile, $^2$Universidad de Islas Baleares, Palma de Mallorca, Spain, $^3$Universidad Andres Bello, Temuco, Chile

Under in situ warming experiment we have detected that the increase temperature favors the carbon gain of only one Antarctic vascular species, *Colobanthus quitensis*; whilst *Deschampsia antarctica* seems to be less responsive. Our in situ warming experiments increasing daytime temperature by about 3 ºC. However, climate change predictions indicate that event of supra-optimal temperatures become more prevalent. This raises the question of whether the differential response between Antarctic species depending on the magnitude of the increase temperature. In other words, would *D. antarctica* be able to show a similar response facing higher temperature increases? With this aim, Antarctic species were cultivated in room chambers at 5, 10 and 16 ºC. Increase temperature favored the net photosynthesis (AN) of both Antarctic species. However, *D. antarctica* requires higher increase temperature to respond. In both species, higher AN were triggered by a reduction in mesophyll conductance, accompanied by changes in leaf anatomy. Therefore, in the long term, it is possible to assume that both species could be affected by regional climate change and their ability to respond will depend not only on functional but also structural adjustments that allow them to grow under the new conditions. 

Acknowledgments: FONDECYT 11130332, PIA ART-1102, INACH RT 13_16 and H. Arctowski Polish Antarctic Station.
At the molecular level, the production of heat shock proteins (HSPs) has been commonly used as an indicator of environmental stress. HSPs are highly conserved proteins that act as chaperones to stabilize and refold denatured proteins, preventing the formation of cytotoxic aggregates. The production of HSPs is a potential ecophysiological mechanism whereby Antarctic sponges can adapt to thermal stress; however, there is mixed evidence that HSPs are an important regulating mechanism in Antarctic organisms. In some Antarctic marine invertebrates the expression of HSP is absent. Although, previous studies on sponges from tropical waters have reported that thermal stress produces rapid molecular shutdown of sponge's molecular systems and increased expression of HSPs, the effect of heat stress on Antarctic sponges remains largely unexplored. In order to identify the heat stress protein in the Antarctic sponges, we obtained a reference transcriptome of Antarctic-endemic sponge *Isodictya* sp. resulted in 125,873 transcripts with an average size of 812 bp. In depth analysis of the data revealed an extensive catalogue of the cellular chaperone systems. Full length sequences were characterized for the chaperones HSP70 and several isoforms were identified during the thermal stress at 3°C and 5°C. Further studies of qPCR analysis will be used to validate changes in the transcript abundance of HSP70 during the heat shock.
Long-term Effects of Climate Change on High Arctic Plant Species

Esther R. Frei1,2 (esther.frei@wsl.ch), Greg Henry2
1WSL Swiss Federal Institute for Forest Snow and Landscape Research, Birmensdorf, Switzerland, 2University of British Columbia, Vancouver, Canada

Rapid climate change leads to changes in the structure and composition of Arctic tundra plant communities with unknown consequences for ecosystem functioning. Plant traits act as key mechanisms explaining feedbacks between climate change and vegetation. We investigated how elevated temperatures and altered snowmelt regimes affect common tundra plant species in a High Arctic evergreen shrub heath community at the International Tundra Experiment (ITEX) site at Alexandra Fiord on Ellesmere Island, Nunavut, Canada. A factorial experiment combining passive warming, snow removal, snow addition and control treatments was established in 1995. We examined phenological, growth and leaf functional trait responses of six common tundra species to two decades of experimental warming and altered snowmelt regimes. Snowmelt timing primarily controlled early season phenology, but had less influence on later phenological stages, on growth and leaf functional traits. Experimental warming generally advanced flowering and seed ripening. Warming effects persisted over the course of the growing season increasing plant growth, but had little effects on leaf functional traits. Our results underline the importance of understanding how interactions of temperature and snowmelt timing drive plant species responses to climate change in the Arctic.
The Distribution of Aerotechnogenic Pollutants on Islands of Arctic

Olga Gommershtadt1 (gommershtadt_olga@mail.ru)
1Moscow State University, Environmental Management, Moscow, Russian Federation

In this study, the results of a year research in the field of Arctic ecology will be considered. This research took place in different islandic territories of Arctic, such as Franz-Joseph Land, Novaya Zemlya, Svalbard, Iceland, Faroe islands. All of these islands are located in the western sector of Eurasian Arctic. In summer 2017 I took moss samples on several islands: Franz-Joseph Land (Heiss, Alger, Hooker islands), Novaya Zemlya (cape Zhelaniya on Northern island), Faroe islands (Sandoy, Mykines, Vágar, Streymoy). Also I have samples that were taken in Svalbard (with help of glaciology students in July, 2017) and Iceland's samples data (taken earlier by MSU research group).

The main goal of this investigation is deep analysis of spatial distribution of aerotechnogenic pollutants in Arctic and mapping it. Knowing the pollution values can help to investigate what affects the ecosphere of these islandic territories.

The main moss samples are mostly represented by following species: Tomentyphnum nitens, Sphagnum, Flavocetraria, Calliergon, etc. All of them have gone through the process of atomic absorption spectrometry analysis which is a procedure for the quantitative determination of chemical elements using the absorption of optical radiation by free atoms in the gaseous state. This type of analysis is considered as one of the most-used type of bioindication.

The results of this research will be represented in Moscow State University in may, 2018.
Meroplankton and Potential for Benthic Colonization in High-Arctic Ecosystems

Katarzyna Walczyńska¹ (katarzyna.walczynska@phdstud.ug.edu.pl), Agata Weydmann¹, Marta Ronowicz², Janne Søreide³, Tove Gabrielsen³

Barnacles (Crustacea: Cirripedia) are an important group of organisms in marine ecosystems, but they are also meaningful from the human perspective. They have big potential for biofouling, which is a significant vector for transferring invasive species. Furthermore, spreading over large distances and colonization of new territories is possible due to possessing planktonic larvae. Still, knowledge about larval development is scarce and because of their small sizes, differentiation of species by morphological methods is almost impossible.

We studied the timing, growth and duration of Cirripedia larvae year-round in a high Arctic fjord Adventfjorden (Spitsbergen). Zooplankton community analyses revealed that cirripedia occasionally was found in February-March, but first busted in abundance in late April at the onset of the spring bloom. DNA barcoding revealed the presence of two species: *Balanus balanus* and *Semibalanus balanoides*, of which the first one totally dominated the zooplankton community in April-May during the peak spring bloom. Image analyses based on photographs taken prior to molecular identification allowed to estimate the duration of each larval stage, including nauplii and cypris, and their growth over 300µm.

Long pelagic presence, large potential for biofouling on ships and larger plastic debris, combined with the disappearance of landfast sea ice and thus less ice scouring opens new opportunities for barnacles to colonize high-Arctic littoral zone.
Why the Arctic *Calanus glacialis* and Boreal *C. finmarchicus* Cannot Hybridize?

Agata Weydmann¹ (agataw@ug.edu.pl), Aleksandra Przylucka², Marek Lubośny², Katarzyna Walczyńska¹, Ester Serrao³, Gareth Pearson³, Artur Burzyński²

¹University of Gdansk, Department of Marine Plankton Research, Gdynia, Poland, ²Institute of Oceanology of Polish Academy of Sciences, Sopot, Poland, ³University of Algarve, CCMAR, Faro, Portugal

Due to the recently observed climatic changes copepods are shifting their spatial distribution northwards, and increasing numbers of boreal species co-occur with the Arctic ones, what may potentially lead to interbreeding between sibling species. We determined the nearly complete mitochondrial genomes of the Arctic *Calanus glacialis* and its North Atlantic sibling *Calanus finmarchicus*, which are key zooplankton components in marine ecosystems. The sequenced part of *C. glacialis* mitogenome is 27,342 bp long and consists of two contigs, while for *C. finmarchicus* it is 29,462 bp and six contigs, what makes them the longest reported copepod mitogenomes. The typical set of metazoan mitochondrial genes is present in these mitogenomes, although the non-coding regions (NCRs) are unusually long and complex. The mitogenomes of the closest species *C. glacialis* and *C. finmarchicus*, followed by the North Pacific *C. sinicus*, are structurally similar and differ from the much more typical of deep-water, Arctic *C. hyperboreus*. This evolutionary trend for the expansion of NCRs within the *Calanus* mitogenomes increases mitochondrial DNA density, what resulted in its similar density to the nuclear genome. Large differences in the length and structure of the sibling *C. glacialis* and *C. finmarchicus* mitochondrial genomes indicate that the species are genetically distinct and have evolved independently for quite a long time. Thus, it seems unlikely that *C. glacialis* and *C. finmarchicus* can hybridize.
The rapid decline in Arctic sea ice (ASI) area and volume during recent decades poses urgent questions regarding its effects on Arctic biota. These trends are occurring before we can understand many of the mechanisms through which ASI is coupled with biological processes both at sea and on land. This, in turn, hampers our ability to predict and manage the consequences of this enormous environmental change, making this a crisis discipline. Here, we propose a framework to study these effects, defining direct effects as those acting on life history events of Arctic biota, and indirect effects, where ASI acts upon biological systems through chains of events, normally involving weather/climate and/or biotic interactions. Examples of these processes, and of the array of methodologies used to study them, are presented. Given the breadth and complexity of ASI’s effects on Arctic biota, Arctic research requires a truly multidisciplinary mindset to address this issue. In the absence of effective global efforts to tackle anthropogenic global warming, ASI will likely continue to decrease, the conservation of many ASI-related taxonomic groups and ecosystems becoming severely compromised, with mitigation actions limited to other processes that interact with the biological effects of ASI, such as industrial human activities.
Phylogeography of *Halicarcinus planatus*: First Marine Alien Reaching Antarctica

Karin Gerard¹ (karin.gerard@umag.cl), Zambra Lopez², Constanza Ceroni¹, Claudio Gonzalez¹,³, Elie Poulin³

¹Universidad de Magallanes, Facultad de Ciencias, Punta Arenas, Chile, ²Universidad de Chile, Santiago, Chile, ³Instituto de Ecologia y Biodiversidad, Santiago, Chile

Climate change directly impacts and shapes the biodiversity. Biological invasions are a crucial component of global change, but also a threat to native biodiversity. Antarctica remains the most pristine and isolated continent surrounded by oceanographic, bathymetric, climatic and geographic barriers. Shallow marine benthic communities around Antarctica exhibit high levels of endemism, gigantism, slow growth, longevity and late maturity. The decapods are highly abundant and diverse in the Subantarctic but almost completely absent from the shallow Antarctic benthos. The West Antarctic Peninsula (WAP) is one of the areas most affected by global warming thus enhancing the probabilities of introduction of alien species. In 2010, a mature female *Halicarcinus planatus* was reported in Deception Island (WAP; Aronson et al., 2015). This species has a circum-subantarctic distribution, a low bathymetric range, an extended planktonic larval duration. In the Subantarctic, the genetic diversity of *H. planatus* is high and the phylogenetic relationships (mitochondrial and nuclear locus) between the Magellanic Region, Falklands/Malvinas Islands and Kerguelen Islands indicates a recent connectivity. However, some genetic differentiation is observed between close locations. An appraisal of the presence of *H. planatus* along the West Antarctic Peninsula at the end of our two first Antarctic expeditions is detailed.
Colobanthus quitensis is one of the two vascular plants native to Antarctica. Antarctic environmental conditions are highly stressful for terrestrial vegetation, for example; low temperatures, low water availability and high winds are combined to make this continent a hostile habitat. Transcription factors DREB / CBF type, regulators of the response to abiotic stress, are activated by low water availability, low temperatures and salinity. The knowledge of this type of transcription factors in *C. quitensis* until now is limited. From the transcriptome sequenced antarctic *Colobanthus quitensis* fifteen putative sequences with a high percentage of similarity from DREB / CBF family were obtained. From these fifteen sequences, eight of them present a high percentage of identity for homologous genes and also present the APETALA2 (AP2) domain, characteristic for the family of this type of transcription factors. An analysis of the sequences, alignment and phylogenetic analysis were performed. Primers were design for eight sequences with greater identity. Results from quantitative real time PCR, showed significantly high levels of relative expression of putative DREB/CBF Colobanthus quitensis genes in response to abiotic-stress treatments.
Host-parasite relationships can be important drivers of population dynamics with community-level consequences. Although these relationships are often studied by monitoring populations through time, spatial variation also plays a role in shaping dynamics of host and parasite populations. In the Arctic, frequent turnover in arthropod community composition between habitats suggests that host-parasite dynamics also vary across the landscape. Moreover, differences in species-specific responses to rapid climatic changes are expected to result in altered host-parasite dynamics, although it is unclear what the primary drivers of these dynamics may be. Here I show that while rates of parasitism in wolf spider egg sacs by parasitoid wasps differ along a latitudinal gradient of tundra in Alaska (0-18%), they are not related to wolf spider population sizes, abundance of egg sac prey, or to abundances of potential parasitoid wasps. Rather, higher rates of parasitoid attacks on wolf spider egg sacs occur in areas that have warmer and wetter climates. Climate projections for N. Alaska include warmer temperatures and increased precipitation, suggesting that wolf spiders may experience higher rates of parasitism in the future with potential consequences for their population dynamics. As wolf spiders are one of the most abundant predators across much of the Arctic, increasing parasitism rates could also have cascading effects on lower trophic levels and on ecosystem functioning.
Integrative Biogeography in Southern Ocean Mollusks

Claudio Gonzalez-Wevar1,2 (claudio.gonzalez@umag.cl), Karin GERARD1, Sebastian Rosenfeld1,2, Thomas Saucède3, Elie Poulin2

1Universidad de Magallanes, Facultad de Ciencias, Punta Arenas, Chile, 2Instituto de Ecología y Biodiversidad, Santiago, Chile, 3Université de Bourgogne Franche-Comté, Dijon, France

The biogeography of the Southern Ocean marine benthic biota and its current bioregionalization are the consequence of major tectonic, oceanographic and climate changes during the last 50 Ma. Here, we present new biogeographical analyses based on nuclear and mitochondrial markers in different groups of near-shore benthic mollusks with contrasting developmental modes that are currently distributed in different provinces of the Southern Ocean; direct developers (Margarella, Laevilitorina, and Siphonaria) and broadcast-spawners (Nacella, and Yoldia). In general, all groups exhibited major levels of genetic divergence between Antarctic and Subantarctic provinces suggesting that the Antarctic Polar Front is an effective biogeographic barrier. Phylogeographic analyses recorded low levels of genetic diversity in Southern Ocean mollusks as a consequence of Quaternary glacial processes that affected population sizes. Surprisingly, direct developers (Margarella, Siphonaria) exhibited high levels of genetic identity, thus supporting that rafting as an important biogeographic mechanism in the Southern Ocean. In contrast, broadcast-spawners (Nacella, Yoldia) showed marked genetic distinction among distant Subantarctic provinces. In this case, life-history traits constrains prevent long-dispersal through larvae in these groups. Finally, current biogeographical patterns in Southern Ocean mollusks are not related to particular groups but to historical and contemporary processes.
The Aryl hydrocarbon receptor (Ahr) pathway is a common entry point for the biological activity of dioxin-like compounds. Currently, no information exists on the presence and functionality of the Ahr in Antarctic notothenioid fishes.

Several proteins have been lost in Antarctic fish. We aimed to investigate if Antarctic notothenioids have conserved a functional Ahr. Specifically, we identified and cloned the Ahr2 sequence and tested its sensitivity to Ahr model-agonists in vitro using a luciferase reporter gene assay in which COS7-cells were transfected to express the Ahr2 ligand binding domain of the red-blooded *Trematomus loennbergii* and the white-blooded *Chionodraco hamatus*, originating from the Weddell Sea.

We firstly demonstrated that Antarctic fish express Ahr2 in liver and found that the Ahr2 of both species was activated by Ahr agonists (e.g. Benzo(a)pyrene & dioxine-like PCBs) in the ligand binding assay. The activation was similar or only 50% in the Antarctic fish compared to the response of the Atlantic cod (*G. morhua*) ligand-binding domain, which served as reference.

Our study revealed that Ahr2 in (the investigated) Antarctic fish have retained the ability of being ligand-activated, and could potentially induce the Ahr2-mediated toxicant metabolism. We thus conclude that Antarctic fish might have the capability to handle anthropogenic pollutants, yet differences in the induction capability and thus xenobiotics metabolism rate may exist to temperate zone fish.
Regulation of a Lost Inducible Heat Shock Response in Antarctic Fishes

Samuel Bogan¹ (bogans@sonoma.edu), Sean Place²
¹Sonoma State University, Biology, Rohnert Park, United States, ²Sonoma State University, Rohnert Park, United States

The perciform suborder Notothenioidei is comprised of Antarctic and sub-Antarctic fishes, several of which have lost their ability to rapidly upregulate major heat shock proteins (HSPs) in response to stress. Rather, inducible HSPs such as the hsp70 and hsp90 families are constitutively expressed under normal environmental conditions and do not upregulate following oxidative damage to the cell. While it was initially suggested that the constitutive expression of HSPs resulted from constant cold-denaturation of the proteome, inducible HSPs are not downregulated by these species following reduced protein damage. It is plausible that this trait is attributed to functional alterations in regulatory elements of the inducible heat shock response (HSR). In order to identify genomic divergence within Notothenioidei that may confer the loss of an inducible HSR, we sequenced the full coding region of the transcription factor HSF1 as well as genome-wide, cis-acting heat shock element (HSE) motifs in two members of the Nototheniidae family: Trematomus bernacchii, which has lost induction of the HSR, and Notothenia angustata, a temperate notothen exhibiting a classical HSR. We have compared the degree of conservation between HSF1 orthologs in both species in addition to their homology and spacing of HSE repeats. These results provide insight into how the regulation of inducible proteins can be modified to confer constitutive expression or activation as a process of adaptation.
Evolutionary Adaptation Potential and Population Structure of Notothenia spp

Henrik Christiansen¹ (henrik.christiansen@kuleuven.be), Franz M. Heindler¹, Bart Hellemans¹, Esteban Barrera-Oro², Anton P. Van de Putte¹,³, Filip A. M. Volckaert¹
¹KU Leuven, Laboratory of Biodiversity and Evolutionary Genomics, Leuven, Belgium, ²Instituto Antártico Argentino and CONICET, Buenos Aires, Argentina, ³Royal Belgian Institute of Natural Sciences, OD Nature, Brussels, Belgium

Global change is fundamentally altering marine ecosystems of Antarctica, albeit with at times opposite effects in different areas, e.g., decreasing or increasing sea ice cover. Marine organisms are expected to cope variably with these changes; some may benefit, while others face extinction. Adaptation to changing environmental conditions is one option to avert demise. Standing genetic variation is key for this as it can facilitate adaptation at much faster rates than adaptation from new mutations. In this context, knowledge of genetic diversity in time and space is important to investigate evolutionary adaptation potential of Antarctic species. We use reduced representation sequencing to genotype thousands of genetic markers in the Antarctic fish Notothenia coriceps and Notothenia rossii. We assess genetic variation and differentiation, particularly in the Western Antarctic Peninsula region. Furthermore, we employ a series of genome scan methods to detect loci that are putatively under selection, i.e., showing signs of recent evolutionary action. Combining patterns of neutral and adaptive genetic variation can give clues as to how species have evolved in the past and how they may react to rapid changes in the future.
Identifying Thresholds for Cellular Stress Responses to Heat in Antarctic Fishes

Bradley Buckley¹ (bbuckley@pdx.edu)
²Portland State University, Biology, Portland, United States

The fishes of the Southern Ocean display profoundly cold-adapted physiologies due to their long evolutionary history in the extreme cold. As oceans warm, these fishes are poised to act as bellwethers for the likely impacts of small incremental rises in water temperature. While the fact that these fish possess some of the lowest upper thermal tolerance limits of any vertebrate species has been established, the impact of sub-lethal heat stress is not as well characterized. Here, we measured the effects of increases in temperature on thermal tolerance and cellular stress responses in the common Antarctic rockcod genus, Trematomus. Interspecific differences in thermal tolerance and heat shock protein expression were characterized among co-occurring Trematomus spp. from McMurdo Sound. Flow cytometry revealed perhaps the lowest upper thermal threshold for the onset of programmed cell death in any vertebrate species, with significant increases in the number of hepatocytes entering apoptosis occurring at only 2°C. A key cell cycle arrest regulator was also induced by heat in these fish. Together these findings provide evidence at the cellular level that even seemingly minor elevations in temperature produce deleterious impacts on species from extremely cold environments.
Correlation between Degree of Herbivory and Gut Morphology in 8 Notothenioids

Eugenia Moreira1 (eugeniamoreira@yahoo.com.ar), Manuel Novillo2,3, Joseph T. Eastman4, Esteban Barrera-Oro1,2,3
1Instituto Antártico Argentino, División Ictiología, Buenos Aires, Argentina, 2CONICET, Caba, Argentina, 3Museo Argentino de Ciencias Naturales ‘Bernardino Rivadavia’, Caba, Argentina, 4Ohio University, Department of Biomedical Sciences, Athens, United States

Although many notothenioid fishes are primarily carnivorous, some species consistently feed on macroalgae and are therefore omnivorous. The degree of herbivory is reflected in the morphology of the digestive tract especially intestine length. We examined a large number of juvenile and adult specimens of eight sympatric notothenioid species collected at Potter Cove during eight consecutive seasons. We compare, in most cases for first time for an ontogenetic series, the distinct proportions of algae and animal prey in their diets (W %), and provide their relative intestine lengths [RIL= (IL/SL)*100]. Based on this correlation a “ranking” or degree of herbivory is established for the fish species analysed, and this was found to be related to their distinct feeding types and strategies. The benthos feeders *Gobionotothen gibberifrons, Notothenia coriiceps, N. rossii* and *Trematomus bernacchii* were the most herbivorous with higher RILs (> 70%). Conversely, *Lepidonotothen nudifrons, T. newnesi* and *Harpagifer antarcticus* were predominantly carnivorous, with lower and intermediate RILs values (< 43–52%). Our results are discussed in context of gut morphology, trophic ecology and buoyancy as aspects of their divergence into to the trophic web of the Antarctic ecosystem.
Notothenioids in the Ichthyoplankton at Potter Cove, South Shetland Islands

Esteban Barrera-Oro1,2,3 (ebarreraoro@dna.gov.ar), Gabriela Piacentino2, Eugenia Moreira1
1Instituto Antártico Argentino, Biology, San Martín, Argentina, 2Museo Argentino de Ciencias Naturales 'Bernardino Rivadavia', Ictiología, Buenos Aires, Argentina, 3CONICET, Buenos Aires, Argentina

At Potter Cove, King George Island/Isla 25 de Mayo, significant ichthyological research has been conducted in the last three decades, mainly on general ecology of notothenioid species in demersal stages from young juveniles to adults. Nevertheless, the knowledge of the ichthyoplankton composition in the cove, necessary for the overall comprehension of the species life-cycles, remained unexplored. Herein we report the first record of early stages of Antarctic notothenioids collected in pelagic hauls at Potter Cove in summers of 2014 and 2016 at depths of 6-9 m from the surface, where total bottom depth ranged 30-190 m. The ichthyoplankton consisted of a), 37 larval stages (preflexion and postflexion) of the species Harpagifer antarcticus (the most abundant), Psilodraco breviceps, Lepidonotothen squamifrons, Pleuragramma antarcticum and Trematomus scotti; b), 15 eggs of Notothenia coriiceps, of which two larvae hatched in aquarium. Part of this material is illustrated with photographs. The presence of early life stages of fish in the cove is linked to the major influx from the Bransfield Strait and also depends on local environmental conditions (i.e. hydrologic, water circulation). In addition to the spawning behavior of Parachaenichthys charcoti already reported in the literature, nearshore localities of the South Shetland Islands such as Potter Cove appear to be spawning sites also for N. coriiceps and H. antarcticus.
Antarctic silverfish (*Pleuragramma antarctica*) are a keystone species in the Southern Ocean, providing an essential link between trophic levels. Pelagic throughout all of their life history, with an energy-efficient foraging strategy, *P. antarctica* population structure is heavily impacted by hydrography and bathymetry. Considering the role of water mass dynamics in the distribution and availability of *P. antarctica* prey species, prey consumption might vary depending on the local hydrographic environment. High abundances of silverfish have been found associated with trough systems in the Weddell Sea. While much is known about the trophic plasticity and habits of adult *P. antarctica*, these data largely come from outside of the Weddell Sea, or from stomach content analysis which tends to represent only a snapshot of an organism's diet in time and space. In this context, we sought to provide a more comprehensive outlook on silverfish diet in the Weddell Sea by employing a lipids-based analysis illustrative of feeding over periods of weeks to months by analyzing fatty acid composition in adult *P. antarctica* and potential prey species. The question of diet variation within the Weddell Sea was framed in a hydrographic context by comparing diet in fish located along a trough inflow in the Filchner Trough, with those collected along the continental shelf near Halley Bay. Our results are a first step towards uncovering how physical-biological interactions impact silverfish diet.
Climate Change and Mitochondrial Metabolism in High-Antarctic Notothenioids

Felix Christopher Mark¹ (fmark@awi.de), Hanna Scheuffele¹, Nils Koschnick¹
¹Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Integrative Ecophysiology, Bremerhaven, Germany

Climate change affects the ocean systems world-wide by unprecedented rates of warming, acidification and deoxygenation. Marine fish possess physiological mechanisms of coping with these drivers, yet to a different extent in different species. While species from habitats with large diurnal or seasonal fluctuations in temperature, \( PO_2 \) and \( PCO_2 \) are naturally better adapted to cope with changing habitat conditions, especially Antarctic fish have been proposed to display very little metabolic plasticity to cope with a warming and acidifying ocean.

To shed more light on the fate of cold-adapted fish in a changing ocean, we investigated the metabolic capacities to cope with ocean warming and acidification in several high-Antarctic notothenioids, including red- and white-blooded species, during the RV Polarstern cruise ANT XXXI-2 to the southern Weddell Sea. Much of the recent climate change research on fish has looked into effects at the whole animal level, while knowledge of the acclimation and adaptation potential of lower levels of organisation, e.g. metabolic pathways, is scarce. We thus focussed on the basis of sustainable aerobic energy metabolism, mitochondrial ATP formation, and investigated the acute effects of warming, rising intracellular \( PCO_2 \) and \([HCO_3^-]\) on the performance and efficiency of the involved biochemical pathways in isolated mitochondria and permeabilised muscle fibers.
The Antarctic silverfish, *Pleuragramma antarctica*, is a key species in the high Antarctic food web and threatened by direct as well as indirect effects of climate change. The lack of a swimbladder is compensated in this pelagic fish by high amounts of lipids which make up to 60% of dry weight, and the functional role of these lipids is discussed since decades. The lipids are not stored in common adipose cells but in intermuscular and subcutaneous lipid sacs, indicating that the lipids might be decoupled from metabolism, i.e. the lipids’ role is limited to buoyancy. If the stored lipids are not available as energy reserve, *Pleuragramma*’s capability to cope with indirect effects of climate change such as (temporal) changes in prey availability and food shortage would be extremely low.

To gain deeper insight, data from several regions with different primary production were compared using a combination of classical ecological methods and Magnetic Resonance Imaging (MRI). Fish condition was found to vary strongly between different regions and these variations were reflected in total amount of lipids and in the size of the lipid sacs. The data clearly show that the functional role of lipids in *Pleuragramma* is not exclusively limited to buoyancy but lipids may be used as energy reserve for periods with limited food supply.
Atmospheric temperature in the West Antarctic Peninsula has increased between 5 and 6°C in the last 50 years. In the mean time, human activity (scientific and tourism) has dramatically increased in Antarctic, and so did the number of exotic species that reached the Antarctic. Until recently, there were no report of marine exotic species established in the shallow Antarctic ecosystem. However, in 2010, an ovigerous female of *Halicarcinus planatus* was reported in the shallow waters of Deception Island (Aronson et al; 2015). *Halicarcinus planatus*, is a small brachyuran crab distributed in southern South-America and Subantarctic islands, with a planktomic larval phase of 45 to 60 days. Moreover, *H. planatus* has the ability to down-regulate hemolymph's Magnesium ion concentration below sea water concentration, that would help to survive in Antarctic cold waters. Through population genetics analysis using SNPs, the population structure and connectivity of *H. planatus* will be evaluated at three different geographical scales: across the Southern Ocean (between Patagonia and Kerguelen), between Patagonia and Falkland Islands, and at regional scale among three locations in Patagonia (Punta Arenas, Beagle Channel and Tortel Cove). The potential of dispersal and capacity to broadcast to the West Antarctic Peninsula will then be discussed. Financial support: Fondecyt 1161358 and INACH DG_14_17.
A Comparison of the Frost Environment of Three Disparate Climatic Locations

Christel Hansen1 (christeldhansen@gmail.com)
1Rhodes University, Geography, Grahamstown, South Africa

Frost processes occur across climatic zones and warming temperatures affect regions where climatic thresholds are narrow. This paper explores the annual, seasonal and diurnal frost environments of three locations: western Dronning Maud Land (WDML) of Antarctica, sub-Antarctic Marion Island, and the High Drakensberg of the Eastern Cape of South Africa. WDML is characterised by annual frost with a paucity of diurnal thaw where permafrost is common and active layers shallow. Permafrost is absent for both sub-Antarctic Marion Island and mainland South Africa. Marion Island is characterised by a dynamic diurnal frost environment, with shallow and high-frequency cycles in evidence. The High Drakensberg of the Eastern Cape of South Africa exhibit seasonal freezing at higher altitudes with frozen ground occurring for up two months at a time at ~ 3 000 m.a.s.l. Global warming scenarios (1°C, 2°C and 5°C increases) and how these affect freezing cycles are explored, as are environmental and locational forcings on freezing cycles observed. Furthermore, results of WDML contribute towards ANTPAS scientific output and research. Higher altitudes show an increase in frost cycles; vegetation cover dampens such cycles. Furthermore, snow cover reduces diurnal frost in WDML, whereas it increases freezing depth on Marion Island. Finally, diurnal frost cycles are highly sensitive to temperature changes and associated thresholds and that such cycles can be used as indicators for warming conditions.
This paper provides a 10-year synopsis of the ground thermal and moisture regime of Flårjuven (western Dronning Maud Land, Antarctica) and contributes to ANTPAS scientific research and output. Flårjuven is associated with sediment of low organic content (TOC < 0.3%) and a coarse texture (fine gravel; fine earth fraction < 40%). The site is characterised by annual frost with a ground freezing index approaching 6 000. This is associated with a negligible thawing index approaching zero for summer, compared to a high freezing index of ~500 for winter. Annual degree days reflect the insulating effect of snow cover on ground thermal regimes and permafrost is present (average temperature of -19°C), with a shallow active layer (~15 cm). Temperature variability is highest for the active layer and lowest for permafrost. Diurnal thaw is rare, although approximately 15% of all diurnal cycles oscillate above and below 0°C. These potential thaw events occur exclusively during spring and summer months and thaw generally occurs from mid-morning to late afternoon (10:00-17:00), with most thaw events representing single diurnal cycles. An analysis of potential thaw events coupled with ground moisture data recorded show that less than half (~45%) of all potential thaw events translate into freeze-thaw events. The greatest active layer depth is reached in December and January, as are the longest ground thaw duration and most freeze-thaw cycles observed.
Geomorphology and Antarctic Ecosystems in Dronning Maud Land

Ian Meiklejohn1 (i.meiklejohn@ru.ac.za)
1Rhodes University, Geography, Grahamstown, South Africa

Active-layer and ground thermal dynamics, together with periglacial landforms have been researched in the Ahlmannryggen and Jutulsessen areas of Droning Maud Land since 2007. Nine shallow boreholes were used to measure ground temperatures and moisture. All boreholes show distinctive ground thermal regimes from a combination of diurnal and synoptic-scale controls. Additionally, thermal conditions in autumn and spring suggest continent-wide controls.

The Nunataks in the Ahlmannryggen originate from ice-heaved pre-jointed and weathered bedrock that have formed blockfields. A spatial inventory has been developed with records of such landforms together with rock glaciers, unsorted and sorted patterned ground, weathering forms, solifluction terraces, lake ice blisters, and pro-nival ramparts. Many of these landforms are the first examples documented in region. Their presence is controlled by lithology, moisture supply and the substrate. Several of the landforms identified, such as the rock glaciers and pro-nival ramparts are unique and their formation and morphology challenge accepted characterisations.

The Geomorphology of Western Dronning Maud Land has resulted in a landscape that is crucial for the provision of a habitat for the region’s biodiversity at a variety of scales. Changes in the landscape, and the associated links between the active layer and biodiversity in a changing climate, provide ideal positions to answer questions created by the SCAR Horizon Scan.
Ulu Peninsula, the northern part of James Ross Island, is the largest ice free area in Antarctic Peninsula region. More than 300 km² of ice-free land offer unique opportunity to study active layer, permafrost and related periglacial processes from different perspectives and in variable environmental conditions within the area. Currently, three main topics are under study by the Czech research team:

1) Analysis of driving factors affecting active layer thermal regime and thickness,
2) Modelling of active layer thickness, permafrost temperature and ground thermal parameters,
3) Spatial monitoring of active layer thickness using geophysical methods.

To reach the goals, the network of about 15 sites for ground temperature monitoring (using Pt100 resistance thermometers) in profiles of depth from 2 to 30-200 cm has been gradually established since 2006 and significantly extended after 2014. Every site also provides data on air temperature. Furthermore, at the key sites of the network incoming radiation, albedo, snow thickness and wind speed and direction are measured as well. Additionally, we installed TDR CS616 sensors (Campbell) for soil moisture measurement and HFP01 plates (Hukseflux) for near-surface ground heat flux measurement at the key sites. The geophysical surveying of active layer thickness has been carried out using GPR Ramac CU-II with 500 MHz antenna (Mala Geoscience) and multidepth electromagnetic conductivity meter CMD-MiniExplorer (GF Instruments).
Little attention has been given to sulphur (S) in thaw lakes, but its chemistry is of special environmental importance, since it plays a key role in natural organic matter (NOM) degradation. To understand sulphur dynamics in thaw lakes, we undertook studies in the Canadian subarctic in summer and winter. Water samples and sediment cores were collected from three thaw lakes. Results show that the amount of S is dependent on lake origin: in lakes derived from organic-rich palsa soils, S content is much higher than in mineral lithalsa lakes. NOM is the main source of S in the thaw lakes and its degradation in the water column and/or in the topmost sediment layers dominates S-mineralization. This process was more efficient in winter when the lake surface was frozen, decreasing oxygen availability, thus increasing the activity of sulphate reducing bacteria. Upon removal of lake ice, a rapid increase of sulphate occurred in the near-surface waters (5 cm) followed by its reduction within minutes, indicating the rapid system kinetics for both S reduction and oxidation. In deeper waters, dissolved sulphides promote the precipitation of metal sulphides, resulting in a sediment surficial layer that is enriched in amorphous trace element sulphides. These results show the importance of sulphur biogeochemistry and its strong linkage to lake origin, thus signalling the need for a regional assessment of sulphur related processes, based on broad, in-depth surveys of thaw lake origin.
The Qinghai-Tibet plateau (QTP), which is also called Earth’s third pole, is the highest and most extensive plateau in the world. The degradation of “warm” and sensitive permafrost on the QTP has resulted in an increase in environmental fragility and the related hazards. Existing permafrost maps that cover the QTP typically rely on sparse air temperature data and employ continuity-based classification systems. In general, the continuity criteria are scale-dependent, inconsistent, not comparable, and are difficult to use in engineering applications. This study presents a new permafrost map based on the thermal stability classification system. The map was developed using a geographically weighted regression (GWR) model to integrate MODIS (Moderate Resolution Imaging Spectroradiometer) land surface temperatures (LSTs) with leaf area index (LAI) values from the Global Land Surface Satellite (GLASS), soil properties from SoilGrids250, highly accurate soil moisture and precipitation data, and in situ mean annual ground temperature (MAGT) measurements made at 142 boreholes distributed throughout the QTP and acquired in about 2010. Cross validation of the permafrost extent shows that the consistency with the latest permafrost distribution map covering the QTP and borehole measurements at 142 sites exceeds 94%. The new map is of fundamental importance for engineering planning and design to reduce permafrost-related hazards on the QTP in the future.
Since 2007, a long-term research focused on the effects of climate variability along the eastern coast of the Antarctic Peninsula on the ground temperature (GT) has been carried out. On James Ross Island, GT was measured in the profile at depths of 5, 10, and 15 cm at control plots as well as those with open top chambers (OTCs). The OTCs were installed in a seashore ecosystem dominated by moss carpet (*Bryum pseudotriquetrum*) supplemented with a patchy distribution of more than 20 lichen species. GT regime in the particular depths was continuously monitored and related to presence/absence of OTCs and annual reference meteorological data from a nearby weather station (close to Mendel Base, Czech Rep.). For majority of OTC installations, the GT increase caused by OTC was apparent in the period of September-March. Detailed analysis of chamber effect on the increases in air and surface temperature, GT, and vegetation cover changes was done for austral summer seasons (Dec-2014 to Feb-2015, and Dec-2015 to Feb-2016). OTCs induced an increase in surface temperature, GT, and moss cover area. The increase in temperature was highest in warm radiation days with low wind speed (WS). On stormy overcast days with high WS, the temperature increase was smaller. Consequences of a long-term manipulation of Antarctic terrestrial ecosystems by OTCs for seasonal dynamics of GT are also discussed. **Acknowledgements:** The study was supported by CzechPolar infrastructure and Ecopolaris project.
The Spatial Distribution of Critical Soil Properties in the McMurdo Dry Valleys

Pierre Roudier\textsuperscript{1,2} (roudierp@landcareresearch.co.nz), Fraser Morgan\textsuperscript{3}, Tommy Robertson\textsuperscript{1}, Ben Jolly\textsuperscript{1}

\textsuperscript{1}Manaaki Whenua Landcare Research, Palmerston North, New Zealand, \textsuperscript{2}Te Punaha Matatini, Auckland, New Zealand, \textsuperscript{3}Manaaki Whenua Landcare Research, Auckland, New Zealand

Despite extreme conditions, a wide range of life forms occurs throughout Antarctic soils, and represent a major part of the Antarctic biodiversity. The spatial distribution of these microbiological communities has been shown to be strongly influenced by soil attributes such as water content, salinity, organic carbon, and pH. But while pedological maps have been published for various ice-free regions across the continent, the spatial distribution of the soil properties (as opposed to genetic classification) is largely unknown.

In this study, we collated different soil surveys in the McMurdo Dry Valleys in order to investigate the spatial distribution of soil properties that are critical for understanding the distribution of life in Antarctic soils: pH, electrical conductivity (EC), organic carbon, and nitrogen. To do so, we used geostatistical analysis to study the spatial structures of these soil properties. Two different sampling depths were considered: the desert pavement (0-2 cm), and the next layer down (2-10 cm), where most of the life forms has been observed. Semi-variograms of the soil properties selected were computed and analysed, and the results can be interpreted in relation to the sampling density that is necessary to capture a given amount of variability in each soil property. Finally, once the spatial structure of these variables has been modelled, maps estimating those soil properties across the region can be produced at the two sampling depths considered.
Effect of Mosses on Ground Thermal Regime in Three Different Areas of Antarctica

Filip Hrbacek¹ (hrbacekfilip@gmail.com), Mauro Guglielmin², Nicoletta Cannone³
¹Masaryk University, Faculty of Science, Department of Geography, Brno, Czech Republic, ²University of Insubria, Department of Theoretical and Applied Sciences, Varese, Italy, ³University of Insubria, Department of Science and High Technology, Como, Italy

The role of vegetation as an insulating factor on ground thermal regime is well-known from Arctic region. However, the knowledge on the interactions between vegetation and ground thermal regime in Antarctica are limited to few studies only from Maritime Antarctica and Continental Antarctica. In this study we evaluate the role of moss carpets on ground thermal regime across latitudinal and climate transect which consists of the sites on Signy Island (60°S, maritime climate), James Ross Island (64°S, maritime to continental climate), Victoria Land (75°S, continental climate) during thawing season 2015/16. The study sites have similar characteristics in terms of altitude, distance from sea and topography. On all sites, ground temperature was measured in profiles under moss carpets and under bare surfaces in depths 2 and 30 cm. The most pronounced effect of moss carpet was observed as smoothing the daily maximums under moss compared to bare ground, which could be lowered by more than 15 °C at 2 cm depth, while about 10 °C difference in maximum was found at 30 cm. This first comparative study of these areas suggest important role of mosses as a very effective insulator of ground temperature in these study areas.
Retrogressive Thaw Slumps: Indicators of Holocene Climate Changes

Roxanne Frappier¹ (roxanne.frappier@outlook.com), Denis Lacelle¹, André Viau¹
¹University of Ottawa, Department of Geography, Environment and Geomatics, Ottawa, Canada

The ongoing climate warming is expected to increase thermokarst activity and their impacts by inducing permafrost degradation and active layer deepening. A retrogressive thaw slump, which represents the most dynamic thermokarst landform, was investigated in the Peel Plateau region of the Northwest Territories, Canada. The exposed material at the thaw slump represents an opportunity to characterize the cryostratigraphy of the uppermost 5 m of permafrost and to make detailed observations of a thaw layer, a relict thaw layer, and four massive ground ice units. Analyses of the stratigraphy, sedimentology, isotope geochemistry and radiocarbon dating are presented. The main conclusions are that
1) the physical and chemical parameters of the massive ground ice exposed at the thaw slump are characteristic of buried glacier ice that experienced water infiltration and partial refreezing,
2) the relict thaw layer represents the period of maximum active layer deepening which occurred during the Holocene thermal maximum,
3) association of the region’s thaw slump activity with paleoclimatic parameters indicate that stream-incised, ice-rich permafrost in formerly glaciated areas, coupled with major rainfall events, represent a set of conditions that is favourable to thaw slump activity.

The conclusions contribute to the understanding of the genesis of thaw slumps and how they fit in the climate history and terrain conditions of the region.
Global warming contributes to the permafrost degradation with destabilization of methane hydrates and the corresponding methane emissions to the atmosphere. Model estimates of the methane hydrates instability in regions of Northern Eurasia and North America with the risk of gas emission into the atmosphere during the Holocene Climate Optimum (HCO), under current climate changes and for future projections are obtained. The risk of craters and gas emissions into the atmosphere can be characterized by the probability that the strength of the soil upper layer with permafrost would be less than the pressure in the methane hydrate deposits. According to model simulations the regional excess of the annual mean temperature in 2008-2017 relative to the HCO could reach 1.5-2°C at a depth of 10 m in high latitudes of Northern Eurasia and North America. This trend contributes to a higher methane pressure during the dissociation of methane hydrates and a lower strength of the overlying layer of soil. In a number of regions of Northern Eurasia and North America the probability of craters and gas emissions into the atmosphere due to the relic hydrates dissociation is estimated from model simulations to be higher than during the HCO. The results of model simulations indicate that the formation of craters of the type identified on the Yamal Peninsula in 2014 is associated with a high surface temperature in the regions of Northern Eurasia during last years.
The infrastructure of the village Qaanaaq in NW Greenland suffers from surface displacement due to permafrost thawing. The typical gable-roofed single-family wooden houses in Qaanaaq are constructed on shallow wooden foundations, which suffer from active layer slope movement and differential settlements from seasonal freeze-thaw cycles.

The aim of this investigation is to assess surface displacements in the Qaanaaq area of NW Greenland from a combination of remote sensing data and in situ measurements.

We have used a number of different techniques and data sources to assess ground movement around the settlement and neighbouring region. This allows a range of temporal and spatial scales to be addressed in the study as well as providing some means of cross-validation of results.

The study uses Sentinel-1 differential radar interferometry, DEM-differencing, long term GNSS survey, ground observations and base maps of the town to determine and validate surface displacements.

Assessment is challenging due to the lack of stable benchmarks in a region where it is likely that surface displacement is occurring non-linearly over a wider area. However, first results indicate that surface displacements occur in order of 3 - 15 cm/yr in the region.
The Permafrost Physics Performance of the Coupled CLASS-CTEM Model

Joe Melton¹ (joe.melton@canada.ca)
¹Environment & Climate Change Canada, Victoria, Canada

The Canadian Land Surface Scheme (CLASS) and the Canadian Terrestrial Ecosystem Model (CTEM) form the land surface component of the Canadian Earth System Model (CanESM). I present results derived from offline simulations of CLASS-CTEM forced with historical observed meteorology at the same model spatial resolution as CanESM. Model results are evaluated against observations from the Global Terrestrial Network for Permafrost for borehole temperatures (18 sites) and active layer depth measurements (51 sites). Several alternative parameterizations of snow and soil physics are investigated to determine their impact on simulated permafrost on a pan-Arctic scale. CLASS-CTEM, particularly after deepening and increasing the number of soil layers, does a good job of simulating the areal extents of permafrost zones and active layer depths of most sites. Borehole temperatures are more challenging to simulate with some sites well captured but other sites showing large differences between the model and observations. Overall, the model physics appear well suited to simulate the soil environment adequately for permafrost regions.
Subsurface permafrost formed in the continental shelf of the Canadian Beaufort Sea has been degraded since the last glaciation. Many studies to reveal distribution of permafrost were done using reflection, refraction and well logging method. However, cross section of permafrost distribution was not provided yet. In 2014, Korea Polar Research Institute conducted multichannel seismic survey with the cooperation of GSC of Canada. We applied the full waveform inversion (FWI) to the multichannel seismic data to get inverted 2-D velocity profile. FWI is a data fitting procedure based on wave field modeling and numerical analysis to extract quantitative geophysical parameters such as P-, S-wave velocities and density from seismic data. Because P-wave velocity in the permafrost varies depend on the concentration of ice, we deduced permafrost distribution from the inverted velocity model. Relatively high P-wave velocity cell is regarded as ice bearing sediment, and higher than 3.2 km/sec is regarded as fully ice saturated sediment. Inverted velocity models show permafrost bodies distributed irregularly and their size range from hundreds to thousands meters. The content of ice is higher in the core of permafrost body and lower in the outer body. Permafrost exists down to 600~700 meters and highest ice concentration exists at the depth of about 400 meters which coincide with previous well logging results.
Periglacial Landforms from Semi-arid Seymour Island, Weddell Sea, Antarctica

Caroline Delpupo Souza¹² (carolinedelpupo@gmail.com), Mariane Batalha Roque³, André Luiz Lopes de Faria⁴, Davi Gjorup⁵, Carlos Ernesto Schaefer⁶

¹Federal Institute of Minas Gerais, Conselheiro Lafaiete Campus, Conselheiro Lafaiete, Brazil, ²Federal University of Viçosa/Núcleo Terrantar, Soil Department, Viçosa, Brazil, ³Federal University of Viçosa, Rural Economy Department, Viçosa, Brazil, ⁴Federal University of Viçosa, Geography Department, Viçosa, Brazil

Periglacial processes and landforms together with the presence of permafrost are among the most relevant geomorphological elements in the northern Antarctic Peninsula region. This study aimed to identify, analyze and map the landform and processes at Seymour Island, Weddell Sea, Antarctic Peninsula. For this, different thematic maps such as lithology, slope and shaded relief were manually overlain. The slope map was an effective tool to determine the occurrence of landforms and their limits, which together with the interpretation of the satellite image and lithology, allowed to identify and quantify the periglacial features of Seymour Island. Twelve landform units were identified, as follows: summit structural surface, little dissected structural surface, highly dissected structural surface, steep slopes, gentle slopes associated with solifluction processes, fluviomarine plain, tidal flat, fluvioglacial plain, beaches, marine terraces and cliffs, talus deposit, patterned grounds, and lakes. The periglacial environment from Seymour Island is less intense than that of South Shetland and primarily conditioned by the regional semi-arid climatic conditions and strong geological and geotectonic control; most landforms and geomorphological processes are related to wind action, hydrogeology, lithological influence and presence of permafrost, in which altitude plays an important role. We acknowledge Fapemig for granting financial support.
The Circumpolar Active Layer Monitoring (CALM) Project has been monitoring 1 ha and 1 km² plots at Toolik Lake on the Alaskan North Slope. These sites are located in the Arctic foothills physiographic province. The 1 ha plot is composed of moist acidic tundra and a water-track complex. Air temperature and soil-surface temperature are measured in-situ daily at the 1 ha plot, and active layer thickness (ALT) is measured annually during maximum thaw (August) at both. This study describes changes over time (1995-2017), reporting an overall slight increase in mean summer (July-August) air temperatures and a slight decrease in mean soil-surface temperatures, resulting in an increase in the difference between these two measurements. Trends in ALT are less clear. Such an increase in the difference between air and soil-surface temperatures may be related to changing vegetation properties. Color-infrared aerial photograph pairs from peak greenness in 1995 and 2017 were analyzed using modern photogrammetric techniques to quantify vegetation change. This research complements coarser remote sensing efforts as well as plot-level biomass measurements showing Arctic greening in this region.
Variations in Ice Sheet Dynamics along the West Antarctic Ice Sheet Margin

Gabriele Uenzelmann-Neben¹ (gabriele.uenzelmann-neben@awi.de)
¹Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Geophysics, Bremerhaven, Germany

Modern global warming and their possible contribution to sea level rise and flooding of low lying coastal areas has moved both Antarctic and Greenland ice sheets into the focus of public and scientific interest. Research has concentrated on reconstructing the dynamics of the ice sheets in order to understand their vulnerability to a changing climate by combining data collection and numerical simulations. Synchronous changes in ice sheet extent along its margin are often assumed. Here, the regional and chronological appearance, distribution, and modification of sedimentary features and structures identified at the slope and rise off the West Antarctic Ice Sheet margin are analysed to test this assumption.

A synchronous West Antarctic Ice Sheet dynamic is not supported but rather a West-East trend with an early Miocene ice advance in the Amundsen Sea, while a glacial advance in the Bellingshausen Sea occurs only post-15 Ma. For the Bellingshausen Sea a stronger variability in depositional energy is observed indicating stronger variability in ice extent. The dominance of down-/along-slope sediment transport is on opposing trends between the two seas, which also reflects the advance/retreat of the local ice sheet and thus an increase/decrease in sediment input from the continent and a modification in intensity and relocation of the bottom currents’ pathways. A possible reason for this may be the local geology, basal geomorphology, and the geometry of the local ice sheets.
Large Impact of the Agulhas Return Current on Late Glacial Indian Southern Ocean

Minoru Ikehara¹ (ikehara@kochi-u.ac.jp), Xavier Crosta², Katsunori Kimoto³, M.C. Manoj⁴
¹Kochi University, Nankoku, Japan, ²Université Bordeaux 1, Bordeaux, France, ³JAMSTEC, Yokosuka, Japan,
⁴Birbal Sahni Institute of Palaeosciences, Lucknow, India

The Agulhas Current is a major actor of the Atlantic Meridional Overturning Circulation and thereof of global climate. Models and paleoceanographic data suggest that the volume of warm and saline Agulhas water leaking into the South Atlantic stimulates regional buoyancy anomalies that ultimately impact convective activity in the northern North Atlantic. Spillage of Agulhas Current into the South Atlantic was shown to strongly vary on glacial-interglacial timescales, possibly in relation to meridional shifts of the mobile Subtropical and Subantarctic fronts and the monsoon system. Conversely, the impact of the Agulhas Current on the Southern Ocean (SO), via its return branch, is much less documented.

Through the analysis of ice-rafted debris, diatom census counts and planktic foraminifera δ¹⁸O and Mg/Ca we here reconstruct cool and icy conditions during the early Marine Isotope Stage 2 (MIS2, 30-23 ka) but warm, ice-free conditions during the full glacial late MIS2 (23-15 ka) in core DCR-1PC from Del Caño Rise (46°S, 44°E, 2632m), Indian sector of the SO. We propose that these unexpected warm conditions result from increased transport of warm waters from low latitudes to the SO via the Agulhas Return Current in time of reduced Agulhas Current leakage due to a northward shift of the Westerlies and SO hydrographic fronts. As such, a general cooling in the SO may conduct, via negative feedbacks, to warm surface conditions in regions of strong western boundary current.
The Newly Discovered Odyssea Drift (Ross Sea): Preliminary Results

1OGS, Sgonico (TS), Italy, 2First Institute of Oceanography, Qingdao, China, 3Plymouth University, School of Biological & Marine Sciences, Plymouth, United Kingdom, 4NOC, National Oceanography Centre, Southampton, United Kingdom, 5University of Trieste, Matematica e Geoscienze, Trieste, Italy, 6ISMAR, CNR, Venezia, Italy, 7Norwegian Polar Institute, Tromsø, Norway, 8KOPRI, Incheon, Korea, Republic of, 9UST-Korea, Daejeon, Korea, Republic of, 10CMCC, Bologna, Italy

The Hillary Canyon is one of the main conduits for dense shelf water forming in the Ross Sea, over-flowing the shelf edge and transforming into the Antarctic Bottom Water (AABW). The main changes in past ocean circulation are recorded in the adjacent sediment drift. A wealth of data were acquired on the drift west of the Hillary Canyon during the 2017 OGS Explora expedition, which included the PNRA ODYSSEA and EUROFLEETS ANTSSS projects. Data were obtained by various technics: single channel seismic, sub-bottom profiling, multibeam bathymetry surveying, gravity and box coring, XBT launching, water sampling, CTD, L-ADCP, ADCP-VM, turbidity and fluorescence profiling. This drift (that we name Odyssea Drift) is elongated in the NNE direction with dimensions of several tens of km. Prominent landslide scars and a giant landslide deposit, over 70 ms thick and spanning 200 km², are visible on the drift. The cores evidence a well-developed cross bedding suggesting vigorous past bottom currents. The oceanographic data show a well defined bottom layer with temperature < 0°C, presumably a newly-formed AABW, with downward increased turbidity and current velocity.

The overall aim of this work is to develop, together with the results of the forthcoming IODP drilling expedition 374, a conceptual model of sediment deposition relating to marine-based ice sheet and oceanic processes along the Ross Sea continental margin occurring through the Neogene and Quaternary.
Four stages of deposition regime have been detected on high-resolution seismic reflection profiles. First, in strata of Paleocene-Eocene age small vertical faults indicate differential compaction of probably anoxic sediments deposited in the still isolated Eurasian Basin.

Than, a high-amplitude-reflector sequence indicates a time of widespread changes in deposition realm associated with the gradual opening of the Fram Strait and ongoing subsidence of the Lomonosov Ridge (LR) in Eocene and Oligocene. Episodical incursions of water masses from the North Atlantic were the consequences and led to the deposition of sediments of strongly different lithology.

The third stage marks widespread and pelagic sedimentation since earliest Miocene. Sediment waves are evidence for paleo-bottom current activity and the onset of an ocean circulation system. The slope of the LR is structured into terraces, indicating fault-controlled sediment drifts arisen due to the onset and intensification of current circulation. Advanced deepening of the Fram Strait likely enabled an effective exchange of water masses between the North Atlantic and Arctic Ocean. Continuous sagging of the LR, reactivation of former faults and bottom currents passing along the ridge may shape the steep sediment free flanks of the terraces in addition.

At least, a continuous regional drape of reflectors marks the transition to glaciation of the northern hemisphere in early Pliocene.
The Greenland Ice Sheet has sensitively responded to past and current climatic fluctuations. In order to reconstruct the past regional environmental and climatic variability, sedimentary cores from two infilled lake basins in the Kobbefjord area, SW Greenland, were retrieved and subjected to multi-proxy investigation. The absolute chronostratigraphic framework was established by ^14^C and short-lived radioisotopes (^210^Pb, ^137^Cs) dating. We further performed analyses of magnetic susceptibility, grain size distribution, element composition by means of XRF and ICP-AES (for C, N, S and BSi content), and diatom biostratigraphy. The presented palaeoenvironmental reconstruction records ~800 years of lake ontogeny that was modulated by catchment processes and regional climate, manifested as alternating periods of enhanced biological productivity and increased influx of clastic material. Our reconstruction agrees with other proxy-based lacustrine, marine and glacier records as well as instrumental measurements. Main cooling events occurred at ~850-650 and ~100-30 years BP. The former coincides with the demise of the nearby Norse Western Settlement. The latter event corresponds to culmination of the Little Ice Age and maximum glacier advances. Warmer periods predominated ~550-150 years BP and in the 20th century, and coincided with mostly negative phases of North Atlantic Oscillation. Current warming is, however, obliterated by transition of the lakes into oligotrophic peat bogs.
The Sabrina Coast, East Antarctica, is an area of interest because
(1) satellite and airborne geophysical studies indicate substantial loss of glacial ice over the past decade, and
(2) the region is underlain by a deep subglacial basin, a configuration that is susceptible to “runaway” ice loss. Quantitative diatom abundance and assemblage data preserved in marine sediments in four kasten cores retrieved from the continental slope during the RV *Investigator* mission IN2017_V01, record Holocene oceanographic conditions as well as the transition from a glacial to interglacial period. During the last glacial period, diatom abundance was low, possibly due to increased sea-ice cover, resulting in light limitation of primary production. In addition, a greater proportion of reworked, extinct species are present, due to the input of older, glacially-scoured sediments sourced from the continental shelf. The environment transitioned steadily from a glacial to interglacial setting, marked by an increase in diatom abundance by up to three orders of magnitude. The mid-Holocene is characterized by the highest productivity, but no significant change in diatom assemblage accompanies the productivity peak. The assemblage is dominated by a single diatom species, *Fragilariopsis kerguelensis*, the signature species of the Antarctic Circumpolar Current, however, greater overall sea-ice cover in the western half of the field area is reflected by increased relative abundance of *Fragilariopsis curta*.

On behalf of the Sabrina Seafloor Shipboard Party, Australian National University, Acton, Australia
Observed melting rates of the Totten Glacier, Sabrina Coast are among the fastest of the East Antarctic ice sheet yet this area remains notably understudied. Piston core C012_PC05, collected from the Sabrina Coast continental slope during the RV Investigator mission IN2017_V01, contains a 16m sediment record of the past nine marine isotopic stages, as estimated using magnetic susceptibility data, sediment lithology, and absolute diatom abundance, and constrained using the diatom biostratigraphic markers Rouxia leventerae, Rouxia constricta and Hemidiscus karstenii. Interglacial periods are characterized by biosiliceous clay-rich silts with low magnetic susceptibility. Glacial sediments are diatom-poor silts and fine sands with relatively high magnetic susceptibility. Quantitative diatom counts document diatom abundances more than one order of magnitude lower during glacial periods compared to interglacials, a consequence of greater sea-ice cover and dilution. Glacial periods also show much higher proportions of extinct species, indicating reworking of sediments. Notable variation in abundance is observed among interglacials; early MIS 5 and mid-MIS 1 contain distinct peaks in productivity while MIS 3 has comparatively low overall productivity. Fragilariopsis kerguelensis is the dominant species (60-90%) throughout, with Thalassiosira lentiginosa subdominant; both open ocean zone indicators. Common sea ice associated species are present, but in low relative abundances.

On behalf of the Sabrina Seafloor Shipboard Party, Australian National University, Acton, Australia
The Whales Deep Basin (WDB) is a paleo-glacial trough that was occupied by the Bindschadler Ice Stream when grounded ice advanced to the outer continental shelf during the last glacial maximum (LGM). A bathymetric saddle that separates the WDB outer and middle continental shelf corresponds to a compound grounding zone wedge (CGZW) formed during post-LGM retreat. The north face of the bathymetric saddle corresponds to the marine foreset of the CGZW. The low slope on the southern side of the WDB saddle corresponds to the subglacial topography that existed prior to a major retreat of the grounded ice towards Roosevelt Island. This GZW topset is mantled by a series of relatively small-scale sinuous ridges. The ridges have amplitudes ranging from 2 to 11 m above grade and have an overall northeast-southwest orientation over an area of at least 500 km² in water depths ranging from ~500 to ~550 m. The ridges have spacing that mostly range between 1 and 2 km. The longest ridges are observed to be 40 km. In our ongoing investigation of these interesting features, we hypothesize that the ridges formed below a rapidly flowing ice stream as it thinned. The rapid ice-stream flow caused the development of large crevasses that reached the seafloor. Subglacial till was injected upward as the crevasses formed. Chronologic data indicates that these crevasse casts formed during rapid sea-level rise at 11.5 kyr BP, i.e., during MWP1B, which partly explains their amazing preservation.
The National Institute of Oceanography and Applied Geophysics (OGS) acquired about 320 km of multichannel seismic profiles offshore the Sabrina Coast (East Antarctica), in the frame of the PNRA Tytan Project, during the CSIRO survey IN2017-V01 on board the RV Investigator (Jan-March 2017).

The project aims at reconstructing the depositional environment of the continental margin off the Totten Glacier, starting from the Miocene, when temperatures and CO2 levels were more similar to those predicted for the next century. The PNRA Tytan project consists in two main research units: Unit 1 is focused on the integrated analysis of the new geophysical dataset and data available through the Seismic Data Library System (SLDS), aimed at identify key acoustic features indicative of advances and retreats of the ice sheet and of variations in the glacial regime. The comprehensive analysis of the seismic dataset will also be crucial to prioritize areas of interest for IODP deep drilling by identifying expanded and well-preserved sedimentary successions. Within Unit 2, sediment core analysis collected during the IN2017-V01 cruise are performed and are focused on Diatom biomarkers and assemblages.

The IN2017-V01 geophysical dataset has been undergoing several processing steps, which greatly improved the data quality. A preliminary analysis allowed recognizing key seismic reflectors indicative of major evolution steps of the continental margin.
Late Cretaceous Model Paleogeography for Antarctica

Graeme Eagles, Jamieson Stewart, Lucía Pérez Díaz

Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Geophysics, Bremerhaven, Germany, Durham University, Durham, United Kingdom, Royal Holloway University of London, Egham, United Kingdom

We present the newest interim versions of ANTScape's Late Cretaceous model paleogeography. Recent plate kinematic reconstruction parameters have been used to reconstruct a late Cretaceous austral landmass with Antarctica at its core, and continental connections to Australia and South America at its margins. The depths of the oceans and continent-ocean transitions surrounding this landmass have been modelled from an understanding of the variety of processes that can be expected to have led them to attain their current depth. In contrast, we model continental paleotopography by applying process-based adjustments to present-day measurements. In view of ongoing controversy regarding the history and development of the Transantarctic Mountains, we present two candidates. In one, the mountains do not figure because they developed as a marginal uplift to the Cenozoic West Antarctic Rift System. In the other, the mountains form just part of a much larger West Antarctic altiplano, supported by thickened crust that formed by long-lasting plate convergence at Gondwana’s active margin. The candidate paleogeographies will be of interest as boundary conditions for paleo-ice sheet modelling and regional circulation and climate modelling.
Simple Model of Melange and Its Influence in an Antarctic Ice Sheet Model

David Pollard¹ (pollard@essc.psu.edu), Robert DeConto²
¹Pennsylvania State University, Earth & Environmental Systems Institute, University Park, United States,
²University of Massachusetts-Amherst, Department of Geosciences, Amherst, United States

Rapid grounding-line retreat and marine ice loss from West Antarctica, and possibly from major East Antarctic basins, may be triggered by climate warming. These rapid retreats are associated with geologic evidence of past high sea-level stands, and pose a threat of drastic sea-level rise in the future.

Rapid calving of ice from deep grounding lines generates substantial downstream melange (floating ice debris). It is unknown whether this melange has a significant effect on ice dynamics during major Antarctic retreats, through clogging of seaways and back pressure at the grounding line.

Observations in Greenland fjords suggest that melange can have a significant buttressing effect, but the lateral scales of Antarctic basins are an order of magnitude larger (100’s km compared to 10’s km), with presumably much less influence of confining margins.

Here we attempt to include melange as a prognostic variable in a 3-D ice sheet-shelf model. Continuum mechanics is used as a heuristic representation of discrete particle physics. Melange is created by ice calving and cliff failure. The melange model is first tested with idealized geometries, and calibrated very basically to observed melange properties in Jakobshavn fjord, West Greenland. The influence of the new melange component is then examined in simulations of rapid Antarctic retreat in response to warm mid-Pliocene climate.
The evolution of Antarctic bedrock topography is a key control on ice sheet behaviour. Evolution of the subglacial landscape over geological timescales is controlled by tectonics, erosion, and deposition, as well as the solid Earth response to these processes. Here we aim to quantify these processes to better constrain the palaeotopographic evolution of the Pensacola-Pole Basin in East Antarctica, a previously unexplored sector of the ice sheet with bedrock situated over 1 km below sea level. The effective elastic thickness of the lithosphere in this region is determined by modelling recently acquired bedrock topography and airborne gravity data. We then use flexural isostatic modelling to quantify the response of the solid Earth to changes in surface loading associated with glacial and fluvial erosion and tectonic activity. Geological constraints on the amount of erosion and uplift include peneplanation surfaces exposed in the Pensacola Mountains and offshore sediment records. We also use 2D forward gravity modelling to determine the upper crustal structure of the basin and examine the role of the inherited tectonic structure in the topographic evolution of the region. By quantifying the landscape evolution of the Pensacola-Pole Basin since ice sheet inception at ca. 34 Ma, we can provide an improved boundary condition for modelling ice sheet behaviour close to the boundary between East and West Antarctica since the Early Oligocene.

A Pliocene $\delta^{18}$O$_{\text{diatom}}$ Record of East Antarctic Glacial Discharge

Freya Mitchison$^1$ (mitchisonf@cardiff.ac.uk), George Swann$^2$, Jennifer Pike$^3$, Melanie Leng$^4$
$^1$Cardiff University, Earth & Ocean Sciences, Cardiff, United Kingdom, $^2$University of Nottingham, Nottingham, United Kingdom, $^3$Cardiff University, Cardiff, United Kingdom, $^4$British Geological Survey, Keyworth, United Kingdom

The East Antarctic Ice Sheet (EAIS) is traditionally thought to have remained largely stable since the middle Miocene. However, some evidence suggests the EAIS retreated substantially during intervening warm periods, e.g. the Pliocene. Given the major societal implications of a more dynamic EAIS, resolving the issue and determining what forces retreat, e.g. a warmer ocean, is essential. However, direct evidence for substantial retreat, and a thorough understanding of ice/ocean interactions during past warm periods, remain elusive. Here we take advantage of the particularly negative $\delta^{18}$O signature of glacial ice ($\delta^{18}$O $< -20\%$) to generate the first Pliocene diatom oxygen isotope ($\delta^{18}$O$_{\text{diatom}}$) record of East Antarctic glacial discharge. The Pliocene can be considered an analogue for future climate, as the last time pCO$_2$ was $>400$ ppm and sea levels were $~20$ m higher than today. Using material from the well-characterised continental rise IODP Site 1165B, our target interval (3.75-3.45 Ma) includes a period of proposed substantial retreat of both the local Amery ice shelf and more distal Aurora subglacial basin, as well as an episode of dramatic circum-Antarctic warming when sea surface temperatures (SSTs) increased to $~6^\circ$C above present. Considered alongside existing diatom assemblage, SST, sea ice and ice-rafted debris records from the same cores, we investigate the role of ocean forcing on ice dynamics and constrain suborbital-scale glacial discharge/retreat during the Pliocene.
Deep-water Evolution in the Southwest Atlantic from New Seismic Profiles

Robert Larter¹ (rdla@bas.ac.uk), Steven Bohaty², Jude Castelino⁴, Claus-Dieter Hillenbrand², Paul Wilson², Kelly Hogan⁴, Gabriele Uenzelmann-Neben³, Thomas Westerhold⁴

¹British Antarctic Survey, Cambridge, United Kingdom, ²University of Southampton, Southampton, United Kingdom, ³Alfred Wegener Institute, Bremerhaven, Germany, ⁴University of Bremen, MARUM, Bremen, Germany

Antarctic Bottom Water (AABW) flowing northwards into the South Atlantic Ocean has to pass around Maurice Ewing Bank (MEB), which lies at the eastern end of the Falkland Plateau. Above the AABW, the Antarctic Circumpolar Current (ACC), the largest ocean current on Earth with a mean transport of >100 Sverdrups, flows eastwards across MEB and the Georgia Basin. The two main fronts of the ACC, the Polar Front and the Southern ACC Front, traverse the region and interact with major topographic features. AABW is a key component of the global thermohaline overturning circulation, whereas the ACC is the main agent of water exchange between the world’s large ocean basins and is important in blocking ocean heat transport towards Antarctica. Both currents initiated and strengthened during the Cenozoic era as bottom water production increased and the Southern Hemisphere westerly winds strengthened due to the intensification of Antarctic glaciation. Over the same period plate tectonic movements resulted in opening of deep gateways in the Southern Ocean, allowing circum-Antarctic circulation. These major currents control patterns of sediment deposition, and thus changes in sediment accumulation patterns through time record the history of the currents. However, seismic profile coverage of the region remains sparse. We plan to collect new multichannel seismic data over the MEB and Georgia Basin on RRS Discovery cruise DY087 in January-February 2018, and will present initial results.
Unravelling a High-altitude Antarctic Blue Ice Field Meteorite Trap

Harry Zekollari¹²³ (zharry@ethz.ch), Steven Goderis², Matthias van Ginneken³⁴, Jerome Gattacceca⁵, Akira Yamaguchi⁶, Philippe Huybrechts³, Vinciane Debaille⁴, Philippe Claeys³

¹ETH Zurich, Zürich, Switzerland, ²WSL Swiss Federal Institute for Forest Snow and Landscape Research, Birmensdorf, Switzerland, ³Vrije Universiteit Brussel (VUB), Brussel, Belgium, ⁴Université Libre de Bruxelles, Brussel, Belgium, ⁵CEREGE, Aix en Provence, France, ⁶National Institute for Polar Research, Tokyo, Japan

Antarctic blue ice zones are the most successful locations for meteorite retrieval missions on Earth. These zones are furthermore of large interest, as they can potentially contain old ice, which is easily accessible and available in large quantities. Despite this, meteorite traps remain generally not very well understood. Here, we use an interdisciplinary approach to improve our understanding of an ice trap in Dronning Maud Land (East Antarctica) on the Nansen blue ice field (2600-3100 m a.s.l.).

From the collected surface blue ice samples, one of the largest observed spatial patterns in the δ¹⁸O to date is found. Relying on ¹⁴C and ³⁶Cl terrestrial age dated meteorites, this surface ice is interpreted to be from the previous interglacial up to the present-day. Based on satellite derived surface velocities, we estimate less than 0.4 new meteorites per year are supplied to the ice field through ice flow. This suggests that the hundreds of new meteorites found after revisiting the ice field after 25 years are mostly meteorites that were previously not found, rather than newly supplied meteorites. By comparing the isotopic signal of the surface blue ice to the one from deep drilling projects, we derive information about the past glaciological and climatic conditions that occurred over this region.
Enhanced Coal Fragment Input in the Chukchi Borderland during Last Deglaciation

Taoliang Zhang¹ (ztl1989@hotmail.com), Rujian Wang¹, Wenshen Xiao¹, Leonid Polyak², Jens Bischof³, Xiaoxuan Huang¹
¹Tongji University, State Key Lab of Marine Geology, Shanghai, China, ²Ohio State University, Byrd Polar and Climate Research Center, Columbus, United States, ³Old Dominion University, Department of Ocean, Earth, and Atmospheric Sciences, Norfolk, United States

Frequent ice discharge events were identified as Ice Rafted Debris (IRD) peaks in the Chukchi Borderland, western Arctic Ocean sediments between the Brown Layers 1 (B1, Holocene) and 2 (B2, mid MIS3), but the timing and sources of these events are still poorly constrained. In this study, IRD (>250 um) grains from this interval in 10 sediment cores recovered from the Chukchi Borderland were examined under the microscope. Coal fragments and detrital carbonates were identified and the peak layers were dated at ~14 ka, making it a proper stratigraphic marker at the Chukchi Borderland during the last deglaciation. The abundances of coal fragments show clear northward and westward decreasing trend in the study area, suggesting a eastern source most probably the northern Alaska. During the deglaciation, the melting water from ice cap on the Brooks Range allowed the entrainment of coal fragments from the coal bearing the North Alaskan Slope terrain to the Chukchi Margin and spread by the Beaufort Gyre north- and westwards.
Characterizing Holocene Climate Variability from Adélie Basin Sediment Core

Katelyn M. Johnson¹,² (katelyn.johnson@vuw.ac.nz), Rob McKay¹, Francisco J. Jiménez-Espejo³, Nancy A. Bertler¹,², Anya Albot³
¹Antarctic Research Centre, Victoria University of Wellington, Wellington, New Zealand, ²GNS Science - Institute of Geological and Nuclear Sciences Ltd., National Ice Core Research Laboratory, Lower Hutt, New Zealand, ³Japan Agency for Marine-Earth Science and Technology, Department of Biogeochemistry, Yokosuka, Japan

In 2010, a 180 m laminated sediment core was collected offshore East Antarctica in the Adélie Basin during International Ocean Discovery Program Exp. 318. Radiocarbon ages date the core to ~12,000 years B.P., and high sedimentation rates at the site suggest a high-resolution record capable of capturing both large and small scale climate variabilities. Initial findings of greyscale analysis on line scan photographs indicate cyclical frequencies of high productivity phytoplanktic bloom events, but these data were noisy due to gas expansion during core extraction and color issues associated with differential oxidation after core extraction. X-Ray Computed Tomography (CT) scans were undertaken to circumvent these issues and improve the frequency and facies characterizations of the phytoplanktic bloom events. Here we present the conclusions of our frequency and greyscale analyses, and how these analyses relate to the core X-Ray Fluorescence (XRF) data. We will also discuss these results in relation to a larger project aimed at linking the Roosevelt Island Climate Evolution (RICE) ice core and the U1357 sediment core. The U1357 site lies downstream from RICE and is influenced by Ross and Amundsen Sea waters, in addition to local variations. The relationship between these highly resolved records will better constrain the seasonal and long-term variations and (dis)connections between polynya activity and ice-ocean interactions in these regions during the Holocene.
The Ross Sea Dense Shelf Water (DSW) comprises about 25% of the Antarctica Bottom Water today. The formation of this DSW is closely linked to the interactions with the Ross Ice Shelf (RIS). Thus the retreating processes of the RIS since the Last Glacial are of great importance understanding past changes of global ocean circulation and climate. Core ANT31-JB06 retrieved from the Joides Trough on the northwest Ross Sea continental shelf during the 31th Chinese Antarctic Expedition was investigated to reconstruct the RIS deglaciation history since the late Marine Isotope Stage (MIS) 3. The analysis includes AMS 14C dating, ice rafted debris (IRD) abundances and grain size. The dating results suggest an fossil carbon contamination of ~3045 years in the organic carbon. The continuous 14C sequence also indicates a lack of sediment disturbance, and the grounding line persistently south of the core site. 27-21 ka marks the coldest period during the Last Glacial, possibly with maximum extension of the RIS at ca. 24 ka. The initial RIS retreat from the Joides Trough started at about 21 ka. Major retreats and disintegration of the RIS occurred at the Antarctic Isotope Maximum (AIM) 1 warm interval (~17 ka - 14 ka) and the early Holocene, while the retreat was slowed down or ceased during the Antarctica Cold Reversal (ACR, ~14 ka - 12 ka). The RIS may have stabilized after about 5 ka, reaching its current location.

The Antarctica Ice Sheet (AIS) plays an important role in modulating global system. Our understanding on its dynamics, however, is still largely insufficient. In this study, the clay mineral composition and ice-rafted debris (IRD) data from two sediment cores retrieved off Prydz Bay extending back to 523 ka are reported to explore the late Quaternary forcing mechanisms of the Lambert Glacier Amery Ice Shelf system (LGAISS) on orbital time scales. The clay mineral assemblage is composed of illite, smectite, kaolinite and minor chlorite. Illite was likely produced by physical erosion of rocks rich in biotite. Kaolinite and smectite were mostly reworked from the older successions beneath the LGAISS and/or the Kerguelen Plateau. The kaolinite/illite ratio reveals the oscillation history of the LGAISS. It presents a power spectral structure similar with that of the global ice volume record, reflecting the dominant role of the northern hemispheric climate cycles in affecting the austral ice dynamics during late Quaternary. A more pronounced obliquity periodicity on the kaolinite/illite ratio may reflect the austral summer energy to exert a significant role in modulating the LGAISS dynamics. The IRD MAR record, however, only responded to the eccentricity forcing, likely indicating the EAIS became increasingly stable in response to the long-term climate cooling and development of the sea-ice field which prevents it from contacting with low-latitude warmer sea water.
Ice-shelf collapse and grounding-line migration may result in rapid ice sheet retreat, representing a significant uncertainty in predicting future sea level rise. Marine ice-sheet processes, strongly influenced by ocean heat, have been monitored for less than 50 years. Geological evidence can extend this record over centuries to millennia, providing insights into the processes and rates of change that drive marine-ice retreat. Associated modelling, evaluated against geological data can aid understanding of these processes and lead to more realistic prediction of sea level changes. In this study, we aim to understand the pattern of thinning and retreat of David Glacier, the largest outlet glacier in northern Victoria Land, Antarctica.

We present the initial results from the 2017 field season, where we sampled ice-transported erratic clasts and bedrock from nunataks adjacent to David Glacier. In situ cosmogenic nuclide exposure dating of glacial erratics, sampled along vertical transects from the modern ice surface to several hundred metres above, constrains the ice-elevation history of David Glacier. We link ice surface lowering rates onshore to the offshore retreat chronology in the Drygalski Trough where at the LGM the David Glacier formed an ice stream, extending hundreds of kilometers into the western Ross Sea. We test the sensitivity of the glacier to ocean warming and ice shelf debuttressing using a flowline model with robust marine grounding line parameterisation.
This study focuses on the sedimentation history along the North-western Barents Sea continental margin after the Last Glacial Maximum (LGM). The sedimentary record contained in the Trough Mouth Fans (TMFs) of the Kveithola and Storfjorden glacial troughs and in the contouritic drift facing the Bellsund Fjord provides several proxies that can be useful for reconstructing the ice-streams dynamics during glacial periods, the onset of deglaciation and the climatic variability during interglacials. This area of the North-western Barents Sea continental margin has been investigated during several international oceanographic cruises: SVAIS onboard R/V BIO Hespérides; EGLACOM, onboard R/V OGS Explora; PNRA Project CORIBAR, onboard R/V Maria S. Marien; Eurofleets-2 PREPARED, onboard RV-G.O. Sars. For this study five cores collected during these international cruises have been investigated through XRD analyses on clay minerals and XRF analyses through Avaatech core scan on the whole length of the cores. In polar areas clay mineral analysis can be used for reconstructing sedimentary processes, associated with glacial and interglacial conditions. XRF data provide useful proxies for environmental changes, provenance studies and core correlation. Here we aim to describe the clay mineral distribution in response to the climatic variations that followed the LGM, the changes in ice-stream dynamics and related oceanographic/environmental changes along the margin.
Past Climate Records from the Ross Sea: Initial XRF Results from IODP Exp. 374

International Ocean Discovery Program (IODP) Expedition 374 will core several sites on the Ross Sea outer continental shelf and slope/rise in January-March 2018 with the primary objective to examine the evolution of the West Antarctic Ice Sheet (WAIS) during the Neogene. Numerical models indicate that the Ross Sea sector of the WAIS is sensitive to changes in ocean heat content, making this an ideal location to examine past changes to improve predictions for future warming. Following initial shipboard characterization of the cores during the expedition, the cores will be shipped to the IODP Gulf Coast Repository in College Station, TX, USA. X-ray fluorescence (XRF) scanning of Ross Sea sediment cores will commence in May 2018 using an Avaatech XRF core scanner at the IODP Gulf Coast Repository. Final scanning details will be determined after the cores are collected, but we initially plan to scan at 9 kV, 30 kV, and 50 kV energies (2 cm resolution) to collect counts of Al, Si, K, Ti, Mn, Fe, Br, Rb, Sr, Zr, and Ba. This non-destructive technique will be used to distinguish lithologies and to make environmental interpretations based on elemental ratios at high resolution. These data will also be used to confirm stratigraphic splices for the continental slope/rise sites (where double or triple coring is planned). Coupled with other postcruise research results, these data sets should provide significant insights into changing conditions in the Ross Sea during the Neogene.
Due to a complex tectonic and magmatic history of West Antarctica, the region is suspected to exhibit strong heterogeneous geothermal heat flux variations. Although the maximum ice extent has retreated from the shelf since the last glacial maximum, the trends of offshore GHF patterns and the overall order of magnitude are hypothetically related to those areas onshore where the West Antarctic Ice Sheet (WAIS) rests on geologically related structures. High-resolution GHF will aid the understanding of the paleo-retreat of the ice sheet in the Amundsen Sea Sector. This presentation builds on our previous studies in which we discussed geothermal heat flux based on 26 in-situ temperature measurements that were conducted in 2010 in the Amundsen Sea Embayment (ASE) in West Antarctica. We found, that the shallow (3 m) in-situ temperature measurements were likely influenced by inter-annual bottom-water temperature variability, leading to GHF estimates biased towards lower values (mean = 33 mWm⁻²). During RV Polarstern expedition PS104 in early 2017 we collected additional 28 in-situ temperature measurements in marine sediments (11 m) for deriving geothermal heat flux in the ASE, which will overall improve the spatial coverage of this region. Furthermore, we monitored the vertical temperature profile of the water column at these stations, which allows to map Circumpolar Deep Water (CDW) distributions across the inner Pine Island Shelf with greater detail.
Sediments on the conjugate Australian-Antarctic margins have been deposited through the interplay between continental sediment supply, tectonic motions, and ocean currents. During the transition from Greenhouse to Icehouse conditions, most of these components underwent drastic regional and global changes. Here, constraints from both conjugate margins are correlated using a comprehensive network of seismic reflection profiles and drill sites. The formation of two major hiatuses (33.6 - 47.9 Ma, 51.06 - 51.9 Ma) recently recovered by the IODP site U1356A offshore Wilkes Land, are the centre of this study. We propose a drastic sediment starvation along both margins during the pre-glacial Eocene period causing those gaps in sedimentation. During the warm and humid Late Cretaceous period (~83 - 65 Ma), fluvial sediments were deposited along both margins. Prominent sediment drift deposits of younger Early Paleogene age (~65 - 48 Ma), can be observed along both continental rises, indicating onset of clockwise bottom currents. With the following progressive global cooling (< 48 Ma) and increasing current strength, a large-scale sediment starvation occurred, which is geologically constrained along Southern Australia and most likely also affected the Antarctic margin till the onset of glaciation (~33.6 Ma). Using this interpretation, we create paleobathymetric reconstructions at ~83, ~65 and ~48 Ma which provide essential information for paleoceanographic and climatic investigations.
Some of the most important and unknown aspects of past ice sheet conditions, such as ice thickness and thermal regime (ice sheet stability), are best enlightened by looking at lava—ice interactions (glaciovolcanology). Lava—ice interactions were recently mapped at Mason Spur, a Miocene to recent eruptive centre approximately 100 km southwest of Ross Island, McMurdo Sound, Antarctica. A newly identified Miocene eruption was interpreted from the voluminous mapped caldera in-fill at this location. The eruption records environmental conditions at the time and may have been significant enough to have affected all of Antarctica’s atmosphere. It occurred immediately after the mid Miocene Climatic Optimum during the descent into a deeper icehouse world, a time that is crucial to understanding how modern global warming and sea-level changes will affect the planet. Lava—ice interactions were also mapped in younger volcanic rocks (< 6 Ma) from which the thickness of the past Antarctic ice sheet can be calculated and wet- versus dry-based glaciation determined. Glaciovolcanology remains critical for understanding ice sheet behaviour; predicting variations in Antarctic ice sheets is a fundamental step in quantifying future global climate and sea level change.
Luminescence dating is micro-dosimeteric technique used on quartz / feldspar to estimate the time elapsed since the last day light exposure of the sediments, specially on Late Quaternary sediments. Sediment samples from the terminal moraines of Vestre and Austre Broggerbreen glaciers of NY-Alesund area, Svalbard, Arctic region were dated by OSL techniques. In order to remove the unstable luminescence signals an optimum heating temperature was found out which yielded best dose recovery. Many Arctic samples were not found suitable for OSL dating because their dose recovery was not optimal. In most of the Arctic samples recuperation is observed because of their dull nature. The correction was of recuperation was made by adding an additional step of Illumination at 2800 C at the end of every run of SAR protocol. The OSL data suggests the advancement of widespread glaciations in this area during Last Glacial Maxima (LGM). The dates of 32±3 ka and 19±2 ka obtained from the terminal moraines highlights deglaciations before and after LGM period. The date 32±3 ka marks the major recession of glacier system of Ny-Alesund region just before Last Glacial Maxima. After this, during LGM time, the glacier system has advanced to a much greater extent. After LGM time, the area has again witnessed the major recession at around 19± 2 Ka coinciding with the Late Weichselian ice sheet retreat as the climate became warmer. The results represent time span of Last deglaciations in Ny-Ålesund area.
The recent depositional architecture of the north-western Barents Sea continental margin derives from past climate changes with alternating deposition of highly consolidated glacigenic diamicton (continental shelf) and debris flows (continental slope) associated to shelf-edge glaciations, and low-density, normally consolidated biogenic-rich sediments deposited during interglacial conditions. In addition, sub-bottom records outline the presence of acoustically laminated deposits locally having thickness of more than 10 m, which lithofacies characteristics indicate deposition from turbid meltwaters (plumites) during short-living, phases of glacial retreat (meltwater pulses, MWP). One of the youngest stratigraphic intervals recognized along the NW Barents Sea margin was related to the MWP-1a that was responsible for the deposition of about 1.1 x 10^{11} tonnes of sediments on the upper slope of the Storfjorden-Kveithola TMFs (south of Svalbard) (Lucchi et al., 2015). New compositional analyses of such plumites revealed a distinct signature that allow us to distinguish deposition from glacial melting form that related to the ice-sheet sub-glacial erosion and transport to the edge of margins. Sediment facies and compositional analyses lead to a new climate-related interpretation of the laminated deposits recognized during Marine Isotopic Stages 3 and 2 on the NW margin of the Barents Sea, including Heinrich Event H2.

Major Climatic Transitions Linked to the Tasman-Drake Tectonic Evolution

Johan Etourneau1 (johan.etourneau@iact.ugr-csic.es), Ari Salabarnada1, Dimitrios Evangelinos1, Adrian López-Quirós2, Marie-Alexandrine Sicre2, Peter Bijl3, Philippe Martinez4, Vincent Klein2, Wilrieke Boterblom3, Karine Charlier4, Carlota Escutia1

1Instituto Andaluz de Ciencias de la Tierra, Armilla, Spain, 2Laboratoire d’Océanographie et du Climat, Paris, France, 3University of Utrecht, Utrecht, Netherlands, 4Université de Bordeaux, Talence, France

The tectonic evolution of the Drake and Tasman passages during the Eocene-Oligocene and Oligocene-Miocene transitions have led to the modern-like Antarctic Circumpolar Current (ACC) accompanied by drastic changes in both terrestrial and oceanic conditions. However, the timing, the oceanic and climatic responses of these tectonic changes on the isolation of Antarctica and their role in the onset of major Antarctic glaciations remain largely debated. This is particularly true for the Drake passage history, for which several ages of opening have been proposed between 40 and 17 Ma. In this study, we aim at focusing on specific period of times by investigating sedimentary archives from the Ocean Drilling, Deep Sea Drilling and Integrated Ocean Drilling programs (ODP, IODP and DSDP, respectively) Sites 696 (~33.35 Ma), U1356 (~30.5-24.5Ma) and 269 (~25-14 Ma). Here we combined a suite of molecular proxies (d13C/dD of the n-alkanes, CPI and ACL indexes) with bulk organic matter parameters (d13C/d15N, TOC) in order to i) characterize the organic matter origin, ii) the related changes in vegetation type (C3 vs C4 plants) and iii) the hydrological variations (eg. precipitation) associated with the two gateways. Preliminary data reveal sufficient amounts of biomaterial for further isotopic analyses and refinement of interpretation. These new results will be presented during the POLAR2018 conference.
The sedimentary record in polar continental margins provides useful insights into the glacial regime and bottom-current changes during the past glacial and interglacial periods. Many of the previous seismic stratigraphic studies have been conducted over the Ross Sea embayment to reveal the Cenozoic Antarctic glacial history. Due to lack of data, however, there have been much less studies that could provide a more continuous record of ice-sheet dynamics and bottom-current activity on the Ross Sea slope and rise. Here, we present a seismic stratigraphic analysis of sediments in the Joides Basin mouth and Central Basin, northwestern Ross Sea using the new and existing seismic and adjacent drill site data. The seismic profiles and sequence maps indicate that gravity sedimentation processes dominated the Central Basin infill, and then downslope sediment supply to the lower slope and rise was gradually reduced through the late Neogene and Quaternary. The bottom-current-controlled sedimentary features that may initiated on the surrounding banks and slopes since the mid-Eocene were overlain by glacigenic debris flows near the Joides Basin mouth after the late Pliocene. These results would indicate that the Antarctic glacial regime was evolved toward a cooler, less erosive through the late Neogene and Quaternary and bottom-current activity was diminished near the paleo-shelf edge after the late Pliocene in the northwestern Ross Sea margin.
Diatom Reworking in the Ross Sea: Evidence for Quaternary Bottom Currents?

Michael Bollen1,2 (bolmi518@student.otago.ac.nz), Christian Ohneiser1, Christina Riesselman1,2, Min Kyung Lee3, Kyu-Cheul Yoo3, Olga Albot4, Robert McKay4, Sunghan Kim3, Jae Il Lee3, Richard Levy5

Temporally accurate paleo-reconstructions of past ocean circulation can help us to understand climate change’s influence on the Southern Ocean and the Antarctic in the past and into the future. Here, we present new chronostratigraphic constraints on an 11.75 m marine sediment core, RS15-LC42, recovered by the RV/IB Araon during the Korea Polar Research Institute cruise ANA05B. Collected from the continental slope in the Ross Sea at 2084 m water depth, this core is composed of alternating laminated muds and IRD bearing sand lithologies.

Our age model is based around a single paleomagnetic reversal at 8.26 meters below sea floor (mbsf), which we interpret to be the Bruhnes/Matuyama boundary (0.781 Ma). This interpretation is supported by the first occurrence (FO) of the diatom Thalassiosira antarctica (0.50 Ma) at 5.40 mbsf. While the presence of Fragilariopsis kerguelensis (FO 2.49 Ma) at 11.65 mbsf provides a maximum possible age for the base of the core, our preferred interpretation assigns the entire reverse polarity interval below 8.26 mbsf to chron C1r.1r (upper Matuyama), which provides a maximum basal age of 0.98 Ma. Diatom reworking is prevalent below 3.25 mbsf, so last occurrence biostratigraphic datums cannot be used to further constrain the age of the core. The transition from extensive reworking to primary accumulation at ~0.25 Ma suggests a change in circulation, which we now aim to evaluate using magnetic fabric as a paleocurrent indicator.
Unlocking Atmospheric Temperatures from Antarctica's past

Jacob Anderson¹ (jacob.anderson@otago.ac.nz), Gary Wilson¹, Craig Cary², David Fink³, Toshiyuki Fujioka³, Christina Riesselman¹
¹University of Otago, Dunedin, New Zealand, ²University of Waikato, Hamilton, New Zealand, ³Australian Nuclear Science and Technology Organisation, Sydney, Australia

Computer model reconstructions of Antarctic ice sheet configurations during Earth’s past warm intervals underestimate the contribution from East Antarctica - i.e. measured sea levels are higher than calculated melt amounts. These climate models employ ocean driven melt as the primary control of ice mass loss rather than atmospheric warming. To date, atmospheric temperatures have not been considered as a mechanism to melt Antarctic ice sheets. Instead, past Antarctic ice sheet configurations have been derived from geomorphic deposits in the Dry Valleys, and sea floor moraines. Such deposits do not reveal temperatures for inclusion in climate models. Deriving a paleothermometer for Antarctica that predates ice core records is required to test the role of atmospheric temperature in ice sheet melt. Recent discoveries of bacteria in Antarctic permafrost samples provide a potential solution. New molecular genetic tools allow microbial diversity and concentrations to be calculated for ancient permafrost horizons. We are developing a terrestrial paleoecological transfer function for palaeotemperature from the microbial diversity and concentrations preserved in these permafrost horizons.
Buried Landscapes in Antarctica are Records of Ancient Local-scale Ice

Stewart Jamieson¹ (stewart.jamieson@durham.ac.uk), Michael Bentley¹, Neil Ross², Chris Stokes¹, Jane Francis³
¹Durham University, Dept. of Geography, Durham, United Kingdom, ²Newcastle University, Dept. of Geography, Politics and Sociology, Newcastle, United Kingdom, ³British Antarctic Survey, Cambridge, United Kingdom

The degree to which The Antarctic Ice Sheet retreated during the Pliocene, mid-Miocene, or between the Eocene-Oligocene Transition (EOT) and the mid-Miocene is not well constrained. This limits our understanding of the potential response of the modern ice sheet to changing climate. A barrier to quantifying past ice distribution in Antarctica is the lack of direct record inland of the coast. However, the geomorphology of buried landscapes may reflect former ice configurations, but is relatively unexploited. We map the distribution of ancient small-scale ice caps and valley glaciers in the highlands of the Weddell Sea region of Antarctica. We exploit patterns visible at the ice surface in MODIS MOA and Radarsat AMM-1 data and map small-scale glacial landscape features including subglacial valleys, ridges and buried cirques. The geomorphology is consistent with glacial erosion under alpine glaciation such that localised ice caps or icefields existed separately from a smaller than present ice sheet. There are no direct dates for these landscapes, but there are 4 possibilities: 1) they document past retreat during the Pliocene; 2) they record ice configuration prior to the establishment of polar conditions during the mid-Miocene; 3) they date from the onset of glacial conditions in Antarctica at the EOT; or 4) they have survived since small-scale Neogene glaciation, for which there is some evidence in the Antarctic Peninsula.

The advance and retreat of the West Antarctic Ice Sheet (WAIS) from the outer shelf and oceanic circulation are the main causes of depositional processes on the Eastern Ross Sea (ERS) continental slope. During the Last Glacial Maximum, the WAIS advanced to outer shelf and then retreated ~1000 km to the inner shelf. Currently Antarctic Bottom Water formation is linked to mixing of the relatively warm Circumpolar Deep Water (that encroaches the continental shelf) with the colder Ross Sea Bottom Water (RSBW).

The objective of our ongoing investigation is to understand interactions between glacial and oceanographic processes that occurred in the past and are currently active on the shelf and the slope of the ERS. Here we use geophysical, bathymetric and oceanographic datasets acquired during two recent campaigns (NBP1502B and PNRA16).

The data reveals several seabed structures:

- incised gullies, canyons and an elongated SSW-NNE ridge on the SE side of Hayes Bank;
- wedges and two large canyons in the Whales Deep Basin;
- ridges and incisions on the western side of Houtz Bank.

Here we discuss if 1) the origin of the structures found on the slope and shelf depends on processes related to bottom currents or sea level changes or 2) shelf structures are most related to grounding-zone repositioning whereas slope structures are caused by erosional processes that are linked to either meltwater discharge and/or RSBW overflow and down-slope flow.
Collapse of the British-Irish Ice Sheet: The Role of Climate and Sea Level Rise

Niall Gandy1 (eeng@leeds.ac.uk), Lauren Gregoire1, Jeremy Ely2, David Hodgson1, Christopher Clark2, Dayton Dove3
1University of Leeds, School of Earth and Environment, Leeds, United Kingdom, 2University of Sheffield, Geography, Sheffield, United Kingdom, 3British Geological Survey, Edinburgh, United Kingdom

The pattern and timing of retreat of the last British Irish Ice Sheet has been constrained in more detail than any other palaeo ice sheet. The Minch Palaeo Ice Stream flowed NW from the Scottish Highlands to the continental shelf edge, and retreated from 30-16ka BP. The ice stream is thought to have been laterally topographically constrained, and on a reverse slope. Using the palæo record it is possible to study timescales far greater than observations of the contemporary record allow. We test if topographic influence and Marine Ice Sheet Instability were influential during the retreat of the Minch Palaeo Ice Stream. We use BISICLES, an ice sheet model capable of accurately simulating marine ice sheets, to simulate the retreat of the Minch Palaeo Ice Stream. We ran a series of model simulations to isolate the influence of topography on the retreat of the ice stream. Experiments with a step-change climate perturbation reveal a non-linear volume and area response, caused by instabilities from basal topography and surface mass balance change. We found that the retreat pattern of the Minch was influenced by instabilities once retreat was established, and mapped a retreat margin beyond which the simulated ice stream did not recover to LGM extent given LGM forcing. A similar model set up has also been used for other domains of the British-Irish Ice Sheet, working to reveal the mechanisms of LGM Irish Glaciation, and North Sea common ice configurations.
The Glaciogenic Records in the Grove Mountains, East Antarctica

Aimin Fang¹ (fam@mail.iggcas.ac.cn), Xiaohan Liu²

¹Institute of Geology and Geophysics, Chinese Academy of Science, Beijing, China, ²Institute of Tibet Plateau Research, Chinese Academy of Sciences, Beijing, China

The glacial sediments in Grove Mountains include:
(1) different kinds of moraine dikes distributes along or perpendicular to the ice moving directions above blue ice or surrounding the nunataks.
(2) glaciogenic deposits occurred as ice debris of solitude tillite or loosen tills in different sizes. They are formed in the ice-sheet frontal area by the activities of local glaciers or the East Antarctic Ice-sheet.
(3) large glacial erratic boulders perched in the outcrops of the basement rocks.

Glacial erosion landforms is ubiquitous in the outcrops of the basement rocks this area, such as horns, cirques, U-shaped valleys, hanging valleys, roches moutonnées and so on. Furthermore, striations on rocks in the Gale Escarpment, and other 3 nunataks are observed and their directions are measured, which show an ice flow direction of 325-345 degree.

All the glaciogenic deposits and erosion marks found in Grove Mountains are closely related to the climatic changes in Antarctica that resulted in the major glacial movements. They involve at least three ice-sheet evolutionary events in east Antarctica. (1) The activities of the East Antarctic Ice-sheet at the period of the Last Glacial Maximum. (2) A warm event, and most probably the Pliocene warmth. (3) The products of the local Mountain glaciers developed before the formation of the Antarctic Ice-sheet. All these records are of great significances in understanding the ice-sheet evolutionary history in east Antarctica.
As observations of the past climate are spatially sparse, climate models can be used to “fill in the gaps” and provide a qualitative estimate of the climatic state of the past, consistent with the proxy data. In this study we aim at investigating the state of the climate during the Marine Isotope Stage 3 (MIS3) as simulated by the climate model EC-Earth. Comparisons of the atmospheric and oceanic circulation patterns as simulated by EC-Earth and another Earth System Model, NorESM, are also carried out to understand the possible climate responses to the MIS3 conditions. Additionally, the sensitivity of the simulated circulation to changes in sea ice will also be addressed by nudging EC-Earth towards different sea ice extents as suggested by proxy data.
Confidence in the ability of numerical ice sheet models to retrodict and predict ice sheet geometries requires model outputs to broadly agree with empirical data. For significant parts of the East Antarctic Ice Sheet empirical data on paleo ice sheet thickness and extent is patchy. MAGIC-DML, a Swedish-US-Norwegian-German-UK collaboration, is working in western Dronning Maud Land to determine the timing and pattern of ice surface changes. A combination of geomorphological mapping using remote sensing data, field investigations, cosmogenic nuclide analyses, and numerical ice sheet modelling are being used iteratively to reconstruct the glacial history. Glacially modified bedrock and erratic boulders were sampled from nunataks at different elevations above the modern ice surface. Measured concentrations of $^{10}\text{Be}$, $^{26}\text{Al}$, and $^{21}\text{Ne}$ in these samples reveal a complex exposure history of the nunataks implying fluctuations in ice sheet thickness since at least the last 3.7 million years.
PNRA Tytan project, supported by the National Institute of Oceanography and Applied Geophysics (OGS), focused on the advances and retreats dynamics of the ice sheet and on variations in the glacial regime. Unit 2 focused on Diatom biomarkers and assemblages analysis on sediments of core PC03, collected during the IN2017-V01 cruise on the eastern flank of the Minang-a (or Whale) submarine Canyon. The project aims at reconstructing the depositional environment of the continental margin off the Totten Glacier and diatom data remained a key tool to constrain past ice-sheet dynamics and to forecasting future behaviour in a warming world. Preliminary dataset from diatom biostratigraphic tools allows to refer the base of the core to Pliocene while the upper part of the core records more modern EAIS dynamics, indicative of minor sedimentary evolution steps of the continental margin.

Diatom assemblage analyses highlight Eocene-Oligocene reworked material and freshwater diatom inputs in Pliocene sequence, strengthening the debate about ice-sheet and paleoceanographic models, WAIS cyclic collapse and suspected Pliocene EAIS retreat into major subglacial Antarctic basins.
The retreat histories of the Greenland, Laurentide and Inuitian Ice Sheets that bordered the northern Baffin Bay during the last glacial are only poorly understood. Glacial landforms visible in high-resolution multibeam data can help to reconstruct the post-glacial retreat of these ice sheets. During two expeditions in 2015 and 2017, extensive surveys with multibeam and sediment echosounders were conducted in the Melville Bay, the Lancaster Sound trough mouth and on the north Baffin Island area to collect bathymetric data and data on shallow sediment architectures. In the recorded data, a variety of ice-sheet marginal and sub-glacial landforms including moraines, crag-and-tails, glacial lineations and grounding-zone wedges can be identified. The distribution of these landforms in the northern Baffin Bay shows that in cross-shelf troughs, grounded ice sheets reached to the shelf edge during past glacials. Grounding-zone wedges in the cross-shelf troughs indicate that the retreat of the ice-sheet margins from their Last Glacial Maximum extents to their recent positions was not continuous but interrupted by repeated phases of stabilisations in mid-shelf positions. Furthermore, the distribution of glacial landforms on the continental shelves indicates an asynchronous retreat of the ice sheets in the northern Baffin Bay. Glacial landforms on the inter-trough banks furthermore point towards localised ice caps on the continental shelf.
Invigorated Southern Ocean Circulation Preceding Oligocene Antarctic Glaciation

Alexander Houben¹, Peter K. Bijl² (p.k.bijl@uu.nl), Appy Sluijs², Stefan Schouten³, Henk Brinkhuis²,³
¹TNO, Utrecht, Netherlands, ²Utrecht University, Earth Sciences, Utrecht, Netherlands, ³NIOZ Royal Netherlands Institute for Sea Research & Utrecht University, Texel, Netherlands

During the Eocene - Oligocene Transition (EOT, 34-33.5 Ma), Antarctic ice-sheets rapidly expanded leading to the first Cenozoic continent-scale glaciation. Quasi-coeval opening of Southern Ocean gateways and resulting changes in ocean circulation are probably not the primary driver of Antarctic glaciation, but the exact role of tectonic changes across the EOT remain unknown. Here we use organic dinoflagellate cysts (dinocysts) to stratigraphically date and correlate critical EOT Southern Ocean sedimentary successions. The results imply that typical, winnowed glauconite-rich lithological units were deposited ubiquitously all around Antarctica starting at ~35.7 Myrs ago, and continued across the EOT. In addition, quantitative biomarker- and dinocyst-based temperature reconstructions show progressive cooling during the Late Eocene. In contrast, the southwest Pacific experienced late Eocene warming, related to troughflow of low-latitude surface currents. Organic microfossil assemblages document a shift towards more productive, vertically mixed surface waters in areas influenced by polar wind-driven currents. The results imply (I) accelerated deepening of the Tasman Gateway, (II) invigorated surface and bottom water circulation at sites affected by polar westward currents (III) progressive southward migration of ocean frontal systems (IV) cooling of the circum-Antarctic surface waters. These positive feedbacks have preconditioned the Antarctic continent for glaciation.
Modelling Long Term Climate and Ice Sheet Changes to Understand Future Warming

Zahra Rahimian\textsuperscript{1} (zrahimia@ucalgary.ca), Shawn Marshall\textsuperscript{1}
\textsuperscript{1}University of Calgary, Geography, Calgary, Canada

This study explores Greenland Ice Sheet reconstructions during the last interglacial period (~125,000 years ago) using the U.S. National Center for Atmospheric Research (NCAR) global climate model. Stable water isotopes (\(\delta^{18}O\)) of precipitation on the Greenland Ice Sheet are traced through the ice sheet and climate system, using precipitation isotopes that are simulated in the NCAR hydrological cycle. Isotope-tracing capabilities in the ice sheet model allow a prediction of 3D \(\delta^{18}O\) fields, which can be compared with modern observed fields (e.g., in ice cores) to better understand and constrain the past. Of particular interest is how the Greenland Ice Sheet changed in response to a warmer climate at this time, and whether some portion of the isotopic signals from the last interglacial period are associated with melt effects on the ice sheet. I will be examining the question of what threshold temperature, if any, causes the decline of the Greenland Ice Sheet, and how isotopes can be used to constrain ice sheet volume and associated sea level rise during this last major warm interval.
The Response of the Totten Glacier to Past Climate Warming Using Marine Sediment

Sian Tooze1 (sian.tooze@utas.edu.au), Taryn Noble1, Jacqueline Halpin1, Zanna Chase1
1University of Tasmania, Institute for Marine and Antarctic Studies, Hobart, Australia

The Totten Glacier is responsible for an average ice-loss of 7 ± 2 Gt/yr from East Antarctica (Li et al. 2016) and upon absolute melting, would contribute to a considerable 3.5m rise in global sea-level (Greenbaum et al. 2015). Marine sediment can be used to expand our understanding of ice dynamics and ocean circulation, which will ultimately facilitate the development of current ice sheet climate models. This study focuses on three marine sediment cores recovered aboard the RV Investigator from the continental slope of the Sabrina Coast. Multiple laboratory techniques have been employed to unravel the response of the ocean and the ice sheet to climate variability over the past glacial cycle. A transition from glacial to warmer conditions of the Holocene is characterised by a prominent peak in biological productivity - implying an ice-free, nutrient-rich photic zone. This transition is supported by trends in the XRF data which illustrate a change from clay-rich glaciogenic sediment (higher K/Ti values) to diatom-rich sandy surface sediments (lower K/Ti values) - and by an increase in the abundance of biogenic barium (Ba/Al) - a proxy of productivity export. Ongoing work will quantify the iceberg-rafted debris flux and measure temporal variations in primary productivity and ocean circulation. The provenance and age of heavy minerals will also be determined to help define the subglacial geology of the Aurora Subglacial Basin.
Late Eocene Marine Transgression Indicated by Glaucy Facies (Drake Passage)

Adrián López-Quirós1 (alquiros@iact.ugr-csic.es), Carlota Escutia1, Antonio Sánchez-Navas2, Fernando Nieto2, Agustín Martín-Algarra3, Dimitris Evangelinos1, Ariadna Salabarnada1

1Instituto Andaluz de Ciencias de la Tierra (CSIC-UGR), Marine Geosciences, Armilla (Granada), Spain, 2Universidad de Granada, Departamento de Mineralogía y Petrología, Granada, Spain, 3Universidad de Granada, Departamento de Estratigrafía y Paleontología, Granada, Spain

The rapid onset of continent-wide Antarctic glaciation during the Eocene-Oligocene transition was the most dramatic climatic perturbation of the Cenozoic. The Late Palaeocene separation of the Tasman Rise and South America from Antarctica led to the establishment of the Tasmanian and Drake Passages and to the development of the Antarctic Circumpolar Current. The Powell Basin formed as the South Orkney Microcontinent (SOM) was rifted from Antarctica in the Late Eocene. Sediments bearing Late Eocene green clay (glaucy) facies are a significant feature in the sediment cores recovered by the Ocean Drilling Program at Site 696 in the southeastern margin of the SOM. The mode of occurrence, mineralogy and chemistry of glaucony facies are important sedimentological proxies for paleoenvironmental reconstructions, as syn- to post-depositional controls determine the texture and composition of authigenic minerals that evolve from iron-rich smectite precursors to glauconite. The morphological, mineralogical and geochemical features of Late Eocene glauconitized fecal pellets/mica flakes denote an autochthonous origin of the evolved (mature) glaucony grains, indicating a period of low sedimentation rate probably associated with rising sea levels related to plate reorganization and opening of Drake Passage. In this scenario, the Powell Basin may have provided pathways for a proto-circumpolar current, favouring upwelling, stratigraphic condensation and glauconitization in the SOM margin.
The 'Ona Paleovalley' (Drake Passage): A Submarine Slope Failure System

Adrián López-Quirós¹ (alquiros@iact.ugr-csic.es), Francisco J. Lobo¹, Carlota Escutia³, Fernando Bohoyo², F. Javier Hernández-Molina¹, Lara F. Pérez⁶, Marga García¹, Dimitris Evangelinos¹, Ariadna Salabarnada¹

The southern Scotia Sea hosts small oceanic basins developed through continental break-up and oceanic spreading during the Cenozoic. Ona Basin is the southwestern most basin of the Scotia Sea. It is bounded by several structural highs: the Shackleton Fracture Zone to the west, Terror Bank to the east, and the South Scotia Ridge to the south. The southern part of the basin is further divided in two sub-basins (the western and eastern Ona basins) separated by the submarine relief called Ona High. The Ona Basin is mainly affected by two major water masses the deeper branch of the Antarctic Circumpolar Current flowing eastwards and a westward flowing branch of the Weddell Sea Deep Water (WSDW). Interaction between mass movement and contouritic processes are likely to occur as a consequence of the complex geologic, physiographic and oceanographic setting. A combined approach including geomorphological, stratigraphic and seismic analyses allows us to document, for the first time, the record of repeated large-scale submarine landslides in the western Ona Basin. A major morphological feature named as 'Ona Paleovalley' is genetically related to large-scale recent gravity/mass transport processes. The valley infill records channelized depositional periods alternated with erosive events when sediments were evacuated basinwards. This morpho-sedimentary pattern is attributed to the interplay between tectonic events leading to gravitational processes and the channelized flow of the WSDW.
Eocene-miocene Paleoceanographic Changes in Drake Passage (Antarctica)

Adrián López-Quirós1 (alquiros@iact.ugr-csic.es), Carlota Escutia1, Johan Etourneau1, Francisco J. Rodríguez-Tovar2, Peter K. Bijl3, Francisco J. Lobo1, Fernando Bohoyo4, Dimitris Evangelinos1, Ariadna Salabarnada1
1Instituto Andaluz de Ciencias de la Tierra (CSIC-UGR), Marine Geosciences, Armilla (Granada), Spain,
2Universidad de Granada, Departamento de Estratigrafía y Paleontología, Granada, Spain, 3Utrecht University, Department of Earth Sciences, Utrecht, Netherlands, 4Instituto Geológico y Minero de España, Madrid, Spain

The timing and impact of the opening of the Drake Passage during the Eocene-Oligocene and Oligocene-Miocene transitions on global climate remain controversial. In this study, we aim to better understand the regional reorganization of the ocean circulation in the southeastern margin of the South Orkney Microcontinent (SOM) that remained isolated from Antarctica during these transitions. We combined a multi-proxy study: sediment facies analysis, diagenesis, ichnology, X-ray diffraction and fluorescence, and geochemical analyses using marine sediment samples from the Ocean Drilling Program (ODP) Site 696. The late Eocene, during which the SOM was still attached to the Antarctic Peninsula, was characterized by a thick, terrigenous sequence deposited at shallow-water (neritic) depths under reduced-oxygen conditions. However, the latest Eocene is marked by syn-depositional glauconitization under slow sedimentation and a relative sea-level rise/subsidence. The continuous sea-level rise led to the establishment of bathyal depths during the early Oligocene. At that time, the water column was stratified and local/temporal anoxic bottom water conditions developed, likely associated with a restricted ocean circulation in the Powell Basin due to the clockwise drift of the SOM from Antarctic Peninsula. The end of the transgressive pulse is detected at the end of the mid Miocene, recorded by a siliceous-biogenic ooze associated with oxic conditions as a result of the modern SOM geography.
Recent observation revealed that the fastest melting rate of polar ice sheets ever observed is ongoing due to the global warming and there is growing concern of greatly rise of sea level in the future. Knowledge of sea level fluctuations in the past warm period provides useful information to better understand future sea level changes. Geological records have suggested that sudden and abrupt rises in sea level (~6 m) were happened during the last interglacial when global mean sea surface temperature was slightly higher than the preindustrial level. If this were really happening, there is a critical ice sheet stability threshold resulting in the catastrophic collapse of polar ice sheets and substantial rapid sea-level rise in the interglacial climate condition. Since the Greenland ice core record showed a 2 m eustatic component from the Greenland ice sheet during the last interglacial, the Antarctic ice sheet greatly contributed to eustatic rise of sea level at that time. However, variability of the Antarctic ice sheets during the period has not been investigated. In this study, we measured paleoclimate proxies in sediment cores collected from different parts of the Antarctic margins in order to reconstruct variability of Antarctic ice sheets during the last interglacial. In this presentation, we will show you preliminary results of our sediment core data.
Ocean Circulation across the Tasman Gateway during Mid-Oligocene to Mid-Miocene

Dimitris Evangelinos¹ (dimevangelinos@correo.ugr.es), Carlota Escutia¹, Tina van de Flierdt², Katharina Kreissig², Luis Valero³, José-Abel Flores⁴, Johan Etourneau¹, Adrián López-Quirós¹, Ariadna Salabarnada¹, C. Hans Nelson¹, Francisco Lobo¹, Marga García¹

¹Instituto Andaluz de Ciencias de la Tierra, CSIC-Univ. de Granada, Armilla (Granada), Spain, ²Department of Earth Science and Engineering, Imperial College London, London, United Kingdom, ³Universitat Autònoma de Barcelona, Facultat de Ciències, Laboratory of Paleomagnetism CCITUB and CSIC-Institut de Ciències de la Terra Jaume Almera, Barcelona, Spain, ⁴University of Salamanca, Department of Geology, Salamanca, Spain

Establishment of deep ocean circulation between Australia and Antarctica through the Tasman Gateway has been suggested to start 30 million years ago (Ma), mostly attributed to the onset and strengthening of the Antarctic Circumpolar Current (ACC). However, uncertainty remains regarding the timing and intensity of such paleoceanographic reorganization because of the lack of data. Here, we present sedimentological records spanning the mid-Oligocene to mid-Miocene at two strategic Deep Sea Drilling Project (DSDP) Sites (a) 278 and (b) 269A from the Pacific and Indian sectors of the Southern Ocean, respectively. Paleomagnetic and biostratigraphic analyses have been conducted to obtain a new age model. In addition, visual core descriptions, conventional sedimentological analyses and geochemical X-ray Fluorescence (XRF) data were performed in order to define the main lithofacies and facies associations. Neodymium isotope ratios (εNd) were obtained from fossil fish teeth to reconstruct regional water masses and ocean circulation. At Site 269A, we find Oligocene/Miocene εNd values of -8.2 to -8.8, indistinguishable from modern deep circumpolar εNd values. More radiogenic εNd values (-6.2 to -6.9) are recorded at Site 278, similar to other records from the region. We conclude that from around 30 Ma, the signature of the ACC records mixing processes between Indian-Atlantic waters with Pacific and possibly Ross Sea deep waters after crossing the gateway.
Sedimentary Evidence for a Pre-Pleistocene Marine Environment in West Antarctica

Rosemary Vieira¹ (rosemaryvieira@id.uff.br), Vanessa Costa², Jefferson Cardia Simões³

¹Universidade Federal Fluminense, Geography, Niterói, Brazil, ²Universidade Federal Fluminense, Niterói, Brazil, ³Universidade Federal do Rio Grande do Sul / INCT da Criosfera, Porto Alegre, Brazil

Elephant Head (79°49.298´S / 83°20.426´15 W), Ellsworth Mountains, is a deglaciated valley in which sediment samples were collected in the moraines. Particle size, morphometric, and chemical and mineralogical composition analyses were performed on the sediments. The predominance of calcium carbonate was observed in most samples; ripple marks suggested the existence of a shallow marine environment. A marine sedimentation possibly filled a shallow inland sea, associated with local tectonic uplift, posterior glacial covering and erosion. Calcareous and clastic sedimentation dominates the valley, reflecting the nature and composition of the main source of the sediments. Conglomerates also reflect the nearby source area. Further glacial conditions have not modified the sediment conditions substantially due to the dry climatic conditions. It is suggested that Elephant Head Valley preserves geomorphologic and sedimentological evidence for a marine sedimentary environment, potentially of pre-Pleistocene glacial cycles, supporting recent inferences from terrestrial deposits, which suggest the continuous presence of the WAIS in the southern sector of Ellsworth Mountains and the preservation of landforms and sediments at the scale of 3.5 Ma. The main unknowns now concern the timing of the events.
The opening of the Tasman Gateway drastically affected Antarctic ice sheet and global climate through its impact on atmospheric and ocean circulations. The relationships between the tectonics, circulation changes and Antarctic glaciation are still debated. We studied late Eocene to early Oligocene age sediments from DSDP Site 274 to provide insights into the relationship between the opening of the Tasman Gateway, the beginning of Antarctic glaciation and the onset of the “proto”- Antarctic Circumpolar Current (ACC). For this, we conducted paleomagnetic and biostratigraphic analyses to obtain a new age model. Sedimentary facies were defined based on visual core descriptions, scanning electron microscope (SEM) images, conventional sedimentological analyses, geochemical (XRF) and mineralogical (XRD) data. During the late Eocene, Site 274 sedimentation was dominated by high terrigenous inputs (silty clays). Towards the latest Eocene, silty clays are interbedded with cherts. From the early Oligocene onwards, sedimentation is dominated by siliceous oozes with sporadic ice rafted debris. We infer that the shift from terrigenous sedimentation to cherts reflects the onset of a prolonged period of high primary productivity. Fossil fish teeth will be analysed for Nd isotopes to identify intermediate/deep water masses across the observed shift in sedimentation and its relation with the establishment of the proto-ACC.
The Late Pliocene is the most recent interval in Earth's history to sustain global temperatures within the range of warming predicted for the 21st century. Global reconstructions and climate models find an average +2°C summer SST anomaly relative to modern during the ~3.3-3.0 Ma PRISM interval, when atmospheric CO2 concentrations last reached 400 ppm. Here, we present a new diatom-based reconstruction of Pliocene (3.8-2.8 Ma) interglacial sea surface conditions from IODP Site U1361, on the East Antarctic continental rise. A prominent feature of this record is the transient southward shift of the Antarctic polar frontal zone during a single interglacial, marine isotope stage KM3 (3.17-3.15 Ma), bathing U1361 in warmer subantarctic waters. Building on this result, we revisited earlier reconstructions to explore the response of the Southern Ocean to peak late Pliocene warmth. By applying a modern chronostratigraphic framework to those lower-resolution records, we identify the same frontal migration in 4 other cores in the Pacific sector of the Southern Ocean, documenting a major migration of the polar front during a key interval of warm climate. These new results suggest that increased summer insolation during KM3, combined with atmospheric CO2 similar to modern concentrations, provided sufficient forcing to overcome bathymetric constraints on polar frontal position, pushing warm subantarctic waters into proximity with vulnerable portions of Antarctica's marine ice sheets.
A 11.75 m-long core RS15-LC42 was collected from the Central basin in the Ross Sea (71°49´ S, 178°35.´E, 2084m deep) in 2015, by the Korean RVIB Araon. The chronology is inferred by paleomagnetism and diatom biostratigraphy, and the core covers about one million years. Magnetic susceptibility, grain size, oxygen and nitrogen isotopes, and concentrations of total organic carbon (TOC), opal, and CaCO$_3$ were measured. Foram oxygen isotopic compositions were analyzed, and elemental compositions were scanned by ITRAX system. The core is composed of two alternating facies:
1) well-laminated greenish gray diatomaceous mud, and
2) massive light gray sandy mud.
Well-laminated facies tend to include higher TOC, opal and carbonate compared to the other, so it is likely that they were deposited during interglacial period, but the possibility of remobilizing of sediments from the outer shelf to continental slope during glacial period cannot be excluded. Around 280 cm (about 0.25 Ma) from the core top, the massive facies is dominant in the upper part, whereas the laminated facies is dominant in the lower part. This indicates that there was a major shift in the depositional condition in the Central Basin at this time and which could be related with the extensive glaciation during Marine Isotope Stage (MIS) 8 in the McMurdo Sound (Christ and Marchant, 2017). Further work like clay mineral assemblage is necessary in order to ascertain whether the laminated sediments are primary or reworked.
Reconstructing the past dynamics of the Greenland Ice Sheet (GrIS) offers invaluable insight into its dynamics under a modern day changing climate. Two sediment cores (GeoB19946-4 and GeoB19948-3) from Melville Bay (NE Baffin Bay), into which 27% of the GrIS drain, were used to investigate the melting history and sedimentary dynamics in the area. The near-by cores were retrieved from two different major shelf troughs that are separated by a shallow sill. These are fed by individual glacier sources which allows for a clear differentiation of two major modes of glacier-derived sediment transport: in a surface plume potentially affecting both core sites vs. near-bed transport affecting only one site. Regarding grain size distribution, sediment elemental composition and microfossil content, both records reveal a very similar alteration of characteristic core sections, where large portions of the cores can be classified as glaciomarine-hemipelagic sediments. However, in both cores these layers are intersected by several meter thick, homogenous and very fine-grained sediment packages, barren of microfossils and showing little to no variation in their elemental composition. Combined, this synchronous, strong and sudden change in sediment characteristics indicates the occurrence of at least one huge, surge-like meltwater event that was not confined to a single trough. This interpretation is supported by initial radiocarbon dates that place the more recent surge at around 7.5 ka BP.
The assessment of the stability of Antarctic ice sheets and of their contribution to the global sea level change as a response to climate change requires the reconstruction of their past volume variations. For instance, dramatic surface lowering of East Antarctic Ice Sheet (EAIS) during the last million years have been recently reported in several publications. However, the spatial distribution of this unloading and subsequent isostatic rebound remain unexplored. In this study, we will decipher the pace of deglaciation and quantify subglacial erosion of the EAIS in the Sør Rondane Mountains in the Queen Maud Land. To do this, we will focus on the Nunataks around Mount Wideroe, Mount Nils Larsen and Perlabandet in the western Sør Rondane Mountains. We will use in-situ produced cosmogenic 10Be, 14C, 26Al and 36Cl to reveal the deglaciation history and amount of subglacial erosion. In the field, we will locate and map the paleo-positions of the ice margin during the retreat in the Nunataks. Measured cosmogenic nuclide concentrations will be then converted to both exposure ages and amount of glacially eroded bedrock. This study will produce scientific knowledge on (1) deglaciation of the Queen Maud Land, (2) amplitude, timing and frequency of the deglaciation, and (3) subglacial erosional processes. The first results will be presented.
Antarctic subglacial lakes contain sediment records of past environmental change and ice sheet history. To interpret sediment records in context it is important to understand the nature, origin and history of such lakes. Here, we determine the long-term landscape evolution of the Ellsworth Mountains region, where at least two subglacial lakes have been suggested as targets for exploration, Subglacial Lake Ellsworth, and Subglacial Lake CECS. New geomorphological observations of exposed areas show that the Ellsworths contain preserved remnants of a pre-glacial landscape, incised by alpine glaciation and subsequent ice sheet glaciation, and with multiple trimlines recording former ice levels. Based on geochronologic techniques we suggest the likely timing of each of these stages of development. Beneath the ice we present a new bedrock topography based on a combination of new and existing radar survey data. Using this coupled to mapping of supraglacial ice topography we identify key features in the landscape including prominent glacial troughs cutting through the Ellsworth-Whitmore Block. Using this new subglacial topography we explore the contemporary subglacial hydrology of the region, and the hydrologic connectivity of the lakes through time. We will explore the implications for subglacial exploration, especially the likely nature of the sediment record preserved in the lakes, and which can provide insight into long-term ice sheet behaviour.
Sets of parallel erosional features have recently been identified on the Lomonosov Ridge in the central Arctic Ocean, indicative of ice grounding in modern water depths of up to 1,280 m. These features have been interpreted as being formed by an ice shelf, either restricted to the Amerasian basin (the ‘minimum model’), or from an ice shelf covering the entire Arctic basin. We use a numerical ice sheet-shelf model of the Arctic and surrounding grounded ice sheets to explore how such a thick Arctic ice shelf could form and determine which ice sheet/shelf configurations are most consistent with the ice-flow features observed in the Arctic Basin. We suggest that such an Arctic ice shelf could only form with complete ice cover in the Arctic Basin, which places a minimum estimate on its volume. We explore how buttressing provided by an Arctic ice shelf would have affected the dynamics of the surrounding terrestrial ice sheets and examine how grounding on the Lomonosov Ridge affects the stability of the ice shelf. Our results also have significance for a hypothesized East Siberian ice sheet.
Exploring the Range of Parameters Favouring Antarctic Glaciation

Jonas Van Breedam¹ (jonas.van.breedam@vub.be), Philippe Huybrechts¹, Michel Crucifix²

²Université Catholique de Louvain (UCL), Georges Lemaître Centre for Earth and Climate Research (TECLIM),
Earth and Life Institute, Louvain-la-Neuve, Belgium

It is generally believed that a large ice sheet started to grow on the Antarctic continent around 34 million years ago. The development of the Antarctic ice sheet occurred at a time when ocean gateways surrounding Antarctica opened and atmospheric CO₂ concentrations declined from values likely above 1000 ppm to below 600 ppm. Recent work suggests that the elevation and configuration of the Antarctic continent was rather different from today when accounting for the effects of erosion and tectonic uplift, which impacts have not yet been studied in much detail.

Previous work considering off-line ice sheet simulations or asynchronous coupling with climate models show that CO₂ might have been the decisive factor in cooling the Antarctic climate and initiating ice sheet growth. Here we present transient simulations around the Eocene-Oligocene transition using HadSM3, a climate model that performs particularly well above the Antarctic continent, coupled with the Antarctic ice sheet model VUB-AISM. The latest insights in paleogeography and bedrock topography are used for the reconstruction of the boundary conditions. We make use of an emulator to predict temperature and precipitation above the Antarctic continent for a large range in CO₂, orbital parameters and ice sheet volumes to determine where ice sheet initiation is favoured.
The interplay of tectonics and climate is recorded in the sedimentary strata within the Victoria Land Basin, McMurdo Sound, Antarctica, where patterns of sedimentation documented from interpretation of seismic reflection profiles are calibrated by drillhole data. Mapping of reflectors marking unconformities identified from the AND-2A core indicates that grounded ice did not extend from the south throughout McMurdo Sound until ~14.4 Ma. Prior to that point, erosion was limited to the western shelf as ice extended eastward from TAM outlet glaciers. Seismic facies patterns suggest that the shelf-slope-basin geometry within McMurdo Sound did not shift laterally through the Miocene, and was very similar to the present morphology. Mass accumulation rates calculated in this study are variable, but the broad trends are dictated by a combination of available accommodation space in the depocenter and ice sheet thermal regime. Sediment volumes and mass accumulation rates calculated for critical climatic intervals show that from ~22 Ma to ~13 Ma the overall trend of mass accumulation rates declined, with a particularly noticeable decline following the onset of cold-based glaciation following the Mid Miocene Climate Optimum ~15 Ma.
Sedimentary Processes at the Northern Svalbard Continental Margin

Andrea Catalina Gebhardt¹ (catalina.gebhardt@awi.de), Dilip Adhikari², Jens Matthiessen³, Felix Gross⁴, Judith Elger⁵, Sebastian Krastel⁶, Wolfram H. Geissler⁶
¹Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Geophysics, Bremerhaven, Germany, ²HafenCity University Hamburg, Hamburg, Germany, ³Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Marine Geology, Bremerhaven, Germany, ⁴Christian-Albrechts-Universität zu Kiel, Kiel, Germany, ⁵GEOMAR Helmholtz Centre for Ocean Research Kiel, Kiel, Germany, ⁶Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

Hydroacoustic and high-resolution seismic data reveal that glacial processes and slope instability extensively shape the sedimentary drape on the shelf north of Svalbard and the southern Yermak Plateau (YP). A complex association of overlapping submarine landforms is linked to the Middle to Upper Pleistocene glaciation history in the Arctic Ocean:
(i) Mega-scale glacial lineations (MSGL) formed either by an ice shelf advance from Svalbard or a coherent mass of large-scale icebergs exiting the Arctic Ocean across the YP,
(ii) Quasi-linear, huge ploughmarks, younger than the MSGL, formed by keels of a mega-iceberg or several icebergs trapped together in multi-year sea ice.
(iii) Freshly-looking large iceberg ploughmarks, and
(iv) irregular smaller-scale ploughmarks formed by keels of small icebergs.
A grounding-zone wedge located close to NW Spitsbergen potentially represents the maximum extent of the youngest advance of the Svalbard-Barents ice sheet. The shelf and slope off Nordaustlandet was subject to the giant Hinlopen/Yermak Megaslide (HYM) some 30 ka ago. Internal deformation of the sedimentary structures reveals secondary, partly incomplete sliding processes of different age. Gas seeping, paleo pockmarks and a former gas-pipe structure are likely linked to the mass failure. Large parts of the Nordaustlandet shelf and slope are currently preconditioned to fail completely in future.
Challenges in Polar Education: Lessons Learnt Since International Polar Year?

Education is a major legacy of the International Polar Year (IPY) carried out in 2007-08. This presentation aims to discuss how certain aspects of polar education have grown. For example, Regular international science education workshops and meetings, POLAR WEEKS (mainly coordinated by the Association of Polar Early Career Scientists (APECS) (with Polar Educators international (PEI) in some countries) are still a huge success while education and outreach is a growing theme within the Antarctic Treaty Consultative Meetings. However, challenges on polar education still stands, such as: a thorough evaluation of long-term educational activity success, and an activity implementation plan for other countries (and in other languages). To meet these challenges, there is increasing need of using the most recent technologies, placing polar subject into national curricula. In POLAR 2018, we will also aim to compare both Arctic and Antarctic education goals and discuss how further international and collaborative initiatives can be developed and implemented, under a polar framework for education.
A Worldwide Glacier Information System to Go

Michael Zemp¹ (mzemp@geo.uzh.ch), Samuel U. Nussbaumer¹, Nico Mölg¹, Jacqueline Huber¹, Isabelle Gärtner-Roer¹
¹University of Zurich, World Glacier Monitoring Service, Zurich, Switzerland

In the forefront of the Paris Climate Conference in December 2015, the WGMS and UNESCO jointly launched a glacier application for mobile devices. The wgms Glacier App aims at bringing scientifically sound facts & figures on worldwide glacier changes to the interested public and teachers. With the launch of the app at high-level events, we target the awareness of decision makers at governmental and intergovernmental levels for climate change. The app provides a map interface based on satellite images that display all the observed glaciers in the user's proximity. Graphs with observation data illustrate the glacier's development, along with information on latest principal investigators and their sponsoring agencies as well as detailed explanations of the measurement types. A text search allows the user to filter the glaciers by name, country, region, measurement type, special events (e.g. floods or avalanches) and the current "health" status, i.e. if the glacier has gained or lost ice over the past decade. A compass shows the closest observed glaciers in all directions from the user's current position. The app further allows the user to submit own glacier photographs and to send feedback. Finally, the card game allows the user to compete against the computer on the best-monitored glaciers in the world. In this presentation, we provide a visual entrance point to the app and discuss our experiences with this new way of sharing scientific observations with a wider audience.
Preparing and Conducting a Live Online Class to Popularize Antarctic Science

This paper reports the process of preparation and delivery of an inaugural class of the distance course for teachers Antarctic or Antarctica?

In order to contribute to the formation of a scientific culture, the preparation started from a dialogical learning approach, in which the teacher must abandon the role of information issuer and assume the place of learning mediator and, together with the student, to produce meanings. It was also considered to insert the polar sciences in contexts of popularization, reducing the abyss and the distance between specialists and laymen.

The class was conducted by a multidisciplinary team with the objective of promoting the connection between participants in Portugal and 14 Brazilian states.

The broadcast of the class was performed live on YouTube by free and open source Open Broadcaster Studio (OBS). In total, 257 participants had access to the class and interacted with six tutors through multiple platforms: YouTube, Facebook and Whatsapp chat.

The use of collective teacher conception together with accessible tools was fundamental for the development of the class by promoting the interaction of people from different locations and the breaking of the barriers imposed for access to scientific knowledge. Synchronous mediation contributed to the consolidation of knowledge about Antarctica and promoted a greater involvement of the participants in the proposed course, enhancing such knowledge.
This article aims to present partial results of a research conducted in the learning process of the participants of a distance teacher training course: Antarctic or Antarctica: How to introduce the polar sciences in the primary school curriculum?

Our theoretical foundation is based on the socio-interactionist approaches, dialogic learning, and collaborative learning.

Antarctic or Antarctica? Is a fourty-hour distance learning course, structured in four modules (Ice, Convergence, Environment, and Life). There is a face to face class, and all others classes happen online and should be finished in ten weeks.

The course is composed of texts, video lessons, puzzles, etc. All the teaching material was prepared in an accessible language to different audiences and can be used by teachers to teach their classes.

Course participants had to answer a quiz before and after the course. Before the beginning of the course, there were a lot of misconceptions about Antarctica.

After attending the course, a few misconceptions persisted. However, most of the participants were able to learn crucial information about the continent.

The course helped participants to understand the importance of teaching about the continent in primary schools. There was significant learning about basic knowledge of Antarctica. Participants were able to contextualize that knowledge in their classes. Producing Portuguese teaching material is crucial to introduce Antarctica into the curriculum.
Over the past 10+ years, through a partnership with elementary school teachers, the United States Polar Rock Repository (PRR) and Antarctic researchers, we have engaged with elementary classrooms highlighting the nature of Antarctic scientific field work. A typical classroom visit involves the use of google earth to orient the students, sharing field videos & photos, an opportunity to dress up in extreme cold weather (ECW) gear and a chance to inspect geologic samples from the PRR collection. In 2017, we expanded on our typical classroom visit to include a school-year-long project whereby a field team engages with the class over the entire life cycle of a field season, including blog updates from the field. After the initial class visit, we introduce the project and challenge the class to submit specific questions to the field team and teachers that may form the basis for a student designed project aimed at planning a field season to Antarctica. Near the end of the school year, the students present to a team of scientists to highlight their plans. For this session, we will present the results of this experiment, share lessons learned and seek input for further refinement.
In its 4th year, Climate Change is a semester elective open from 10th to 12th grade students at a private boarding school in Connecticut, USA. This course focuses on Earth systems, key environmental issues, political actions, social and cultural impacts as well as developing science literacy skills. Ideas are presented from both sides of the spectrum and students are able to arrive at their own opinions as they evaluate science sources. There are great discussions but also hands on labs, field trips and group projects. Students read through the Intergovernmental Panel on Climate Change report learning how to read various graphs and charts. Students observe the long term studies which enforces the difference between weather and climate. The variation in potential outcomes shows the difficulties of modeling and the meaning of uncertainty. Beyond reading technical papers, students also follow scientists, expeditions and latest news through various social media platforms. A final project is to have students craft a local project on campus that will last longer than their enrollment in the class. This is necessary to leave the students empowered as often when they become savvy to these dire issues there is an overwhelming sense of urgency and powerlessness. For the youth, having a real but hopeful take away message is imperative. This course has been highly successful, encouraging students to take further environmental courses or pursue higher studies in this field during college.
The Tiny Silverfish. A Journey of Discovery through the Southern Ocean

Eva Pisano1,2 (eva.pisano@ge.ismar.cnr.it), Laura Ghigliotti2, Marino Vacchi2, Clive Evans3
1University of Genoa, Department of Educational Sciences, Genoa, Italy, 2National Research Council of Italy, Institute of Marine Sciences (ISMAR-GE), Genoa, Italy, 3University of Auckland, School of Biological Sciences, Auckland, New Zealand

Ross and Sesi are two tiny fish, waiting to come to life in the midst of the Antarctic sea ice. After hatching from small eggs they travel across the Southern Ocean, growing up in a fantastic environment inhabited by wonderful creatures and dangerous predators. Children are involved in this adventure, following Ross and Sesi as their life journeys unravel, and participating in the experience of discovering Antarctic marine life. This children’s book, published in Italian in 2013, is now translated and available in English, ready to reach a wide audience of young readers and primary school teachers. In the book, the life cycle of a key fish species of the Antarctic Ocean, the Antarctic silverfish, and its unique relationship with sea ice, are translated into appealing graphics to illustrate the basic structure of the Antarctic ecosystem and the implications of ongoing climate change. The book is a result of the project "Communicate polar science: Antarctic fish", supported by the Italian Programme for Antarctic Research (PNRA). Both the graphics and the text are set with rigorous attention to the educational message in polar scientific issues, and to gender equality. The book is dedicated to John Macdonald, a much appreciated Antarctic researcher from the University of Auckland who, together with the authors, participated in the discovery of the Antarctic silverfish nursery in the northern Ross Sea region.
Training Scientists in Effective Science Communication via Lightning Talks

Jessica Rohde¹ (jrohde@arcus.org), Emily Osborne²
¹Interagency Arctic Research Policy Committee, Washington, United States, ²National Oceanic and Atmospheric Administration, Washington, United States

Scientists are regularly expected to communicate their research and results with non-scientists although they often don't receive training in how to do so effectively. Further, with a growing emphasis on interdisciplinary research, scientists must also become adept at communicating with scientists outside of their discipline who may not be familiar with the discipline's base-level knowledge and jargon. The Interagency Arctic Research Policy Committee (IARPC) in the United States provides a unique platform to expedite communication between the research community and US agencies which fund Arctic research. The IARPC has created a virtual opportunity via the IARPC Collaborations website (iarpccollaborations.org) for early career scientists to receive training on communicating science to communities outside their discipline, non-scientists and policy makers. IARPC Collaborations hosted a workshop to train early career researchers in conducting a "lightning talk," or a short format presentation that emphasizes streamlined communication. The training focused on developing communication skills such as considering audience, avoiding jargon, and utilizing narrative structure. Following the workshop, participants presented their lightning talks to an audience of interdisciplinary Arctic scientists and Federal program managers. IARPC plans to repeat this workshop to promote interdisciplinary networking through IARPC Collaborations and continue to provide communication training.
Permafrost Young Researchers Network: The Next Generation of Permafrost ECRs

Alevtina Evgrafova¹,² (alevtina.evgrafova@gmail.com), Caroline Coch³, Denis Frolov⁴, Florence Magnin⁵, Justine Ramage³, Simon Dumais⁶
¹University of Bern, Bern, Switzerland, ²University of Koblenz-Landau, Koblenz, Germany, ³Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Potsdam, Germany, ⁴Moscow State University, Moscow, Russian Federation, ⁵University of Oslo, Oslo, Norway, ⁶Laval University and CNRS, Quebec, Canada

The Permafrost Young Researchers Network (PYRN) is a platform created to engage future generations of permafrost early career researchers (ECRs) to promote multidisciplinary research collaboration, establish exchange on scientific news and activities around the world and make career development opportunities available by supporting activities, improving communication among permafrost ECRs and engineers, accumulating and sharing technical and non-technical information on permafrost such as upcoming events, travel grant and scholarship opportunities, and job postings. PYRN has been actively using the social media such as Facebook (https://www.facebook.com/PYRNofficial), Twitter (https://twitter.com/PYRN_official) and Instagram (https://www.instagram.com/pyrn_official) in order to reach as many ECRs as possible. PYRN also works in close collaboration with the International Permafrost Association (IPA) and other partners in order to assist with the organization of the ECRs’ activities during the regional and international permafrost events such as the coordination of travel grant programs and student presentation awards as well as organization of international PYRN workshops (e.g. EUCOP, ICOP), which represent a key contribution of the PYRN to the permafrost research community. In addition, PYRN has been continuously developing and the PYRN North America was established in order to increase the collaboration among ECRs based in Canada and in the USA in December 2017.
Use of Facebook for the Polar Sciences Popularization

Silvia Dotta¹,²,³ (silviadotta@gmail.com), Diego Marques⁴, Paulo Lopes⁴, Emmanuel Duarte⁴, José Norberto Sousa Lopes⁴, Lucas Almeida⁴

¹Federal University of ABC, Mathematics, Computation and Cognicion Centre, São Paulo, Brazil, ²Polar Educators International, Santo André, Brazil, ³APECS - Brazil, Santo André, Brazil, ⁴Federal University of ABC, Mathematics, Computation and Cognicion Centre, Santo André, Brazil

Social media are spaces for collaboration, information sharing and collective construction of knowledge. Facebook (FB) has in Brazil a penetration in 45% of the population, therefore approximately, 90 million of the users connected to the internet. This is the main reason the social platform was chosen to host an activity on the distance learning course to teachers Antártica or Antártida?

Sharing information, news and curiosities about Antarctica, on the Portuguese language, was the main objective along eight weeks when the students had to post on their FB profiles at least one weekly article about Antarctica, followed by the hashtag #CursoAntarctica.

114 students published at about 912 posts on different subjects covering Antarctica. Beyond sharing news and curiosities, it was realized that the students were engaged in the dissemination of what they have learned and researched, reaching the largest number of people among their connections on Facebook. Those posts had a potential reach of 1317 users, with 10 potential influential subjects that amplified the discussions about Antarctica. The sum of those users’ Share of Voice reached a score of 99.491, therefore proving the potential of Facebook to popularize science.

The creation of a connected people network was fundamental to popularize science. Social networks are part of the students’ lives and allow the educators new pedagogic possibilities, enabling flexible contexts, individual and collective approaches etc.
Igor Osipov¹ (igor@uberresearch.com), Euan Adie², Lars Kullerud³
¹Digital Science / UArctic Research Analytics Institute, Moscow, Russian Federation, ²Altmetric, London, United Kingdom, ³University of the Arctic, Arendal, Norway

The Arctic and Polar North have seen a dramatic increase in global attention from policy-makers and industry due to several important topics, including climate change and resource competition. International Arctic research collaboration has existed since the 19th century and, irrespective of political conditions, has grown visibly over the last decades through initiatives such as “International Polar Year” and annual activities and meetings of the Arctic Council.

As a result of these developments and the growing scale of research data there is an increasing need to regularly analyze research cooperation, activities and outcomes, identify centers of excellence, and to foster further international collaboration between disciplines and across geographies.

It is apparent that there are a lot of new insights that the Polar research community and decision makers can gain through the lenses of various research metrics. Questions that this session will address include:

- How big-data analytics tools and methods can be used to identify and evidence challenges and gaps in knowledge, and what solutions they might offer.

- A review of how policy makers and global audiences have engaged with the research - and what that might mean for its future.

- A discussion of we can identify centers of excellence and surface new opportunities for collaboration.

The session is open to anyone with an interest in the development of research programs, collaborations, evaluation and connected data.
Homeward Bound: Leadership, Science, Strategy and Gender in Antarctica

Justine Shaw1,2 (j.shaw6@uq.edu.au), Mary-Anne Lea2,3
1The University of Queensland, Centre for Biodiversity Conservation Science, Brisbane, Australia, 2Homeward Bound, Melbourne, Australia, 3University of Tasmania / Institute for Marine and Antarctic Studies, Hobart, Australia

The world’s first leadership, strategy and science program for women in science, set sail for Antarctic in December 2016. It was the first voyage of a 10 year outreach initiative to build a 1,000 strong global collaboration of women in science, who have had shared experience and learning in Antarctica, with a curriculum focusing on leadership, strategy and science. Antarctica was the backdrop for this initiative and we report on how why Antarctica was pivotal to Homeward Bound’s success.

The 2016 program selected 76 female scientists from around the world. They worked on a range of projects focusing on global change and sustainability throughout the year. They met for the first time as they embarked on a 20-day trip to Antarctica. Together and individually, they learnt to elevate their leadership capabilities, refining their ability to design and execute strategy, and devise plans for future collaborations as science leaders working towards a sustainable future. While undertaken this transformational journey, an immersive science program on Antarctic conservation, marine and terrestrial ecosystems, was delivered by experts. A participant led science symposium was held at sea, off the Antarctic Peninsula. There were 76 science presentations, the scientists then explored opportunities for collaborations, with new initiatives emerging from the voyage. The program is rolling out again in Feb 2018 with a new cohort of scientists, and a third voyage is fully subscribed for 2019.
Earth’s polar regions contain extreme environments that are the best analogs to those on other planetary bodies, like Mars and Europa. Furthermore, they can serve as analogs to early Earth, allowing us to explore questions about how life starts and thrives. Polar environments also serve as testing grounds for prototypes bound for other solar system locales.

A compelling combination of science, art, and gaming can inspire curiosity in young people about extreme environments of our polar regions, astrobiology, and frontiers in science and engineering. Teens love gaming, making them the perfect audience for this lesson series. Art and games can make abstract science concepts more accessible and help youth envision themselves as polar scientists.

The series begins as youth play a game about extremophiles, matching their environments with extraterrestrial environments within our solar system. Next, students compare and contrast environments of Antarctica and Europa, which are then highlighted in student-created, annotated artwork. After that, they play Microbe Madness, a game of evolution in which the microbe with the best genes survives changes over time. As a culmination of the lesson series, youth create their own game about being an polar astrobiologist, modeled after a “choose your own adventure” style of board game. Templates of the activities are offered for easy modification for other outreach purposes and goals across science disciplines.
The UK Polar Network: An Interactive Journey through UKPN Outreach and Workshops

Kyle Mayers1,2 (kyle.mayers@soton.ac.uk), Chelsey Baker1,2, Archana Dayal1,3, Tun Jan Young2,4, Malu Avila2, Samantha Buzzard2,5
1University of Southampton, Southampton, United Kingdom, 2UK Polar Network, Cambridge, United Kingdom, 3University of Sheffield, Sheffield, United Kingdom, 4Scott Polar Research Institute, University of Cambridge, Cambridge, United Kingdom, 5University College London, London, United Kingdom

The UK Polar Network is the UK branch of APECS, one of our main aims is running education and outreach activities to excite and inspire young people about the Polar Regions. Another main aim is to run workshops and provide networking opportunities for early career researcher’s interested in Polar Science. In 2017 the UKPN ran two ECR workshops, which included a session where participants thought up innovative outreach ideas and were awarded funding to the best idea from each workshop. One idea was a soundscape called ‘Sounds of Change: Greenland Ice Sheet Melt’ to be used in classrooms and outreach activities. A clip of the soundscape will be debuted and discussed during our talk. The UKPN also works with collaborators, such as the International Polar Foundation, using Arctic and Antarctic map continental jigsaw puzzles at science festivals to engage children and the general public. The UKPN also leads the APECS Antarctic flag project in which schoolchildren design a flag for Antarctica, which is then taken to Antarctica by scientists and photographed for the students to see. During this interactive presentation showcase the innovative outreach tools used by the UKPN at a variety of recent events. We will share our experiences on what we believe are effective outreach tools for polar science. We hope to provide others with ideas, as well as begin discussions on the best way to deliver polar science outreach now, and into the future.
In recent years, several worldwide museums, especially those focusing on archaeology, have launched virtual galleries of artefacts in order to enable a detailed observation of these items through 3D technology. Precious objects can now be observed at home, at the computer, virtually turned around and zoomed without any risk or damage for the museum item. In the biological field, such 'virtual galleries' of museum vouchers are not that common and, usually, are limited to type materials and new species. In the last year the Italian National Antarctic Museum (MNA) has launched the first 'virtual gallery' of 3D models of Antarctic organisms with the aim of providing the widest accessibility to the MNA collections and of producing materials useful for educational purposes. In this way, researchers from all around the world can have a 'direct' access to these museum materials and find hints and information for outreach activities. This initial set of biological 3D models will soon be increased by the addition of 3D models of historical artefacts related to the history of exploration of Antarctica, equipment, rocks, meteorites, etc. The 3D biological models of the MNA virtual gallery produced so far are based on micro-computed tomography for smaller specimens and on photogrammetry for larger ones. Either way, these 3D models are suitable to be printed. The MNA 3D virtual gallery is now visible on Sketchfab at: https://sketchfab.com/MNA.
Methods for Training Early Career Researchers in Polar Prediction

Fiona Tummon¹ (fiona.tummon@apecs.is), Gerlis Fugmann², Alice Bradley³, Kirstin Werner⁴, Jonathan Day⁵
¹University of Tromsoe, Tromso, Norway, ²APECS Directorate/Alfred Wegner Institute, Potsdam, Germany, ³Dartmouth College, Hanover, United States, ⁴Alfred Wegener Institute, Bremerhaven, Germany, ⁵University of Reading, Reading, United Kingdom

Rapidly changing weather and climate is profoundly affecting the Arctic region, opening up new opportunities but also exposing new challenges such as environmental hazards. A growing user community thus requires enhanced predictive capacity at multiple spatial and temporal scales. The Horizon 2020 APPLICATE (Advance predictions in the Polar regions and beyond) project is bringing together a wide range of stakeholders to improve our predictive capacity for the Arctic and beyond. Knowledge transfer is a key aspect of APPLICATE and as part of it a training school is being organised in collaboration with the Association of Early Polar Career Scientists (APECS) and the Year of Polar Prediction (YOPP).

The second Polar Prediction School will take place in Abisko, northern Sweden, from 17-27 April 2018. The school will provide in-depth training on all aspects of making polar weather and climate predictions. This includes hands-on field measurements, exercises using computer models, and lectures covering topics ranging from chaotic systems to high latitude ocean processes. Each component of the course forms a crucial pillar of the prediction problem; combining these will provide participants with a complete overview of what is required to predict polar weather and climate. This presentation will describe the curriculum and learning tools developed to train early career researchers in polar prediction, focusing on active and skills-based learning through small projects and exercises.
Today’s students are eager to understand climate change, global warming and greenhouse gases. Therefore the evaluation of the following question plays an important role “Are teaching programs adequately planned for students to understand what is happening in Polar Regions?” Providing students with the perspective and skills to address these challenges often requires instructional approaches from a variety of disciplines.

Today’s early career scientists have more opportunities to develop their science communication skills with the range of tools and resources. For instance, visual tools such series of photographic, cinematographic images, clips and methodology currently being utilized to educate and inspire people around the world, in regard to Polar Regions issues. In this study, we share experiences, resources and lessons learned while teaching about climate change, also describe how students in all contexts arrive at understandings or problem-solve in response to the challenges. We aim to share new ideas and technologies that enhance Polar Regions education, advance learning and literacy.
Educational Role of Polar Researches

Deniz Vural¹ (vrl.dnz@gmail.com), Sinan Yirmibesoglu¹, Dogac B. Isiler¹, Ozgun Oktar¹, Burcu Ozsoy¹
Istanbul Technical University, Polar Research Center, Istanbul, Turkey

Climate is studied with parameters as temperature, sea, wind and humidity. Temperature differs from season to season depending on the location. Likewise; Seas warm up slowly than the land and keep the temperature longer to balance the warm and cold water currents. Wind, plays an important role for the climate, allows to flow from one place to another depending on the variant in the temperature in the world. Another catalyst in the system is the moisture which is created by the water evaporating from sea and lakes. Moisture, is proportional to the temperature of the air, is able to carry the evaporated water and air currents in the seas to the interior of the land due to its continuous motion. We can refer those components as mechanism that works harmoniously with each other.

Sustainability of Earth’s current mechanism including Polar Regions have faced with extended difficulties because of the over-growth in population and accompanying role of industrialization. As of APECS Turkey, we teach climate mechanism including Global Climate Change by visiting primary-secondary-high school students with specifically established curriculum for twenty weeks. The general aim here is to spread social awareness starting from individuals. This has been an ongoing effort since APECS Turkey was established and we have created awareness by sharing dedicated disciplines of climate and polar regions to students. Therefore, this study will share APECS Turkey experiences and activities.
Experience about Scientific Committee on Antarctic Research (SCAR) Photo Exhibit

Sinan Yirmibesoglu¹ (sinanybo@gmail.com), Deniz Vural¹, Ozgun Oktar¹, Dogac B. Isiler¹, Burcu Ozsoy¹

¹Istanbul Technical University, Polar Research Center, Istanbul, Turkey

This study provides the information about the exhibition; “Our Antarctica - Images from the Great White South” which exhibited several places in Turkey which aimed to raise awareness and inform people about scientific activities in Polar Regions. Ministry of Foreign Affairs hosted the photo exhibition, jointly with the Council of Managers of National Antarctic Programs (COMNAP), the Scientific Committee on Antarctic Research (SCAR) and Istanbul Technical University (ITU) Polar Research Center (PolReC). The exhibition included boards by PolReC illustrating Turkey’s scientific activities in Antarctica. The opening reception was held on 14 October 2016 at the Ministry’s art gallery in Ankara. National and foreign diplomats, including ambassadors, officials from Turkish government departments and academics attended the opening ceremony. Furthermore, ITU PolReC hosted the images in Istanbul. Significant number of people, from national maritime community, government departments, non-governmental maritime organizations, academicians, ITU maritime students and graduates, visited the exhibition. ITU PolReC and APECS Turkey arranged the photo exhibition to travel to several middle and high level schools in Istanbul. Exhibition took a lot of attention of young generation. This study will visualize the SCAR photo exhibition experience in Turkey. We do believe that SCAR photo exhibition reached more than a thousand citizens about of the importance of scientific activities in Antarctica.
Outreach Activities During and after Antarctic Expedition

Turkish Antarctic Expedition - I (TAE - I) was carried out by participation of nine scientists between February-April 2017 onboard the Research Vessel Australis. Authors, APECS Turkey members, were participant in the expedition used the iridium satellite system to communicate with middle school and high school students via writing on blogs for interactive education from Antarctica. After the expedition, more interactive arrangements were made about polar science to raise awareness and knowledge about Southern Ocean. Additionally, many seminars had been given to students from primary schools to universities about conducting science in Polar Regions.

Those nine scientists took nearly twenty five thousand photographs during the Antarctic expedition. After some detailed evaluation, best thirty of them were chosen. These photographs were displayed to raise knowledge about Antarctica in the public areas and museums as TAE - I Photo Exhibition. The first exhibit for the TAE - I Photo Exhibition was held during Polar Science Workshop, conducted at Istanbul Technical University in April 2017. Finally the exhibit moved with great effort to the many public and private schools, aimed as outreach activities about polar science by Turkish Student’s Polar Research Team (PolSTeam) and APECS Turkey.
If a six-year old knows all about a Tyrannosaurus Rex they can certainly make sense of Cryospheric Processes. Although, just as with the misconceptions regarding the T-Rex, science content needs to be presented appropriately with collaboration from science research experts and experienced primary educators. The issues are not localized; this need is recognized internationally. A greater quality educational opportunities are available for middle and secondary education, leaving primary educators with the task of adapting material for use with younger students, as best they can. This can result in an oversimplification, or misconception of the science. This presentation is both a call for assistance from scientists and a sharing of some effective strategies and activities that are both engaging and appropriate. Collaborations help to get it right.
There is a need for more research in the polar regions and an increased public understanding of science. Scientific funding is stretched and the public rarely has opportunities to engage with scientists. Quixote Expeditions’ Guest Scientist Program supports scientific efforts and provides passengers (non-scientists) with the opportunity to engage and participate in research. The program provides free room and board to one scientist per trip for research. The scientist is encouraged to involve the guests and give presentations. For most of the Guest Scientists this is their only way to access Antarctica, as projects not associated with national research programs are often left without necessary logistical support. Highlights for scientists are the flexibility of a small vessel, and the enthusiasm of passengers. The guests interact daily with the scientists, asking questions throughout the day and helping with small tasks: from holding an instrument to making an observation. Most guests return home as ambassadors for Antarctic and its science, often giving talks to friends and family. The presentation will discuss the Guest Scientist Program and its impact, as well as its life cycle from the application process to onboard experiences of scientists. The data collected as a part of this program has been presented in a wide range of outlets, including PhD theses and academic manuscripts, as well as aiding public policy decisions.
The IceCube Neutrino Observatory launched the citizen science project Ghost Particle Catchers in winter 2018 to engage learners of all ages in the analysis of neutrino data taken at the South Pole. This project is built on Zooniverse, the largest platform for online citizen science projects in the world, and has been developed with four high school internship cohorts with a total of 15 students (7 girls and 8 boys) from four Madison (WI) area schools.

Volunteers examine data to help improve existing IceCube analyses, such as searches for astrophysical neutrinos or for new physics in the neutrino sector. Volunteers are trained to categorize data, e.g., determine the direction and whether more than one particle path is seen. Interns studied small samples of data with both the 2D displays implemented on Zooniverse and the more complex interactive 4D displays that IceCube scientists use. The results show that their classifications have an accuracy similar to computer algorithms when they use 2D displays but can be improved after practice with interactive 4D displays.

A main goal of this project is to inform enhancements to current algorithms and search for unexpected neutrino signatures. We will present the analysis of the first data from volunteers for Ghost Particle Catchers, which will inform a future IceCube in 4D citizen science project.
The Tale of Anna Schwartz

Judit Hersko (jhersko@csusm.edu)

California State University San Marcos, Art, Media and Design, San Marcos, United States

This performance lecture is based on speculative eco-feminist autobiographical/historiographical fiction and draws on my multimedia artwork including, photo-collage, sculpture, and projections. It builds on my collaboration with scientists and my experience in Antarctica as a recipient of the NSF Antarctic Artists and Writers Grant.

It examines Polar exploration and science from the perspective of a fictitious, unknown, female explorer, Anna Schwartz, who travels to Antarctica with the 1939 Byrd Antarctic expedition. Schwartz is a photographer and a naturalist obsessed with the microscopic and transparent planktonic snail the *Limacina helicina* and its predator the *Clione antarctica*. While the character of Schwarz is fictitious, I insert her into real events, and thus, her “archives” contain factual materials from the past and present. They also include objects and images created by me in the name of my protagonist. Hence my art making process is intricately linked to the narrative that explores bi-Polar research on climate change as well as the contrasting histories of exploration at the two Poles (with the presence of native populations in the north and their absence in the south). The archives also incorporate materials pertaining to Schwartz’s daughter, who follows in her mother’s foot-steps and finds that her mother’s beloved planktonic snail, the *Limacina helicina*, functions as the canary in the coalmine when it comes to ocean acidification.
This project is a collaboration between an artist and scientists exploring commonalities such as applied methods and instruments, and visualizing the process of modeling in natural science. The goal is showing in an intuitive, tangible way how contemporary science is made to a wider public. Scientists are not only creating the most powerful actual pictures of our contemporary world, they are also shaping our awareness of the world. The starting point for this collaboration is the first Swiss Antarctic Circumnavigation Expedition ACE. By investigating snowflakes, the science project “quantifying precipitation and its contribution to surface freshening in the Southern Ocean” seeks to understand the fundamental question of how much snow falls over the Southern Ocean. Better information on precipitation is critical to the improvement of atmospheric models for the Antarctic. The ACE scientists collected Formvar replicates of falling snow on microscopic slides for quantification of precipitation characteristics and amounts. They collected similar samples for the artist on plates 24 time the size of the microscopic slides, applying the Formvar solution with an artistic tool, a paint brush. In the context of an art exhibition, the artwork questioned the non-scientific audience regarding whether the scientists were involved in the act of creating in the same way an artist would be? When collecting the flakes on larger sheets of glass, did the scientists actually compose a picture?
The soniDOME Project

Timothy Weaver1, Jody Deming2 (jdeming@uw.edu), Jennifer Biddle3, Jonathan Berger4
1University of Denver, Emergent Digital Practices, Denver, United States, 2University of Washington, School of Oceanography, Seattle, United States, 3University of Delaware, College of Earth, Ocean & Environment, Lewes, United States, 4Stanford University, Center for Computer Research in Music & Acoustics, Stanford, United States

The soniDOME project (Sonification of Deep Ocean Microbial Ecology) innovates a sensorial path of inquiry for artist-scientist collaborations related to polar and deep ocean microbial ecologies. This unique collaboration spans data development and analysis through display, interaction, open-source software toolkit distribution and public engagement. We are expanding the sensoria of existing methods of complex data interpretations from visual forms to interactive soundscapes to explore and interpret structures, interactions and dynamics of remote microbial communities. Investigative outcomes include: creation and documentation of artist-scientist collaboration from data development through translation to sonic and listening-space outcomes; development of a 'lexicon' for enlightened data modeling/simulation, display, interactions and ecoinformational narratives in a shared spatiotemporal context; fostering of collaboration among scientists, artists and students in microbiology, marine ecology, digital media and sound arts; 'reduction-to-practice' of methods and vehicles for expressing sonic representations of “master ecological narratives”, specifically datasets of polar origin; and 'case studies' for workshop production, software toolkit distributions, exhibitions, concert performances and journal articles to further consciousness to polar oceans and the deep ocean biosphere. The soniDOME project is sponsored by the National Academies Keck Futures Initiative (NAKFi).
Art for the [Ant]Arctic's Sake: A Call for Greater Artist Involvement in APECS

Alexander Eliot Thornton1 (alexander.e.thornton@gmail.com), Jean Holloway2, Hanne Nielsen3, Alice Bradley4, Gerlis Fugmann5
1University of Alaska Fairbanks, College of Fisheries & Ocean Sciences, Fairbanks, United States, 2University of Ottawa, Ottawa, Canada, 3University of Tasmania, Hobart, Australia, 4Dartmouth College, Hanover, United States, 5Association of Polar Early Career Scientists, Alfred-Wegener Institute, Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

The Association of Polar Early Career Scientists (APECS) prides itself on being at the forefront of developing innovative science communication techniques, and to continue doing so means we need to advocate for greater involvement of artists in our work. By including professionals from these creative fields, STEM education becomes STEAM (Science, Technology, Engineering, Art, & Mathematics), an acronym more reflective of the interdisciplinary nature of modern polar research. APECS recognizes that including art in educational outreach increases public engagement and makes academic research more accessible to those without extensive STEM backgrounds. With nearly 3,000 members in over 67 countries, APECS' network represents a diverse group of professionals interested in Earth's polar regions and wider cryosphere. We aim to utilize uniting features of art to bridge barriers to, for example, language or geographic proximity to increase engagement from traditionally underrepresented places and cooperation amongst future polar experts. As well, we hope to improve understanding and inclusion of Indigenous peoples through artist partnerships. We will discuss how APECS has included art in past outreach efforts—such as biannual Polar Week celebrations—and call for greater artist involvement in the future. We believe that both our members and artists can benefit from collaborations, and that we can more effectively influence positive attitudes towards polar research by working together.
Art-science in the Development of IceCube Volumetric LED Displays

Mark-David Hosale¹, James Madsen² (james.madsen@uwrf.edu)
¹York University, Toronto, Canada, ²University of Wisconsin - River Falls, Physics, River Falls, United States

Artist Mark-David Hosale (York University, Toronto, Canada), and physicist James Madsen (University of Wisconsin, River-Falls, USA) have been working regularly with each other since 2012. This presentation will describe several projects they have jointly developed that explore the visualization and sonification of data sets collected at the cubic kilometer South Pole IceCube Neutrino Observatory. The primary approach is in the construction of scale models of the observatory. The 3-D models have a one-to-one mapping to the actual ICECUBE array, where each light sensor in the array is represented by a full-color LED in the model. We have developed two versions of the display, one two meters in each dimension and the other one meter. The addition of spatial sonification (sound mapping) of the data enhances the representation of events on the models, allowing observers to audio-locate events as well as see them. Through these projects we create a high quality experience of the information being presented, with the goal of knowledge dissemination and the development of an intuitive understanding of the operation of the detector. The creation of novel interfaces of this kind represent an epistemological nexus between art and science. It has the potential to facilitate an empirical approach to sub-atomic astrophysics by using art methodologies to find optimal means for the expression of data in the domain of the human sensorium.
The Language of Ice

Tamsin Edwards¹ (tamsin.edwards@kcl.ac.uk)
²King’s College London, Department of Geography, London, United Kingdom

What do you think of when you hear the word ice? Frozen - not only cold, but unchanging and brittle. Silent, white, lifeless. But ice is far richer than this. If we listen to the language of ice, we hear whispers of its secrets. And imagining polar landscapes can give voice to inner worlds and unheard stories.

Drawing on work using images and metaphors with art therapists, themes of polar exploration with 8-11 year old artists, and other collaborations, I will use images and myths to show beauty, contradictions and surprises of ice in the natural world, and how we - as scientists, artists, and storytellers - respond to them.
Emotional Response to CryoZenGarden: Installation on Ice Melt and Sea Level Rise

Julia Dooley1 (julia.dooley@gmail.com)
2Polar Educators International, Oxford, United States

For some, an abstraction of scientific objectivity resonates more clearly. CryoZen Garden installation operates as visual metaphor, modeling cryospheric processes and exploring the resulting effects of a warmer global climate on sea levels. For this installation, the tranquility of a traditional Zen garden is disturbed. In this altered garden, blocks of ice melt continually over the course of the exhibition. The melt water drips and pours into the neatly raked lines in the sand, creating jarring interruptions. The sound of dripping water is discordant with the expected static tranquility. As ice continues to melt, ocean levels rise. Flooding is a result.

Over the course of several months, viewers of this work responded with varying comments, but few expressed indifference. Rather, questions were raised and dialogue ensued. It is through this dialogue that engagement with science concepts occurs. A favored response was, “your CryoZen Garden is freaking me out!” And that was the point.

Flights of Fact and Fancy: Birds as Messengers in Antarctic Writing

Elizabeth Lewis Williams¹ (elw0168@gmail.com)
¹University of East Anglia, Literature, Drama and Creative Writing, Norwich, United Kingdom

In *The Ancient Mariner*, a poem partly inspired by narratives of polar travel, the shooting of an albatross triggers a series of events which leads to the mariner's eventual transformation. He pays a heavy penance for his crime against Nature, freed from his suffering only when he learns to appreciate the beauty of the creatures in the world around him.

Birds are a consistent presence in writing about the Antarctic: they are trapped, shot, admired, preserved, dissected, and eaten. Cook's published journals record careful observations, of their appearance, their habits and their numbers, as well as a sense of their watching consciousness. Birds are a focus of scientific interest and of personal affection. The base record for Port Lockroy in 1954 describes the behaviour of cold and hungry sheathbills becoming "cocky" and bossing one another about after being given food; a later entry notes that a seagull with a broken leg "failed to appear for scraps".

Physical creatures of the air, birds are a natural symbol, intermediaries between the spiritual and human worlds. A study of the ways in which they are represented in Antarctic writing reveals birds, real and imagined, as messengers; more than repositories of information, they are embodiments of a particular quality of the continent as a place where the actual collides with the metaphorical, the scientific with high art, and the material with the spiritual; in fiction and in fact, birds have something to tell us.
Delimitation of the Arctic Shelf: Harmonizing UNCLOS, Customary International Law

Alexander Vylegzhanin¹ (danilalvy@mail.ru), Inna Dudykina¹
¹MGIMO, Moscow, Russian Federation

Among the Arctic Coastal States Canada, Denmark, Norway and Russia are parties to UNCLOS, while the USA is not. According to prevailing teachings, most rules of UNCLOS reflect customary International Law, but neither Part XI (about the Area - a “common heritage of mankind”) nor article 76 of UNCLOS (about delineation of the continental shelf from the Area; in contrast to article 83 of UNCLOS - which definitely reflects customary rules of International Law on delimitation of the continental shelf. The paper provides what is an indisputable title of all five Arctic Coastal States relating to their respective parts of the Arctic continental shelf - independently of the fact whether a specific State is a Party to UNCLOS or not. In such a complicated legal environment, the paper provides critical analysis of the contemporary “Shelf rivalry” created by submissions of Russia, Norway and Denmark according to art. 76 of UNCLOS - in contrast to more conservative Arctic legal policy of Canada and US aimed at securing their established rights on the Arctic Shelf as existing ipso facto and ab initio. Taking into account specific factual and legal peculiarities of the Arctic Ocean it is argued that only international customary law is applicable for delimitation of the Arctic Shelf in the High North.
The Soundscape of a Calving Glacier: Blomstrandbreen, Western Svalbard

Elias Strandell Erstorp\textsuperscript{1} (eliasse@kth.se), Peter Sigray\textsuperscript{2}, Nina Kirchner\textsuperscript{3} \\
\textsuperscript{1}KTH Royal Institute of Technology, Stockholm, Sweden, \textsuperscript{2}Swedish Defence Research Agency, Stockholm, Sweden, \textsuperscript{3}Stockholm University, Department of Physical Geography, Stockholm, Sweden

In the rapidly changing Arctic, investigation of its marine sectors, and especially the underwater domain, has become increasingly important and is of interest to benefit areas ranging from environmental monitoring to safeguarding society. A robust characterization of the soundscape of the polar marine domains is essential if autonomous underwater vehicles shall be used in these regions. A first step is to characterize the ambient sound near to a glacier and to relate sound levels to specific dynamical events. Ambient sound will not only contain information on the glacial activity but will also pose challenges for communication between autonomous underwater vehicles and underwater sensor nodes. Here, we report on first results describing the soundscape in front of the calving glacier Blomstrandbreen, Kongsfjorden, western Svalbard, based on acoustic data collected during September 8-10, 2017. This project is carried out within SMaRC, the Swedish Maritime Robotics Centre.
Acoustic Observations of Melting of Glaciers in the Arctic

Latha Ganesan¹ (latha@niot.res.in), Ashokan Muthuraj¹
¹National Institute of Ocean Technology, Ocean Acoustics, Chennai, India

Underwater acoustic observations in the ocean provide the ambient noise prevailing in the location and they are useful for variety of applications. An ocean Ambient Noise Measurement System (ANMS) consisting of a hydrophone, a data acquisition system and power pack, has been developed to withstand the environmental conditions in the polar region and incorporated with the IndArc mooring in the Kongsfjorden region, Arctic sea, which was jointly deployed by NIOT and NCAOR, India. The ANMS has been placed at 30 m depth in the mooring where the ocean depth is 192 m. ANMS was first deployed with IndArc in July 2015 and continuous data for a period of 280 days were obtained. The sampling rate was 50 kHz, for a duration of 60 seconds, in every 3 hours. Later, in July 2016, hourly samplings were made, at the rate 25 kHz for a duration 180 seconds and 240 days of time series data obtained. It is observed from the analysis that the noise in Kongsfjorden ice bay in summer is strongly associated with different types of ice melting mechanisms such as calving, bobbing and blooping. Comparison of noise spectra in the summer 2015 and 2016 reveals that the melting events are more in 2016. Detailed analysis reveals that the maximum noise is produced below 2 kHz. In winter, the peak noise is due to marine animals. The main aim is to understand the arctic acoustic environment from the continuous measurements of noise and its usefulness in climate change studies.
Climate change is altering the underwater acoustic environment of the Pacific Arctic as loss of sea ice results in higher levels of environmental, biological, and anthropogenic noise. Since 2008, a long-term recorder has been moored at the Arctic Ice Monitoring site (75.1 N, 168 W) on the Chukchi Plateau. The recorder was deployed in October annually (except for 2012-13 when ice conditions impeded mooring servicing); recording duration varied by year due to battery life. This is a location that, although within the region of rapid sea ice loss and ocean warming, is still sea ice-covered for most of the year. Indeed, other instruments at the AIM site provide detailed information on sea ice, including surface cover, movement, thickness and topographic features (floes, leads and ridges). Overall, sound sources include wind and waves during the open water and shoulder season (August through early November), Arctic marine mammals from May into September or October, some ships and airguns August through October, primarily from seafloor mapping efforts, and ice failure, and ridge building, and blowing snow during the months with heavy ice cover (usually late October through early August). Overall, sound levels at this high Arctic location are low relative to sites further south in the Pacific Arctic and compared to data from further north in the Atlantic Arctic.
The main objective of this study was to reveal the presence and to explore the temporal patterns of fin whale vocal activity in an offshore area on South-West Indian Ridge (SWIR). Data were obtained from a 10-element ocean bottom seismometer network deployed near 13°E and 52°S, at an average depth of 3500m. Recorders digitized seismic and acoustic signals at a rate of 100Hz, continuously for about 1 year, from December 2012 to November 2013. Data were analyzed by using a custom MATLAB code for the automatic detection of 20-Hz calls. About 60.300 hours of acoustic data from 8 recorders were analyzed and calls were detected in about the 75% of the recording time. The spectral features of detected 20-Hz calls were consistent with other observations reported for southern fin whale populations (1-50 Hz frequency band). Results show that the animals were present and acoustically active in the study area from February 2013 to November 2013, when they stopped singing or left the area. Moreover, a periodicity was observed in call detection rates, with greatest peaks between August and October 2013. A positive correlation was also found between peaks in call detection and Sea Surface Height values obtained from satellite data. This possibly indicates that the meandering ACC (Antarctic Circumpolar Current) fronts may influence the location and possibly formation of prey aggregations and hence act as a driver for presence and acoustic activity of fin whales in the area.
Sonification of Deep Ocean Microbial Ecology (soniDOME)

Timothy Weaver\textsuperscript{1}, Jonathan Berger\textsuperscript{2}, Jennifer Biddle\textsuperscript{3}, R. Eric Collins\textsuperscript{4}, Zachary Cooper\textsuperscript{5}, Jody Deming\textsuperscript{5} (jdeming@uw.edu)  
\textsuperscript{1}University of Denver, Emergent Digital Practices, Denver, United States, \textsuperscript{2}Stanford University, Center for Computer Research in Music & Acoustics, Stanford, United States, \textsuperscript{3}University of Delaware, College of Earth, Ocean & Environment, Lewes, United States, \textsuperscript{4}University of Alaska Fairbanks, College of Fisheries and Ocean Sciences, Fairbanks, United States, \textsuperscript{5}University of Washington, School of Oceanography, Seattle, United States

The soniDOME Project is a National Academies Keck Futures Initiative (NAKFI) sponsored art-science investigation into novel means to model and experience deep ocean microbial ecosystems, and expand the perceptive foundations of research, all through sound. Parallel to the critical understanding, perception and interpretation of the natural ocean soundscape, we are investigating the sonic display of ecoinformatic data forms to expand current versions of deep ocean information beyond visualizations to explore ecological paradigms and representations of deep ocean microbiology, beginning with deepwater formation in polar regions. Our work investigates exemplary datasets as sources and structures for sonic transcoding. As an experimental ‘reduction to practice’ for our methods, a ‘master ecological narrative’ library of software processes and sound representations is being developed for polar and deep ocean, deep biosphere and pelagic microbial ecosystem data sets. This presentation will review our application of transcoding and sonification processes to the hima meta-database of Low Temperature Genomes and Metagenomes as an exemplary dataset for sonic interpretation, one that links sequences and phenotypic data of cold-active microorganisms from all three domains of life. Specifically, we will review our investigation into the use of sonic sensoria for the interpretation of \textit{Colwellia} spp. from sea ice microbial communities, the Arctic cryosphere and the deep ocean.
This paper describes long-term passive acoustic recordings in the seasonally ice-covered ocean north of the Svalbard archipelago (eastern Arctic Ocean) from July 2016 to September 2017. Data from two mooring deployments has been analyzed for ambient noise spectra and noise statistics at frequencies from 10 Hz to 8 kHz. We present seasonal spectra and compare these with historic data from the Arctic Ocean. We discuss characteristics of the spectra and noise levels in relation to environmental forcing factors including ice cover, wind and sea state, and oceanographic conditions. Identification of components of the soundscape including transients due to marine mammals and anthropogenic noise will also be presented. The measurements were performed with AMAR Ultra Deep acoustic recorder instruments fitted to bottom-moored rigs. Technical details of the mooring design, deployment and retrieval will be discussed.
Here we present a comprehensive description of the acoustic environment approximately 31 km west-northwest of Minstrel Point, Elephant Island, Antarctica at 210 m water depth based on three years (Jan 2013 - Feb 2016) of subsampled (5 min per hour) passive acoustic recordings. Long-term spectrograms reveal a notable recurrence of acoustic environments between years. Fin and Antarctic blue whale calls dominate the low (< 100 Hz) part of the biophonic spectrum energetically from end of January to late July/early August. November through early January are dominated by leopard seal vocalizations at around 300 Hz. Concurrently, the geophonic spectrum exhibits strong fluctuations between days, both due to storm and tidal influences, causing flow and shackle noise from the instrumentation itself. Manual analysis of every second day of the subsampled data by visual and aural screening (employing short term spectrograms) was used to examine the data in greater detail for additional acoustic contributions and to assign the various acoustic signatures to their sources. Six cetacean and two pinniped species were identified based on their acoustic signatures and analysed for seasonal and diel patterns in occurrence. Anthropogenic signatures were attributed to air guns on 3 % of the analysed days. Vessel noise was noted between 10 and 12% of days on annual averages, occurring mainly in austral summer and fall with sporadic events throughout the remainder of the year.
Polar ecosystems are undergoing major changes driven by sea ice decrease, air temperature warming and increasing anthropogenic activities. The ocean acoustic environment, called the “marine soundscape,” consists of biological, abiotic and anthropogenic sounds. In polar seas, biological sound sources include marine mammals, fishes, and benthic organisms. Abiotic sound sources correspond to physical processes such as ice dynamics and meteorological events. Contributors to anthropogenic noise are classically commercial shipping and military activities.

In order to monitor how anthropogenic changes is impacting polar ecosystems, the first step is to identify, describe and quantify the features of soundscape contributors. Since 2013, underwater acoustic recorders have been deployed up to several months in several locations of the Arctic (Spitzbergen, Greenland) and the Antarctic.

In the Arctic, results show a strong variation of ambient noise levels between sites and seasons. Noise levels measured in Spitzbergen in October 2013 are up to 15 dB re1µPa higher than those measured in Mai 2013, due to an increase in wave and water flow noises. The Daneborg acoustic recordings display extreme differences in noise levels between August 2015 and August 2016 with a very quiet environment in 2015 and many ice sounds in 2016.

Antarctica soundscape is dominated by biological sound sources: benthic sounds and marine mammals vocalizations (including weddel seals, orcas and blue whales).
Since 2004 the Australian Antarctic Division has collected over 100,000 hours of underwater sound recordings in Southern Ocean off East Antarctica. The bulk of these recordings were made by mooring autonomous acoustic recorders in deep water. Continuous year-long recordings were made at sites along shipping routes during the annual resupply of Australia’s three stations in East Antarctica, and many sites have now yielded several years of data. Initial work focused on blue and fin whales, but the number of species recorded has increased over the years in step with improvements in instrumentation. Since 2013, recordings have been able to provide information on the presence and behaviour of many top predators including some toothed whales, most pinnipeds, and all Antarctic baleen whales. Here we present an overview of this rich acoustic dataset to highlight advantages and challenges of remote acoustic monitoring in the Southern Ocean. We begin with investigation of wind and ice driven ambient noise. Then we present the highly seasonal contributions of blue, fin, and minke whales and leopard seals to the soundscape. Lastly we present systematic observations of sperm whales and preliminary observations of crabeater seals and humpback whales. Continued acoustic data collection and analysis are planned by the Southern Ocean Hydrophone Network (SOHN), a joint long-term project of the IWC's Southern Ocean Research Partnership (IWC-SORP) and the Southern Ocean Observing System (SOOS).
Spatio-temporal Patterns in Antarctic Marine Mammal Community Composition

Ilse Van Opzeeland1,2 (ilse.van.opzeeland@awi.de), Helmut Hillebrand2,3
1Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Ocean Acoustics, Bremerhaven, Germany, 2Helmholtz Institute for Functional Marine Biodiversity (HIFMB) at University Oldenburg, Oldenburg, Germany, 3Institute for Chemistry and Biology of Marine Environments [ICBM], Oldenburg, Germany

Passive acoustic monitoring tools have the potential to provide insights into community structure as devices can autonomously collect data on the acoustic presence of species. Data can provide information on local species diversity, residency times and patterns in species co-occurrence. Here, we apply multiple biodiversity measures to explore how marine mammal community composition develops over time using information derived from multi-year passive acoustic data from 6 sites throughout the Atlantic sector of the Southern Ocean, the Weddell Sea. Overall species richness showed relatively little variation over time, showing that a substantial number of species remains in Antarctic waters throughout austral winter, but community composition showed almost complete seasonal overturn, recognizing that species replace each other throughout the year. For all 6 sites, community dissimilarity increased with increasing temporal distance reflecting temporal trends in community composition beyond seasonality. Species co-occurrence analyses showed that a number of species exhibited either consistently positive or negative relations, while at the recording site off the Western Antarctic Peninsula, some relations were inversed compared to the oceanic sites. Patterns in co-occurrence are suggestive of predator-prey relationships between species, inter-specific interference with respect to prey species as well as acoustic interference between co-occurring marine mammal species.
Eiji Watanabe\textsuperscript{1} (ejnabe@jamstec.go.jp)
\textsuperscript{1}Japan Agency for Marine-Earth Science and Technology, Yokosuka, Japan

Seasonal and interannual variability in biogenic particle sinking was captured by the multi-year bottom-tethered sediment trap moorings in the Northwind Abyssal Plain (Station NAP: 75°N, 162°W, 1975 m water depth) of the Arctic Chukchi Borderland. The analysis of trap samples revealed summer and early-winter flux peaks of the biogenic particle including fresh organic materials and lithogenic minerals [Watanabe et al., 2014; Onodera et al., 2015; Watanabe et al., 2015]. In this study, background mechanisms of the observed variability on a couple of timescales were investigated using a numerical modeling approach. A pan-Arctic sea ice-ocean general circulation model COCO is coupled with a lower-trophic marine ecosystem model Arctic NEMURO, which represents both sea ice algae and pelagic plankton species (e.g., diatom, flagellate, and copepod). The horizontal resolution is about 5 km so that mesoscale eddies and narrow boundary currents are resolved [Watanabe et al., 2017]. An interannual experiment from 2001 to 2014 demonstrated that the higher sinking flux of Particulate Organic Nitrogen (PON) was located along the pathways of mesoscale shelf break eddies originating in the Barrow Canyon. Ongoing works with additional trap data newly obtained north of the Barrow Canyon (Station NBC), north of the Hanna Canyon (Station NHC), and in the Chukchi Abyssal Plain (Station CAP) will also be reported.
Pan-Arctic Phylogeography and Connectivity of *Pseudocalanus* (Copepoda)

Jennifer M. Questel¹, Ole N.S. Aarbakke², Leocadio Blanco-Bercial³, Russell R. Hopcroft⁴, Fredrika Norrbin⁵, Claudia Halsband⁶, Agata Weydmann⁶, Elizavert A. Ershova², Ksenia N. Kosobokova⁷, Ann Bucklin¹
(ann.bucklin@uconn.edu)

¹University of Connecticut, Marine Sciences, Groton, United States; ²University of Tromsoe, Arctic and Marine Biology, Tromsoe, Norway; ³Bermuda Institute of Ocean Sciences, St. George’s, Bermuda; ⁴University of Alaska - Fairbanks, Institute of Marine Science, Fairbanks, United States; ⁵Akvaplan-niva AS, Tromsoe, Norway; ⁶Polish Academy of Sciences and University of Gdańsk, Institute of Oceanology, Sopot and Gdynia, Poland; ⁷P.P. Shirshov Institute of Oceanology, Moscow, Russian Federation

Phylogeographic analysis of marine zooplankton species can reveal patterns of population connectivity. Three species of the copepod genus *Pseudocalanus* exhibit widespread distributions over polar and sub-polar latitudes of the northern hemisphere. These species are frequently highly abundant, and are ecologically important as trophic links in pelagic food webs. We report findings based on phylogeographic analysis of the mitochondrial cytochrome oxidase I (COI) gene for *Pseudocalanus acuspes*, *P. minutus* and *P. newmani* from Atlantic and Pacific sectors of the Arctic Ocean. Population connectivity was evaluated using Migrate-N to estimate the magnitude of directional, asymmetrical, non-equilibrium migration rates and evaluate hypothesized migration models based on Bayesian statistics. Pan-Arctic dispersal patterns and pathways were shown to differ among the three species of *Pseudocalanus*: the N. Atlantic Current and Pacific currents are most important for *P. acuspes*; *P. minutus* shows Pan-Arctic connectivity; and *P. newmani* shows panmixia among the sampled locations. Pan-Arctic phylogeographic analysis of widely-distributed and ecologically-important species can provide new insights into how a warming Arctic with diminishing sea-ice cover may reduce barriers to gene flow and alter patterns of population connectivity for Arctic and sub-Arctic copepods and other marine zooplankton species.
Light exerts a primary control on photosynthesis. In the Arctic Ocean, this control differs from the classical open water situations because of the complex match between the very specific solar input and the seasonal variations in the icescape, including contributions of open water, bare ice, snow and melt ponds, all exhibiting large spatial and temporal variations.

Here, we question how well satellite or modelling products could be used to derive under-ice light, in a relevant manner for ecosystem studies at pan-Arctic scales. To address this problem, we combine various satellite and modelling products to describe the seasonal evolution of the icescape characteristics. Using a simple radiative transfer formulation, we retrieve daily maps of under-ice light fields, from which various estimates of the photoperiod can be retrieved. We perform a sensitivity analysis to see which sea-ice phenology transitions are the most critical in terms of photo-period.
Making and Breaking Stratification in the Kitikmeot Sea

William Williams¹ (bill.williams@dfo-mpo.gc.ca), Bodil A Bluhm², Kristina Brown¹, Eddy Carmack¹, Seth Danielson³, C.J. Mundy⁴, Lina M. Rotermund⁵, Adrian Schimnowski⁶
¹Fisheries and Ocean Canada, Institute of Ocean Sciences, Sidney, Canada, ²UiT The Arctic University of Norway, Institute for Arctic and Marine Biology, Tromso, Norway, ³University of Alaska - Fairbanks, Institute of Marine Science, Fairbanks, United States, ⁴University of Manitoba, Winnipeg, Canada, ⁵University of Victoria, Victoria, Canada, ⁶Arctic Research Foundation, Winnipeg, Canada

The Kitikmeot Sea Science Study was initiated in 2014 to provide the Canadian High Arctic Research Station a scientific basis for long-term ecological monitoring and research in the southern central Canadian Arctic Archipelago. The region is unique in the Arctic due to massive freshwater input relative to its area and its shallow bounding sills. Thus, 3 foci guide the study: the Pacific-origin estuarine inflow, which sets the oceanographic structure; the origin and pathways of freshwater, which influence the nutrient balances and stratification; and tidally influenced biological communities in narrow passages. To investigate these, we apply a suite of tools deployed from the R/V Martin Bergmann.

Our results show that the Kitikmeot Sea is characterised by two-layer estuarine flow, with surface outflows and sub-surface inflows across the bounding sills. River inputs along the southern boundary deliver freshwater, terrestrial nutrients, and carbon to the riverine-coastal domain, which then spreads throughout the system. Strong tidal currents in narrow passages enhance vertical heat and nutrient flux to maintain ice free conditions in winter and tight benthic pelagic coupling in summer. These sites have hard bottom substrate inhabited by suspension feeders, while elsewhere are soft sediments with deposit feeders. Our analysis reveals a dynamic ecosystem characterised by pelagic benthic coupling forced by the physical flow field and external inputs of nutrients and freshwater.
In November 2016, the US Bureau of Ocean Energy Management, Office of Naval Research, and National Science Foundation supported a workshop to create a unifying pan-Arctic conceptual model of the current state and future changes of the Arctic Marine Ecosystem (AME). One component of this conceptual model is a matrix of interactions that determine the functioning of the AME. This matrix was developed using a parsimonious list of Key Elements, distributed between five categories: Atmosphere, Land-Ocean/Shelf-Interior Connections, Physical Environment, Biology, and Human Impacts. To determine the strength and direction of connections between Key Elements, direct interactions were characterized in a matrix array by evaluating directionality, relative magnitude, and scientific (un)certainty. Indirect interactions were removed, because these should be captured by chains of direct interactions. As described in Part A, further work is needed to explore indirect causal pathways and the existence of multi-element feedback loops. In Part B participants can explore connections between Key Elements through an interactive platform. With this participatory presentation we hope to elicit feedback, comments, and criticisms of the interactions presented, including their magnitude and the direction of their effects now and into the future. Discussion generated during this presentation will be used to refine the matrix.
The Arctic is changing at an unprecedented pace. Sea ice plays a central role in the Arctic system, and its decline and thinning has a multitude of implications ranging from physics and biology to geopolitics and economics. To enable robust future projections, a holistic pan-Arctic approach spanning across multiple disciplines is required. Arctic in Rapid Transition (ART; www.arcticinrapidtransition.com) is an international and interdisciplinary pan-Arctic scientific network, developed and steered by early-career scientists, aimed at implementing such an approach to address present and future changes of Arctic systems. The main goals of ART are bridging time-scales by incorporating paleo-studies with modern observations and modelling, and applying various science disciplines to better understand the past and present response of the Arctic marine ecosystems to changes in sea-ice cover, thus improving our capability of predicting their future state. Initiated in 2008, ART became an official IASC network in 2013. Past ART activities included the organization of science workshops, the coordination of a special issue in Polar Research, and the publication of topical priority fact sheets for the future of Arctic research, which contributed to the ICARP III process. Focusing on active data collection, ART led the TRANSSIZ expedition onboard RV Polarstern in 2015. Along with these activities, the new 5-year Strategic Plan of ART will be presented.
The Kara, Laptev and East Siberian Seas are wide and shallow interior Arctic shelves, with ecosystems dominated by the interplay between large rivers, seasonal ice cover, complex bathymetry and strong oceanic fronts. The seasonal sea ice system features mobile pack ice and a landfast ice cover that extends hundreds of kilometers across the shelf. Polynyas frequently open along the fast ice edge in winter and spring and contribute to the region's strong sea ice formation and export to the Transpolar Drift. Hydrography and ecosystem processes are dominated by freshwater runoff from the Lena, Ob and Yenisey, some of the largest rivers on earth. The distribution of the river plumes is variable and depends on the atmospheric circulation in summer. The river water controls water column stratification and therefore vertical mixing processes as well as biogeochemical conditions on the shelf. Summer expeditions in 2013 and 2014 provided comprehensive information from two years with contrasting winds and are now used to highlight the physical and biogeochemical linkages based on shipboard sampling and year-round oceanographic moorings. These recent observations combined with earlier campaigns to this under-explored part of the Arctic Ocean provide the base for the conceptual understanding of the Laptev Sea, representative of the interior Siberian shelves. In this presentation we link the important components of the ocean, sea ice and ecosystem, and discuss them in a pan-Arctic context.
Epibenthic Feeding of *Chrysaora melanaster* Jellyfish in the Arctic

Maciej Mańko¹ (mmanko@ug.edu.pl), Jennifer Purcell², Andrew Juhl³, Craig Aumack⁴

¹Institut of Oceanography, Department of Marine Plankton Research, Gdynia, Poland, ²Western Washington University, Biology Department, Bellingham, United States, ³Lamont-Doherty Earth Observatory Columbia University, Palisades, United States, ⁴Georgia Southern University, Statesboro, United States

Ecological and economic impacts of gelatinous zooplankton are increasingly apparent in the pelagic realm, but few studies have explored the idea that jellyfish can be of similar importance for benthic communities. Jellyfish exert a strong predatory pressure on invertebrates in the water column, controlling the population size of zooplankton, including pelagic larvae of zoobenthos. Unfortunately, no research so far has directly examined the idea that jellyfish may prey upon benthic fauna.

Video recordings made from 2011 to 2014 beneath land-fast sea ice in the Chukchi Sea near Utqiaġvik (Barrow, Alaska) demonstrate that large overwintering *Chrysaora melanaster* medusae often drag tentacles along the seabed, apparently feeding on zoobenthos as implied by the observation of an isopod entangled in the tentacles. We also review the existing, circumstantial evidence on benthic feeding by jellyfish and, with our own observations we propose that epibenthic feeding may be a common, but periodic trait of gelatinous predators, even in areas as remote as the Arctic.
Pelagic larval stages of benthic animals (meroplankton) can play a seasonally significant role in planktonic communities, as well as influence the abundance and distribution of benthic species, yet are frequently overlooked by both plankton and benthic studies. Within the Arctic, the role of meroplanktonic larvae may be particularly important in regions of inflow from the Atlantic and Pacific Oceans, where they can serve as vectors of advection of sub-Arctic species into the Arctic. In this study, we describe the links between the distribution of meroplankton on two important inflow shelves: the Bering/Chukchi Seas and the Barents Sea, using molecular tools to resolve larval taxonomic diversity, and the benthic macrofaunal and epifaunal communities in the region, based on original and published data from the past decade. We observed limited correlation between observed larval and adult benthos at similar locations, particularly for infaunal organisms, suggesting that most larvae are advected from other areas rather than produced locally. Seasonality and distribution of water masses were the most important parameters shaping meroplankton communities. We discuss differences between the two sectors and the implications of changing oceanographic and climatic conditions on the potential of range extensions by temperate species into the Arctic Ocean.
A conceptual model is a representation of a system, made of the composition of concepts which are used to help people know, understand or simulate a subject the model represents. Here and before switching to Antarctica, I focus upon the central Arctic Ocean which is not isolated, but advection of water, nutrients and biomass: it is tightly connect to the hitherto ice-covered, lest known World Ocean and a gateway to/from the northern Pacific and Atlantic Oceans. The Arctic Ocean is thus an integral part of the oceans of the Northern Hemisphere and cannot be understood in isolation. The concept of the advective contiguous domain illustrates to which degree and how the integration of the Arctic Ocean is effectuated. Four advective contiguous domain are distinguished: The Atlantic, the Pacific, the Barents Sea and the Transpolar Drift domain. These lengthy contiguous domains connect subarctic with the arctic biota, supporting both primary production and higher trophic level consumers. In turn, the Arctic influences the physical, chemical and biological oceanography of adjacent subarctic waters through southward fluxes. In contrast to the central Arctic Ocean characterized by mainly perpendicular advective contiguous domains, strongly circular and isolating contiguous domains characterize Antarctica and the high latitude Southern Ocean.
How to Establish a Legitimate Claim to Territory in the Antarctic

Cara Nine¹ (cara.nine@gmail.com)
¹University College Cork, Philosophy, Cork, Ireland

Despite the fact that the Antarctic Treaty has ‘frozen’ claims to territory, countries continue to perform actions intended to establish future claims in Antarctica. They hope to build the basis for a claim to territory, when such claims become politically feasible.

This paper aims to outline the moral basis for a claim to territory. That is, this is a moral strategy for legitimacy, not a legal or political strategy. The moral strategy is commonsensical and rooted in the values at the foundation of contemporary international law. As such, it should carry significant weight in the thinking of international actors.

This paper draws on recent work done in political philosophy that characterizes morally legitimate claims to territory. Legitimate claims:
- are established by a verified political authority (i.e., not rogue governments or military dictators);
- contribute measurable value to the region and resources;
- do not take more than their fair share (defined broadly) of the Earth’s natural resources; and
- make a claim to an area to which the group has a thick historical ‘attachment’.

The paper argues that the final, attachment, condition is the least applicable in the context of Antarctica, especially given that the continent has never been home to a permanent population. It may be possible, though, to build the basis for future territorial claims through political, juridical, scientific and economic institutional investment that adds measurable value to the region.
The Annex VI to the Protocol on Environmental Protection to the Antarctic Treaty “on Liability Arising from Environmental Emergencies” was adopted by the Antarctic Treaty Consultative Meeting (ATCM) in 2005 after 14 years of negotiations. It will enter into force once has been approved by the 28 Consultative Parties that had rights to participate in that meeting. Up to now (October 2017), only 15 Consultative Parties have approved it. The reasons why the approval process has been so slow are of course multiples, including the diverse domestic rules to approve an international agreement. But there are also some legal and political factors that were discussed in the negotiation and that are present in the text approved which can explain why States haven’t shown a more enthusiastic attitude. The adopted text was unsatisfactory to several Parties. As well it has some elements that will do very complex its implementation if the Annex finally entry into force. It isn’t clear that can be possible to reach an effective and better environmental protection with the Annex VI as we know it today. The presentation will review negotiation process of Annex VI, the finally adopted text, its approbation process and its domestic implementation by some States that have approved it. Some conclusions are presented and different alternatives to advance to a more effective regime of liability for Antarctic environment damage are discussed.
The expansion of international society brought to Antarctica its primary institutions, although they have not been incorporated in similar terms. Sovereignty primary institution was suspended by the Antarctic Treaty in 1959, establishing a particular governance framework to the region. As a regional international society is formed when a region's institutions are absent at the global level, or when this region presents different interpretations for global level institutions, this work aims to understand Antarctica as a regional international society. Antarctic practices have been normalised despite the lack of a definition of its sovereignty and challenges have always emerged when the remaining international primary institutions (territoriality, diplomacy, balance of power, equality of peoples, nationalism and trade) demand addressment, producing different normative arrangements. Therefore, this work examines how resource management and environmental protection issues created particular norm localisation for primary institutions in the region. Resource management resulted in side agreements such as the 1964 Agreed Measures for the Conservation of Antarctic Fauna and Flora, the CCAS, the CCAMLR and the attempted CRAMRA. Likewise, the establishment of the Environment Protocol resulted from the environmental stewardship primary institution's growth, consolidating environmental preservation (along with peace maintenance and scientific cooperation) as Antarctica's own institutions.
The establishment of Marine Protected Areas is one of the key issues discussed at the annual meetings of the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR). CCAMLR members decided by consensus to establish a Marine Protected Area (MPA) on the South Orkney Islands (2009) and the other in the Ross Sea (2016). Other MPA proposals still remain under discussions, such as a MPA around the Western Antarctic Peninsula proposed by Argentina and Chile. In this context, this conference paper examines the politics of MPAs at CCAMLR and the role of Argentina and Chile within this context.

This conference paper analyzes the transformations in the politics of Antarctica and discussions around MPAs at CCAMLR. It also addresses Argentina and Chile as original signatories of the Antarctic Treaty by analyzing the main guidelines of their Antarctic diplomacy and domestic policy on MPAs as well.

The research results suggest that the politics of MPAs in antarctic waters at CCAMLR happens in a context of antarctic environmental changes, a rising demand for natural resources and asymmetrical relations between states members of the ATS. In order to understand the role of Argentina and Chile within this framework, it is necessary to consider the importance of historical territorial claims in Antarctica, the role of science as a tool for diplomacy and also MPAs policies in the domestic domain.
The Protocol on Environmental Protection to the Antarctic Treaty (PEPAT) sets forth the environmental principles governing activities in Antarctic. It expresses the conviction of the signatories regarding the protection of the Antarctic, designating the white continent as a natural reserve, devoted to peace and science (Art.2). More strikingly, PEPAT expresses the commitment to protect “the intrinsic value of Antarctica, including its wilderness and aesthetic values” (Art.3). These resolutions are to work as key elements in the planning and conduct of all activities in the Antarctic Treaty area (Art.3). Interestingly, there is no mention in PEPAT of one of the most remarkable elements of the Antarctic Treaty, namely, the freezing of State sovereignty on the Antarctic territory (AT Art.4). In a post-Westphalian world, this omission is problematic: comprehensive protection of the environment and its value requires reflecting on the question of state sovereignty claims over a territory. Although issues about the environment and its value are not central elements in most theories of territory, in this presentation I sketch an account of territory that both takes seriously PEPAT’s idea on the intrinsic value of the Antarctic and incorporates environmental sustainability considerations as key aspects of legitimate territorial claims. The proposal, I argue, is a normative account of territory that is more adequate to face the environmental challenges in Antarctica motivating PEPAT.
As global extinction rates have accelerated, international regimes, such as the Convention for the Conservation of Antarctic Marine Living Resources (CCAMLR), have proposed a variety of responses, including establishing networks of marine protected areas (MPAs). To address threats posed to Antarctic marine ecosystems by fisheries and climate change, CCAMLR endorsed efforts to establish a representative network of MPAs. In 2012, the United States and New Zealand proposed the Ross Sea Region MPA (RSRMPA) and following several years of negotiations it was agreed to by CCAMLR signatories in 2016. This research effort applied the collaborative governance framework, which stresses engaging state and non-state actors in building consensus to manage public resources, to identify the influential factors that contributed to this agreement and understand how it might be replicated in the future. More than forty interviews, ranging from twenty-five to ninety minutes, were conducted during and following CCAMLR’s 36th meeting with delegation heads, chief scientists, committee chairs, Secretariat leadership, and observer delegates to provide a representative sample of key actors. Thematic coding of interviews using QSR Nvivo revealed the key drivers of consensus, which will be presented along with recommendations on how to incorporate the lessons learned from the RSRMPA negotiations into ongoing efforts to develop a network of Southern Ocean MPAs.
Even though the current and increasing natural resources dwindling might put pressure on the ATS, it seems that the core principles enshrined in it, such as Article IV of the Antarctic Treaty establishing the agreement to disagree on sovereignty, as well as Article II of the Madrid Protocol, designating Antarctica “as a natural reserve, devoted to peace and science”, are strongly rooted enough to prevent any future litigation’s arousal on land.

At sea though, and especially under the sea, the legal regime remains highly uncertain, and the expected forthcoming pressure calls for its acute determination.

Indeed, with the recent evolution of the law of the sea and the fast development of new maritime areas, stagnant legal issues call for further certainties on austral seabed’s legal regime.

Are Southern Ocean seabed’s resources to be exploited in the future? Shall it be protected? Which State(s) or international entity should be in charge of doing so?

This communication proposes to focus on the issue of Antarctica seabed’s legal regime, especially emphasizing on the articulation between two distinct regimes: seafloor’s global legal regime, set up in the UNCLOS, as well as the specific one supposed to govern the seabed in the southern area according to the ATS.

A particular attention will first be brought on the general adequacy of those regimes, before moving to its apparent contradictions.

Finally, different proposals to avoid those contradictions will be evoked.
The Region of Antarctica is biologically distinct from other regions. And, the increasing introduction of non-native species to the Antarctic Region is presenting a serious risk to biodiversity and environment of the Antarctica. Introduction of non-native species may arise from two different ways; native Antarctic species are moved by human activities between biogeographic regions, or non-native species established in one Antarctic biogeographic region and then are distributed to other regions by human or natural mechanisms.

At the 39th Antarctic Treaty Consultative Meeting (ATCM) Resolution 4 (2016) was introduced. The Annex of the Resolution introduces the “Non-native Species Manual”. The Manual aims to establish key guiding principles for minimising the risks associated with the introduction of non-native species. International Maritime Organization’s (IMO) newly entered into force “International Convention for the Control and Management of Ships’ Ballast Water and Sediments, 2004” deals with non-native species as well. Taking into other international law instruments, it is to say that, there is a multi-level protection of Antarctica against to non-native species. This paper aims to analyse the multi-level protection of Antarctic Region from a critical viewpoint, tries to extract gaps and overlaps among different international legal documents. Accordingly, the paper aims to provide recommendations for better coordinated and synchronized legal regime for the Antarctic.
Establishing Indigenous TTP in Evenkia, Russia

Nikita Kaplin¹ (kaplinik@bk.ru)
¹Union of Indigenous Communities of the Evenkia Municipal District, Krasnoyask, Russian Federation

According to the Federal Law No. 49, Government of the Krasnoyarsk region had recently adopted the order on establishment of the traditional land use areas (TTP) of the indigenous peoples of the North. The Agency for Northern Development and Support of the Indigenous Minorities is designated an authorized executive for this action. The formation of such territories is to be carried out by decision of the regional government on the recommendation of the relevant Commission which is to consider the appeals of indigenous persons, communities or their authorized representatives. For the TTP decision process, it is necessary to take into account the prospects for socio-economic and investment development of the region, including possible negative effects from the imposed environmental protection and other restrictions on the use of aboriginal lands. The TTP establishment should not compromise or violate the rights and freedoms of other ethnic communities inhabiting these lands. This is a very important step in protecting the ancestral habitat of the indigenous minorities of the North in Evenkia district. Regional government took into account the proposals of neighboring provinces where TTP have already been formed: Irkutsk, Khakassia, Sakha (Yakutia), Khanty-Mansi (Yugra). But at the same time many legal obstacles on the way for protecting traditional land use areas are still existent and the perspectives for their operational management are to be revealed and analyzed.
State Intervention in Whaling: A Case of Whaling in the Faroe Islands and Taiji

Nazuna Nakao¹ (nnazuna@outlook.com)
¹Doshisha, Global Studies, Kyoto, Japan

Disputes about whaling have been polarized into for or against, and ignored to form a platform for diversified agenda such as politics, international relationships, environment, and animal welfare. In particular, subjects concerning indigenous knowledge of whaling and ethics based on rules shared among local people were less focused. I wish to discuss coastal whaling not from for or against point of view. My research fields are the Faroe Islands and Taiji town of Japan. In the past decades, traditional whaling in the two regions have been affected by anti-whaling movements and the controversies have changed them. In Taiji, they inevitably have made changes such as their method and regulations of killing, and reinforce security control. The Japanese government have taken some measures for protecting whaling in Taiji, however, its aim is in another issue, to protect the vested rights of government sponsored whaling. Another changes could be observed is local people’s awareness of whaling. As the town exposed worldwide criticism some people have started questioning by themselves reasons of continuing whaling. In contrast, people in the Faroe Islands have not been tossed about by the changes compared to Taiji. From examining these findings, I have concluded that the state intervention greatly changes whaling and it may also affect people’s way of thinking. I wish to show the difference of the changes in the regions and hope I could make a few contributions toward this subject.
Since October 2013, Greenlandic politicians have their own legislation regulating the exploitation of their soil’s natural resources. Following this parlementarian vote, several companies and private industrials have shown their interest for the mineral resources of Greenland, leading to the construction of the first Greenlandic uranium and rare earths mine in Kvanefjeld (South Greenland).

In response, an anti-uranium movement began to actively criticize the Environmental and Social Impact Assessment procedure, thus being at odds with Greenlandic politics and private companies. Hence, the mine of Kvanefjeld has become a social debate articulated at different levels between farmers, anti-uranium activists, the government of Greenland, and with the international private sector.

Through a multi-located ethnography - political spheres, anti-uranium movement, farming communities adjoining the mine - and understanding the criticisms towards the Assessment procedure, this contribution aims to articulate the farmers’ knowledge of the land and their will to be part of the implementation plan with the socio-economic necessities that motivate each stakeholder.

The study of this case is a tool to deepen the discussion about the place and role of Indigenous Knowledge and include them meaningfully by taking the socio-economic perspectives into account; in order to produce Indigenous Governance Model locally constructed connecting Indigenous People and Foreigners.
Future Challenges for Arctic Indigenous Peoples

Anna Deteva¹ (anna.deteva@gmail.com)
¹Arctic Council IPS, Tromsø, Norway

Multiple drivers of environmental and social change can be identified across the Arctic and more change is expected. Infrastructure development is currently the most significant driver of change in land use. Climate change is an increasing threat to traditional livelihoods. Impacts on indigenous peoples are exacerbated by their lack of voice in the development of adaptation tools and strategies for future planning and development. Arctic Indigenous Peoples cooperate in the Arctic Council in Unique way through the Indigenous Peoples Secretariat in Arctic Council for more than 20 years. Building competence locally is important to be able to adapt to these changes.
Clan communes (KROs) offer a mechanism by which families and groups of indigenous persons can request an allocation land on which to pursue their traditional activities (e.g. reindeer herding, hunting). KROs have been formed since the early 1990s. A federal law governing their creation passed in 2000. Local laws in various regions of the Russian North often preceded this: for instance, in the Sakha Republic (Yakutia), a law on KROs passed in 1992. Over the past 25 years, a variety of legislative revisions have affected KROs. KROs are best protected when situated inside a “Territories of Traditional Nature Management” (territoriiya traditsionnogo prirodopol’zovaniya or TTP). TTPs, governed by a 2001 law, provide protection of lands for traditional use, including some capacity to exclude industrial activities that might negatively affect traditional activities. Our paper will present the application of a cartographic-geoinformation method for studying the TTPs in the Republic of Sakha (Yakutia) under the situation of intensive industrial development. This method allows the identification of changes in the organization of TTPs as they are related to changes in the boundaries of the KRO, and thus the withdrawal of land from economic circulation, in areas of potential conflict between industrial and 'traditional' users Completed maps can be used as an documents to protect and defend the TTPs, and thus the KROs situated within them, in case where legislation is changed.
Vessels play a pivotal role in science and science support for the national Antarctic programs operating in the Antarctic Treaty Area. In fact, vessels not only deliver people and supplies to coastal infrastructures but also, while sailing, conduct an array of multi-disciplinary scientific projects thanks to their on-board facilities and personnel. The Council of Manager of National Antarctic Programs (COMNAP) developed two tools to display and share vessels position data for national Antarctic program vessels operating in waters below 60°S (as per ATCM XXXVI Resolution 4 (2013)). These tools help to foster international scientific projects through, and with, the support of national Antarctic programs and are also useful in times of emergency. The poster showcases examples of successful international collaborations on board of vessels operated by COMNAP Members, and hopes to create new opportunities for future multi-disciplinary and “big science” international projects. The sharing of capabilities on vessels amongst the international scientific community is another good example of international co-operation in Antarctica.
Information Exchange: How COMNAP Productises Data for Members & the Community

Andrea Colombo1 (sec@comnap.aq), Brad Herried2, Michelle Rogan-Finnemore1
1COMNAP Secretariat, Christchurch, New Zealand, 2Polar Geospatial Center, Minnesota, United States

The Council of Managers of National Antarctic Programs (COMNAP) often requests information from its Member national Antarctic programs. Once collected, the information is housed in the COMNAP database and is used and exchanged in a range of COMNAP products. Those products support the work of COMNAP Member national Antarctic programs in regards to international co-operation in science, science support, operations, logistics, and in Search and Rescue (SAR) situations to name only a few examples. COMNAP has produced procedures for such information exchange and there are also information exchange requirements which are an obligation on Antarctic Treaty Parties in Articles III and VII (5) of the Antarctic Treaty, in several articles of the Protocol on Environmental Protection to the Antarctic Treaty and in a number of Recommendations, Measures, and Resolutions as adopted by the Parties. This poster gives an overview of the projects and products served by the COMNAP database and how these can inform and advance exchange of information with Members, the wider Polar community and the general public. The COMNAP database was developed as a source of information primarily for use by Member national Antarctic programs and the COMNAP Secretariat. However, advances in technology coupled with good planning in development mean that information exchange into duplicate fields in separate databases is now possible.
Antarctic Facilities: Hubs for Science and Environmental Protection

Andrea Colombo¹ (sec@comnap.aq), Michelle Rogan-Finnemore¹
¹COMNAP Secretariat, Christchurch, New Zealand

This poster showcases a portion of the facilities-related data in the Council of Managers of National Antarctic Programs (COMNAP) database. Ninety-seven facilities (stations, camps, laboratories, refuges, depots, and airfield camps) are run and personned by the COMNAP Members in the Antarctic Treaty Area (2017-18 season data). A great array of facilities-related data, from main scientific disciplines supported, to hydroponics facilities, through medical capabilities and climate-related data, are available for the Members through the COMNAP database. The non-sensitive data, are also available to the Antarctic Treaty System organisations and to the general public.

In light of the COMNAP Antarctic Roadmap Challenges (ARC) project outcomes, sharing information on facilities and capabilities are seen as a tool which can directly support the key goal of improving international co-operation in Antarctica. The poster introduces some of the facilities-related data in the COMNAP database showcasing scientific activities, measures in place to reduce direct impact on the environment and waste management practices. The final aim is to stimulate the exchange of knowledge, scientific personnel and best practices furthering international co-operation.
China’s potential contributions to SOOS and MOSAiC

Dake Chen (dchen@ldeo.columbia.edu)
Second Institute of Oceanography, State Oceanic Administration, China

The Southern Ocean Observing System (SOOS), and the Multidisciplinary drifting Observatory for the Study of Arctic Climate (MOSAiC), are two of the major ongoing international initiatives for polar research. SOOS was officially launched at the end of 2011, and since then it has built a network of stakeholders and contributors, all working together to achieve its well-defined mission and objectives. Currently SOOS is implemented based on its regional working groups and there is a clear need for a broad-scale circumpolar design. On the other hand, MOSAiC is a more focused, short-term experiment presently at its final planning stage. It will have a three-tiered observational strategy, including a central observatory, a distributed network and a large-scale connection, as well as a comprehensive modeling hierarchy. This calls for a strong international collaboration to provide scientific, technic and logistic supports.

Here we first briefly review the scientific goals of SOOS and MOSAiC from a global perspective, and then discuss the potential roles of China in these two international initiatives, in accordance with our national polar research programs supported by various agencies. In particular, starting with a description of our existing capabilities in both Antarctic and Arctic research; we outline our plans for future enhancement in technology and infrastructure, as well as our suggestions on the implementation of SOOS and MOSAiC. The take-home messages include:

1. China is now in the process of largely enhancing its polar research activities, which certainly will lead to significant contributions to SOOS and MOSAiC;
2. For SOOS, we propose a multi-platform, multi-disciplinary circumpolar “Big Ring” design to serve as its sustained “backbone”;
3. For MOSAiC, we will participate in all three tiers of its field observations as well as modeling efforts, aside from providing logistic support.
Keynote Lecture II
Frozen in time - Unlocking the Earth’s climate history using ice cores

Elizabeth Thomas (lith@bas.ac.uk)
British Antarctic Survey, UK

Ice cores have proved to be a powerful tool for reconstructing past climate. These “two-mile time machines” have driven our understanding of global climate variability, tracing the transitions from glacial to interglacial over the past 800,000 years. And yet the secrets in the ice are still being unlocked. In this presentation I will outline recent advances in ice core research, touching on the development of exciting new climate proxies and demonstrating the power of international collaboration in producing continental reconstructions with unprecedented spatial coverage. I will focus on climate variability over human timescales, decades to centuries, in Antarctica; a continent experiencing dramatic climate change in recent decades but one with the shortest historical observations and arguably the largest potential to drive future climate through its contribution to global sea levels. I will summarise findings from two recent community based reconstructions, of past surface temperature and snow accumulation, capturing the drivers of Antarctic climate variability and its influence on global sea levels during the 20th century.
Despite the importance of Atlantic Water (AW) to Arctic halocline formation and sea ice distribution, the dynamics and seasonality of the AW inflow and redistribution north of Svalbard are not well documented. Here we use a high resolution (800 x 800 meter) eddy-resolving sea ice and ocean model to characterize the boundary current, with particular focus on eddy formation. The flow regime in the Yermak Plateau (YP) region is variable, with flow over the YP alternating between a faster, narrower northern current and a slower, more diffuse current. Downstream of the Yermak Plateau, the current follows the shelf break. Directly north of Svalbard the current is most unstable between October-March, similar to previous findings from Fram Strait. Further East, the current is most unstable several months later. The boundary current sheds AW eddies along most of the length of continental slope considered, from the western YP to 40°E, though eddies forming east of 20°E are likely more important for slope-to-basin transport. Eddy formation seasonality reflects current instability in the eastern portion of the study domain, but on and immediately east of the YP eddy formation is out of phase with current instability, with formation rates highest during summer. Most of the AW eddies are anticyclonic, with radii close to the local deformation radius, and are centered in the halocline. They transport roughly 0.1 Sv of AW and, due to their warm cores, nearly 1.0 TW away from the AW current.
Circumpolar Deep Water Variability in High Resolution Coupled Climate Models

Hannah Zanowski¹ (zanowski@uw.edu), Frazer Christie², Kyle Armour¹, Cecilia Bitz¹, Eric Steig¹
¹University of Washington, Seattle, United States, ²University of Edinburgh, Edinburgh, United Kingdom

Observations have shown that West Antarctic ice shelf basal melt is strongly related to warm Circumpolar Deep Water (CDW) impinging on the continental shelf in this region. This critical discovery has led to multiple, high-resolution regional modelling studies aimed at identifying the underlying mechanisms that lead to CDW intrusions on the West Antarctic continental shelf and their subsequent circulation in ice shelf cavities. However, many of these models do not include a coupled atmosphere, potentially missing relevant ice-ocean-atmosphere interactions that impact CDW variability in the West Antarctic. Here we characterize West Antarctic CDW variability in two coupled climate models with 0.1° oceans and identify the mechanisms that control this variability on interannual to decadal timescales. Consistent with observations, we find that temperature variability on the West Antarctic continental shelf is related to wind stress curl along the shelf break in the models. In addition to wind stress curl, we explore a range of local and large-scale atmospheric and oceanic processes, such as ENSO, that could contribute to CDW variability, and quantify the relative importance of each in controlling shelf water temperature variability.
Circum-Antarctic Eddy/Tidal Overturning and Shoreward Heat Transport

Andrew Stewart¹ (astewart@atmos.ucla.edu), Andreas Klocker²,³,⁴, Dimitris Menemenlis⁵

¹University of California Los Angeles, Atmospheric and Oceanic Sciences, Los Angeles, United States, ²University of Tasmania, Institute for Marine and Antarctic Studies, Hobart, Australia, ³University of Tasmania, Australian Research Council Centre of Excellence for Climate System Science, Hobart, Australia, ⁴University of Tasmania, Antarctic Climate and Ecosystems Cooperative Research Centre, Hobart, Australia, ⁵Jet Propulsion Laboratory, California Institute of Technology, Science Division, Pasadena, United States

The passage of warm Circumpolar Deep Water onto the Antarctic continental shelf is dynamically obstructed by the continental slope to varying degrees around the Antarctic margins. Previous studies indicate that high-frequency processes, such as tides and mesoscale eddies, are required to overcome this dynamical barrier and supply heat to the Antarctic coast. In this study we use a very high-resolution (1/48 degree) ocean/sea ice simulation to quantify the relative roles of mean flows, eddies and tides in transporting heat across the entire Antarctic continental slope and shelf. We find that eddies transfer heat across the continental slope, but tides make the largest contribution to the shoreward heat flux across the shelf break. However, the tidal heat flux is almost entirely compensated by an opposing offshore heat transport by mean flows. Consequently, the shoreward eddy heat fluxes coincides closely with the net shoreward heat transport across the shelf break. Approximate overturning circulations for the mean, eddy and tidal components of the cross-slope transport also show strong compensation between mean flows and tides at the shelf break, with negligible eddy-driven overturning. Taken together, these results suggest that eddy stirring of heat anomalies along isopycnals or along the ocean bed is the primary mechanism of heat transfer across most of the Antarctic continental shelf/slope.
Observations in the Arctic are often sparse in space and time. Mesoscale and sub-mesoscale processes are poorly captured by typical hydrographic sampling from large icebreakers, which is often the only way to provide access to the challenging ice-covered regions. In 2014 and 2015, the US Office of Naval Research funded a pair of programs designed to capture important processes in the changing Arctic Ocean and promote the use of autonomous technology and intense ship sampling. In particular, Seagliders surveys conducted as part of the Marginal Ice Zone Program in 2014, and ship-based underway CTD sampling in the SeaState Program in 2015 provide repeated sampling of important regions in the Beaufort Sea high spatial and temporal resolutions, capturing several eddies and upper ocean fronts. Eddies appear particularly important near the ice edge and near the shelf breaks. In this presentation, we synthesize observations from these intensive programs and describe the dynamics of mesoscale and sub-mesoscale processes in the Arctic, as well as the characteristics of dominant water masses (Pacific and Atlantic Waters) over the basin.
Small-scale processes and their effects get more and more attention when it comes to understanding processes and changes in the (Arctic) ocean. Here we present a study on physical processes and ecological responses at a submesoscale front in Fram Strait at the interface between the Arctic Ocean and waters of lower latitude origin investigated using an autonomous underwater vehicle (AUV). The AUV is equipped with several physical and biogeochemical sensors.

High-resolution observations from the upper 50m of the water column, show extremely large physical and biogeochemical gradients associated with the frontal system. Extraordinarily high chlorophyll $a$ values between 20m and 40m water depth were observed to be associated with polar surface water, which may recently have been raised above the compensation depth resulting in the subsurface bloom. A mooring in the vicinity showed that the chlorophyll $a$ patch was present for a few days. Additional observations conducted from a Zodiac in parallel to the AUV survey show that the observed patch had an along-front extent of more than 400m. This indicates, that the observed feature was a dynamically active front, possibly experiencing wind-driven frontogenesis or the growth of mixed layer eddies.

The study was conducted in Fram Strait but the results are most likely transferable to other, dynamically comparable frontal systems in the marginal ice zone that experience large horizontal density gradients, e.g. in the Southern Ocean.
During the last three decades, AABW has exhibited a striking warming and contraction in volume over much of the global ocean abyss, particularly in the South Atlantic. The causes of these changes are unknown. In the Atlantic sector, observations suggest that climatic variations in the basin-scale properties of AABW downstream of its sources in the Weddell Sea are primarily controlled by wind-forced changes in export, via a mechanism involving the modulation of small-scale turbulent mixing in the Orkney Passage. To test this hypothesis, the U.K. DynOPO (Dynamics of the Orkney Passage Outflow) programme set out to measure the circulation of AABW in the Passage, and to assess the dynamical controls underpinning the water mass transformation in the region. With this goal in mind, a finescale-resolving mooring array was recently deployed in the Passage for 2 years (2015 - 2017), and a research cruise was conducted to measure the turbulent properties of the AABW outflow with fine- and microstructure instrumentation and the autonomous underwater vehicle Autosub Long Range. Here, we will present results from the project. These indicate that: (1) the AABW outflow experiences concurrent broadening, deceleration, and intense mixing as it navigates the Passage; (2) these changes are underpinned by a distinct mechanism involving downslope Ekman flows and submesoscale dynamical instabilities. The implications of these findings for our starting hypothesis will be discussed.
Not Just Penguins: Increasing Public Understanding of Antarctic Ecosystems

Claire Christian¹ (claire.christian@asoc.org), Amanda Lynnes², Lisa Kelley²

¹Antarctic and Southern Ocean Coalition, Washington, DC, United States, ²International Association of Antarctica Tour Operators, Newport, United States

People love pictures of cute penguins and seals, but often know little else about Antarctic marine ecosystems. Most Antarctic organizations and programs recognize these gaps but have limited resources to do large public education campaigns. Partnerships between organizations are therefore a logical choice to enhance capacity and reach a wider audience. In this presentation, we will analyse the outcomes of a successful joint social media campaign between the Antarctic and Southern Ocean Coalition (ASOC), an environmental organization, and the International Association of Antarctica Tour Operators (IAATO) to promote knowledge of lesser-known species. We developed a series of tweets and Facebook posts containing facts about Antarctic invertebrates, with accompanying videos, photos and graphics.

We will share our analysis of the campaign’s success as measured by audience engagement with posts and tweets, as well as lessons learned. A key conclusion is that a multi-day, fact-based series of posts and images seems to be more popular on Twitter than on Facebook. The overall increased engagement demonstrates that social media campaigns are therefore an effective way to reach out to followers who are already interested in Antarctica (as well as gain new ones) and can be used to increase public understanding about Antarctic issues. Partnership was also effective as it expanded the content available to both organizations, and helped distribute the workload.
Building a Scientific Culture on Antarctica through a Discussion Forum

Silvia Dotta\textsuperscript{1,2,3} (silviadotta@gmail.com), Eduardo Rodrigues da Silva\textsuperscript{1}
\textsuperscript{1}Federal University of ABC, Mathematics, Computation and Cognicion Centre, Santo André, Brazil, \textsuperscript{2}Polar Educators International, Santo André, Brazil, \textsuperscript{3}ApECS - Brazil, Santo André, Brazil

This paper aims to analyze the contribution of a discussion forum for the process of building a scientific culture on Antarctica.

The concept of scientific culture is broader than that of scientific literacy since it incorporates a social component of analysis and interpretation into the appropriation of the knowledge process. Communication and pedagogical strategies that seek scientific literacy, more focused on appreciation, lead to the incorporation of scientific knowledge as much to the social imaginary of the individual as to the surrounding society.

Recognizing science as "interesting, stimulating and entertaining" is more realistic than equating the knowledge of non-specialists with that of scientists.

A discussion forum was conducted at a distance-learning training course for primary school teachers to whom were asked to discuss conceptual errors about Antarctica. It proposed the debate on where the lung of the world is: The Amazon or Antarctica. Participants were encouraged to defend predetermined ideas, based on scientifically consolidated arguments. 114 students and 6 tutors attended. Over three weeks, 577 messages were exchanged. Most of participants (76\%) returned to interact with colleagues and tutors.

A forum is a tool that can contribute to incite interest in the research and dialectical construction of knowledge. Dialogue around the ways of problem solution has helped to encourage the popularization of socio-constructed scientific knowledge about Antarctica.
Using Media to Drive Conservation in the Ross Sea: Protecting the Last Ocean

John Weller¹ (johnwellerphotography@gmail.com), Cassandra Brooks²
¹Pew Marine Fellow & Safina Center Fellow, Boulder, United States, ²University of Colorado Boulder, Environmental Studies, Boulder, United States

During this session, John B. Weller, an internationally acclaimed photographer, filmmaker and author, invites you to journey above and below the ice in Antarctica. In 2004, Weller and Antarctic ecologist David Ainley founded The Last Ocean Project - the first dedicated campaign for a marine protected area of the Ross Sea, Antarctica. They later co-founded The Last Ocean Charitable Trust with New Zealand filmmaker Peter Young and also brought on Antarctic scientist Cassandra Brooks. Weller’s photographs of the Ross Sea became the face of Antarctic conservation efforts worldwide. He will explain how his efforts to protect the Ross Sea, Antarctica inspired a global coalition of organizations, scientists, diplomats and more than a million people, and helped entrain world leaders from the White House to the Kremlin. Twelve years of work came to fruition in October 2016 in a stone fortress in the center of Hobart, Tasmania, where diplomats from 24 countries and the EU adopted the Ross Sea Marine Protected Area - one of the most profound international environmental agreements of our times. It is the first large-scale international marine protected area and the largest MPA in the world. Focusing on lessons learned and the creative applications of media to emerging conservation opportunities, this session will examine ways in which media can help drive marine conservation.
Social Media Outreach Coordinated across a Multinational Polar Research Project

MAGIC-DML is an ongoing Swedish-US-Norwegian-German-UK collaboration focused on improving ice sheet models by filling critical data gaps in our knowledge of the timing and pattern of ice surface changes in Dronning Maud Land (DML), Antarctica. Outreach and science communication through social media is a priority in this international collaboration, and involves students, scientists, and communication staff at the partner universities and the Swedish Polar Research Secretariat (SPRS). One main focus of our outreach has been an online presence with an SPRS component focused in particular on research expeditions, and coordinated with the project website, blog, and social media elements (Facebook, Twitter, Instagram). Scientists and staff at the partner universities and SPRS coordinate with the overall social media, and repost/tweet to enhance impact. We will share both the challenges and achievements of coordinating social media across multiple organizations and countries with different levels of communications expertise and resources, and with target audiences that include the general public, teachers/students, and colleagues/peers. Quantitative and qualitative analyses of the social media component of our outreach program will also be presented, including special events (competitions), types of material posted, timing of posts, coordinated ‘shares’, and interactive elements.
An IceCube Interactive and Immersive Exhibit for Learners of All Ages

Silvia Bravo Gallart¹, Andrew Chase², Phil Dougherty³, David Gagnon³, James Madsen⁴ (james.madsen@uwrf.edu), Kevin Ponto², Melanie Rush², Ross Tredinnick²

¹University of Wisconsin - Madison, Wisconsin Icecube Particle Astrophysics Center, Madison, United States, ²University of Wisconsin - Madison, Wisconsin Institute for Discovery, Madison, United States, ³University of Wisconsin - Madison, Madison, United States, ⁴University of Wisconsin - River Falls, River Falls, United States

Research shows that virtual and interactive environments can boost learning outcomes for learners of all ages. These technologies can also increase engagement of underrepresented communities, since these environments are not usually associated with performance stereotypes and academic language proficiency.

The IceCube Neutrino Observatory in Antarctica has partnered with technology and education researchers to develop a virtual reality exhibit that connects users to the polar observatory, which is leading a new field in astronomy. IceCube detects small particles called neutrinos that can help us explore the universe in ways that cannot be done with light.

This novel exhibit combines a multitouch table and commercially available virtual reality (VR) head-mounted displays to facilitate learning of polar research. The exhibit, launched in November 2017, is studying how immersive VR can enhance informal STEM learning.

We will discuss the challenges and opportunities of working with an interdisciplinary team as well as assessment results. They seek to evaluate how technology can improve engagement of all learners, and to determine which technologies are better suited to enhance STEM learning. Contributing to the understanding of these questions is the goal of this NSF-funded project, which in the future plans to port this exhibit to more affordable platforms-such as tablets and google cardboards-, as well as integrate Antarctic research from other disciplines.

The @OceanseaiceNPI Initiative: Polar Science Communication using Social Media

Amelie Meyer1, Alexey Pavlov1, Anja Rösel1 (anja.rosel@npolar.no), Polona Itkin1, Jean Negrel1, Lana Cohen1, Jennifer King1, Sebastian Gerland1, Stephen Hudson1, Laura de Steur1, Paul A. Dodd1, Nick Cobbing2, Mats A. Granskog1

1Norwegian Polar Institute, Tromsø, Norway, 2National Geographic Magazine, Washington, United States

Successful science communication is essential but also challenging with time constrains, limited financial resources and a lack of incentives in the academic environment. Many social media platforms have recently emerged, providing free and simple science communication tools to reach the general public, journalists, fellow scientists, and younger generations in particular. While individual researchers and large institutions are present on social media, smaller research groups are under-represented.

@oceanseaicenpi is a science communication initiative led by a small group of polar oceanographers, sea ice, and atmospheric scientists at the Norwegian Polar Institute in Norway. Here we present our experience establishing, developing, and maintaining this successful Arctic science communication initiative on Instagram, Twitter, and Facebook. The initiative is run entirely by the team of 25 researchers with limited time and financial resources. Over 4 years, it has built a broad audience of more than 7000 followers. The initiative has boosted the alternative metric scores of our publications and helped researchers in the group to become better writers and communicators. We hope to inspire other research groups by sharing our experience on how to develop and conduct effective science communication using social media!
Marginal Ice Zone Processes Observed from Unmanned Aircraft Systems

Christopher J Zappa\(^1\) (zappa@ldeo.columbia.edu), Scott Brown\(^1\), Tejandra Dhakal\(^2\), Carson Witte\(^1\), Ajit Subramaniam\(^3\)

\(^1\)Lamont-Doherty Earth Observatory of Columbia University, Ocean and Climate Physics, Palisades, United States, \(^2\)Lamont-Doherty Earth Observatory of Columbia University, Marine Geology and Geophysics, Palisades, United States, \(^3\)Lamont-Doherty Earth Observatory of Columbia University, Marine Biology, Palisades, United States

Unmanned Aircraft Systems (UAS) are ideal to study sub-pixel satellite variability as well as providing “eyeballs over the horizon” information for both ship- and land-based field studies. For the past 5 years, we have developed and flown a number of payloads to study under-observed sea ice regions aboard long-range (5- to 20-hour endurance) UAS including most recently fixed-wing UAS with vertical take-off and landing capability. We have demonstrated the capability from both land and ships during a number of experiments in Alaska (Beaufort and Chukchi Seas) and Svalbard, Norway. We have developed and deployed payloads that include:

1) Down-looking hyperspectral visible imaging spectrometer to determine ocean color and biogeochemical mapping;
2) Upward- and downward-looking pyranometers (solar) and pyrgeometers (longwave) to measure full hemispheric irradiance to quantify the surface energy budget and map sea ice, ice floe, and ocean solar albedo;
3) High-resolution visible and infrared imaging is used to discern sea ice extent and coverage, whitecapping and other upper ocean processes as well as SST skin and ice temperature;
4) air-sea-ice turbulent fluxes as well as wave height, ice freeboard, and surface roughness with a LIDAR; and
5) drone-deployed micro-drifters (DD\(\mu\)D) deployed from the UAS that telemeter both atmosphere and upper ocean data. Measurements from UAS offer a unique opportunity to observe physical processes at sea-ice margins and will be explored here.
Additional activity in Arctic waters requires reliable environmental & domain awareness information critical for ecosystem, resource, community & emergency management & economic sectors including transportation, fisheries, tourism, & energy & mineral industries. Ice hazards that originate in the Arctic threaten maritime shipping in mid-latitudes further expanding the domain of Arctic impact on safe maritime operations. To address these issues, an international study team identified observational needs & developed mission objectives using UAS. The range, altitude (~20 km), & endurance (~26 hr) of High Altitude Long Endurance (HALE) UASs like the Global Hawk. This capability can fill critical gaps for Arctic Domain Awareness observations required for sea ice forecasting, transportation safety, oil spill detection & response, & extreme weather watches & warnings. Demonstrating HALE technology & communication innovations in the Arctic are needed for the growing number of requirements & stakeholders operating at high latitudes. The study team prioritized & developed flights that demonstrate Global Hawk’s observational capability for providing: a) enhanced environmental knowledge; b) maritime awareness & responsiveness; & c) insight into weather extremes in the Arctic. We present the concept of a month-long campaign, GLOBAL ARCHER (ARCtic High altitude Environmental Research), to demonstrate how Global Hawk can advance our capabilities & responses in a rapidly evolving Arctic.
As part of the Polarstern cruise ANT-XXIX, the Meteorological Mini Aerial Vehicle (M²AV) was operated in the Antarctic Weddell-Sea during winter 2013. It was the first time that unmanned aerial system (UAS) were used on board Polarstern and the authors have gained high expertise in performance of UAS influenced by harsh polar environment (cold temperature, high wind speeds, potential of icing) since then. The aircraft’s nose is equipped with fast meteorological sensors in order to investigate turbulence in the lowermost 1000 m. The main aim of the study was to analyse the effect of open water in sea ice that causes an internal boundary layer due to the high temperature difference of around 30 K between sea ice surface and open water in the small horizontal extent of several metres. Taken from studies in modelling, the small-scale effect influences the Earth’s climate. However, the knowledge of the extent is poor and leads to a high uncertainty in weather and climate predictions. Therefore, horizontal flights were operated with M²AV perpendicular to open sea ice with a flight distance of at least 4 km in low heights of 15-150 m. Fluctuations of 3D-wind vector and potential temperature were significantly affected by one crack of around 500 m wide and showed updraft up to the height of 100 m, however downdraft above and near the inversion layer. The crack led to pronounced fluxes of sensible heat and turbulent kinetic energy, in contrast to measurements above closed sea ice.
RPAS Based Observations on the Arctic ABL over Sea Ice in the Baltic Sea

Stephan Kral\textsuperscript{1}, Joachim Reuder\textsuperscript{1}, Line Båserud\textsuperscript{1}, Gabin Urbancic\textsuperscript{2}, Marius Jonassen\textsuperscript{1}, Alexander Rautenberg\textsuperscript{4} (alexander.rautenberg@uni-tuebingen.de), Jens Bange\textsuperscript{4}, Marie Hundhausen\textsuperscript{6}, Philipp Hilsheimer\textsuperscript{5}, Burkhard Wrenger\textsuperscript{5}, Carsten Langohr\textsuperscript{5}, Hendrik Voss\textsuperscript{5}, Martin Müller\textsuperscript{4}, Christian Lindenberg\textsuperscript{6}, Timo Vihma\textsuperscript{7}, Irene Suomi\textsuperscript{7}, Ewan O’Connor\textsuperscript{7}, Rostislav Kouznetsov\textsuperscript{7}

\textsuperscript{1}University of Bergen & Bjerknes Centre, Geophysical Institute, Bergen, Norway, \textsuperscript{2}University of Bergen, Geophysical Institute, Bergen, Norway, \textsuperscript{3}University Centre in Svalbard, Longyearbyen, Norway, \textsuperscript{4}University of Tuebingen, Tuebingen, Germany, \textsuperscript{5}Ostwestfalen-Lippe University of Applied Sciences, Detmold, Germany, \textsuperscript{6}Lindenberg und Mueller GmbH & Co. KG, Hohenhameln, Germany, \textsuperscript{7}Finnish Meteorological Institute, Helsinki, Finland

The purpose of the research project ISOBAR (Innovative Strategies for Observations in the Arctic Atmospheric Boundary Layer) is to increase our understanding of the Atmospheric Boundary Layer (ABL) in the Arctic. In February 2017 we carried out a measurement campaign on the Finnish island Hailuoto in the northern Baltic Sea. During the three-week long field period, we studied processes within the ABL over the sea-ice of the Bothnian Bay, based on observations from several different Remotely-Piloted Aircraft Systems (RPAS) as well as ground based flux and automatic weather stations and remote sensing systems (Doppler Lidar and Sodar). Turbulence measurements from different altitudes were obtained by two different fixed-wing aircraft systems (MASC and miniTalon). A small fixed-wing system (SUMO) was used for atmospheric profiles from about 30 to 1800 m. In addition, different multicopter systems were applied to take profiles from the ground to an altitude of up to 400 m. In total more than 150 scientific flights were conducted during the three weeks with five intensive observational periods. Together with the ground based and remote sensing data this results in an extensive high-resolution data set of observations on the stable ABL which will be used for detailed investigations of the processes within the stable ABL. We further aim to take these processes into account in new ABL parameterization schemes for numerical models.
Sandia National Laboratories (SNL) has operated a tethered balloon system (TBS) at the Advanced Mobile Facility 3 (AMF3) in Oliktok Point, Alaska, since 2015 on behalf of the U.S. Department of Energy’s (DOE) Atmospheric Radiation Measurement (ARM) Climate Research Facility. The TBS was flown as part of ICARUS (Inaugural Campaigns for ARM Research using Unmanned Systems) and AALCO (Aerial Assessment of Liquid in Clouds at Oliktok).

The TBS offers advantages for Arctic observations. Our TBS has operated for over nine continuous hours, within clouds, and at altitudes up to 1.45 km above ground (AGL). Varied instruments have been deployed simultaneously on the TBS, including Distributed Temperature Sensing (DTS) systems, printed optical particle spectrometers, a condensation particle counter, and supercooled liquid water content sensors (SLWCs). Measurements from these sensors, and their comparison with sUAS, radiosonde, and ground-based measurements are discussed. Additionally, technical aspects of DTS measurements, including the use of a fiber optic rotary joint, and comparisons of results from two DTS systems, are shown. Varied deployments of the TBS and DTS are touched on, including recent efforts to measure ocean temperature profiles as conducted on a research vessel deployed offshore of Oliktok Point, and DTS measurements collected by an sUAS.
Manned Aircraft vs. UAS Surveys for Arctic Cetacean Density and Distribution

Megan Ferguson¹ (megan.ferguson@noaa.gov), Robyn Angliss¹
¹NOAA Alaska Fisheries Science Center, Marine Mammal Laboratory, Seattle, United States

Manned aerial surveys are routinely used to assess cetacean distribution and density, often over large geographic areas. Unmanned aircraft systems (UAS) have been identified as a technology that could augment or replace manned aerial surveys for cetaceans. To understand what research questions involving cetacean distribution and density can be addressed using manned and UAS technology in the Arctic, we conducted a three-way comparison near Utqiagvik, Alaska, among visual observations made by marine mammal observers aboard an aircraft; imagery autonomously collected by a Nikon D810 camera system mounted to a belly port on the manned aircraft; and imagery collected by a similar camera system on a remotely-controlled ScanEagle UAS. Each survey platform conducted five flights within a 16,800 km² study area. The manned aircraft collected 23,580 images in 17.9 flight hours, during which marine mammal observers simultaneously collected sighting data. The UAS collected 20,568 images in 21.8 flight hours. Various technologies and operational procedures contributed to the ability to conduct routine, successful and safe beyond line-of-sight UAS flights. Comparisons of density estimates, associated estimates of uncertainty, data processing time, and cost can be the basis for design of future large-scale UAS projects.
The very high albedo of snow means that changes in its coverage have a significant impact on the Earth's global energy budget. Thus, Northern Hemisphere snow cover, which comprises approximately 98% of the global total area of seasonal snow, is responsible for the largest annual and interannual differences in land surface albedo. Here we examine recent changes in snow cover in the Khibiny Mountains on the Kola Peninsula in Arctic Russia, a region that has undergone significant climate change in recent decades. Future changes in snow cover have the potential to have a major socio-economic impact in this region, which is primarily dependent on mining and skiing for its economy. We used a combination of remote sensing data, meteorological observations and field data in our analysis. Field measurements of snow parameters were employed to validate the MODIS (Moderate Resolution Imaging Spectroradiometer) fractional snow cover and albedo products. First and last days of snow cover were derived for each year and compared to snow depth observations from three field stations in the Khibiny Mountains and three additional meteorological stations in the region to look for systematic biases in the satellite data. These 'locally calibrated' MODIS data were then used to determine the trends and variability in the duration of the snow season across the Khibiny Mountains from 2000 to 2016.
Are Accumulation Regimes of Central Asian Glaciers Changing?

Marlene Kronenberg¹ (marlene.kronenberg@unifr.ch), Horst Machguth¹,², Silas Walter¹, Margit Schwikowski³,⁴, Martin Hoelzle¹
¹University of Fribourg, Department of Geosciences, Fribourg, Switzerland, ²University of Zurich, Department of Geography, Zurich, Switzerland, ³Paul Scherrer Institute, Villigen, Switzerland, ⁴University of Bern, Department for Chemistry and Biochemistry, Bern, Switzerland

Various studies have shown that glacier mass loss in certain areas of Central Asia is low compared to the global average. The reasons for glaciers in these regions being relatively close to equilibrium, however, remain unresolved. A possible explanation is increased accumulation due to changes in atmospheric circulation. For the regions concerned, however, precipitation data are sparse. This lack of data could be mitigated by using in-situ measurements of glacier accumulation rates.

Here, we focus on the firn cover of Abramov glacier located in the Pamir Alay, southern Kyrgyzstan. Abramov glacier is the only glacier with a very rich set of historical scientific data located close to the areas of near-equilibrium mass balance. We use snow pits, firn cores and GPR measurements to derive present-day accumulation characteristics including annual accumulation rates and snow distribution. Furthermore, we compile past accumulation rates from the exceptionally detailed glacier mass balance measurements from the 1960s to the 1990s as well as from ice cores reaching down to the early 1920s. The accumulation rates and snow distribution patterns from the different periods are used to quantify temporal changes of the firn cover of Abramov glacier. First results suggest that annual accumulation rates may have increased during the last years.
Using Weather Radar Data to Estimate the Winter Mass Balance on Swiss Glaciers

Rebecca Gugerli1 (rebecca.gugerli@unifr.ch), Matthias Huss1,2, Nadine Salzmann1
1University of Fribourg, Fribourg, Switzerland, 2ETH Zurich/VAW, Zuerich, Switzerland

Precipitation estimates in high-mountain regions are essential for environmental studies in many research fields (glaciology, meteorology, hydrology, etc.). Although precipitation data exist for the Swiss Alps, accuracy is limited by data sparsity and measurement challenges in high-mountain regions. In glaciology, we propose a novel approach to estimate the snow water equivalent (SWE) on glaciers and to spatially integrate these measurements by combining continuous observations of SWE, conventional glaciological surveys and operational measurements of solid precipitation.

We investigate the application of weather radar data compiled by MeteoSwiss to estimate the amount and the spatial distribution of solid precipitation on glaciers in winter. To validate the time evolution of snowfall, we use a cosmic ray sensor (CRS) which directly measures the SWE of the snowpack. The CRS has shown a satisfying agreement with manual measurements (snow pits) taken over two winter seasons on the Glacier de la Plaine Morte in Switzerland. To expand the validation over several Swiss glaciers, we use end-of-winter glaciological surveys (snow pits, snow probings) provided by the Swiss monitoring network (GLAMOS). The advantage of the weather radar data is its spatial footprint with which we gain further insights on the snow distribution on glaciers, especially at high altitudes. Hence, we can show the usefulness of readily available weather radar data for the application in cryospheric studies.
Quantifying Sublimation and Melt from Snow in the Semi-arid Andes

Shelley MacDonell¹ (shelley.macdonell@ceaza.cl), Marion Réveillet¹, Simon Gascoin², Christophe Kinnard³, Nicole Schaffer¹, Arno Hammann¹
¹Centro de Estudios Avanzados en Zonas Aridas (CEAZA), La Serena, Chile, ²Centre d'Etudes Spatiales de la Biosphère (CESBIO), Université de Toulouse, Toulouse, France, ³Université du Québec à Trois-Rivières, Trois-Rivières, Canada

Water is a critical resource in semiarid Chile, as the area supports more than 55% of the country’s population, and the regional economy depends on agricultural production and mining, which are two industries that rely heavily on a consistent water supply. Despite the importance of snow cover for water resources in this region, there is currently a limited understanding of snow depth distribution and mass balance. Analysing relative ablation rates are critical for understanding snow depth sensitivity to variations in climate and simulating the evolution of the snow pack over a larger area and over time. This study aims to quantify melt and sublimation rates over a catchment during two contrasting years to determine the impact of El Niño and La Niña climatic modes on snow distribution and ablation. In this study, we model the snow cover evolution using a distributed snowpack model (SnowModel) in the instrumented watershed of La Laguna (3150-5630 m above sea level, 30°S), during 2014 and 2015. The model is calibrated and forced with meteorological data from seven Automatic Weather Stations (AWS) located in the watershed, and modeled WRF results. Temporal evolution of the simulated snow depth is validated using the snow depth measured at each AWS. The snow duration and snow cover extent are compared to MODIS and selected Sentinel-2 images. Results highlight the importance of accurately accounting for the precipitation forcing and the sensitivity to the chosen roughness length.
Monitoring the Evolution of the Surface Snow on the East Antarctic Plateau

Ghislain Picard1 (ghislain.picard@univ-grenoble-alpes.fr), Laurent Arnaud1, Eric Lefebvre1, Quentin Libois2
1Institut des Géosciences de l’Environnement, Saint Martin d’Hères, France, 2Centre National de Recherches Météorologiques, Toulouse, France

The Antarctic Ice Sheet has a highly dynamical surface playing an active role in the exchanges of energy and mass between the atmosphere and the firn. The evolution of the surface geometry and snow properties are mainly driven by the local atmospheric conditions which in turn impacts the radiative and turbulent exchanges. This coupling results in feedback loops that can amplify or weaken the Antarctic response to global changes. Understanding the surface evolution is a major issue to address the prominent questions of the fate of Antarctic climate and ice sheet, the continental warming and the contribution to sea-level rise.

For nearly 10 years, we have been studying the surface and the upper snowpack at Dome C and on the East Antarctic Plateau. To this end, we have deployed automatic instruments, conducted intensive measurements during summer campaigns, organized long-term data collection in winter and participated to scientific traverses. The accumulated information concerns snow properties (SSA, density, temperature), surface properties (pictures, roughness) and snow accumulation. We found that the evolution of some variables (SSA or snow temperature) conforms to state-of-the-art model simulations while others (surface roughness or density) remain hard to explain using existing tools. This presentation will give an overview of the available observations, show the successful modeling simulations and discuss future developments needed to model Antarctic specificities.
Modelling the Impact of Drifting Snow on the Surface Mass Balance of Adelie Land

Christoph Kittel\(^1\) (ckittel@ulg.ac.be), Charles Amory\(^1\), Cécile Agosta\(^{1,2}\), Hubert Gallée\(^1\), Xavier Fettweis\(^1\)

\(^1\)Laboratoire de Climatologie, ULiège, Liège, Belgium, \(^2\)LSCE (UMR 8212 CEA-CNRS-UVSQ/IPSL), Université Paris Saclay, Paris, France, \(^3\)Université Grenoble-Alpes, Institute of Geosciences and Environment, Grenoble, France

The transport of snow by the wind is an important component of the Antarctic surface mass balance (SMB) as drifting snow counts up for a large amount of snow ablation over the ice sheet. However, this process is frequently neglected in atmospheric models. Two simulations (one with drifting snow and one without) were performed at a resolution of 8 km with the regional climate model MAR forced by ERA-Interim, in order to assess the impact of drifting snow on the SMB of Adelie Land (East Antarctica) during the period 2002 - 2016. We evaluated results against field observations (including meteorological and snow skate measurements). Besides to better represent climate surface as airborne snow particles can sublimate and interact with the lowest atmospheric levels, the drifting snow simulation improves the modelled spatial distribution of the SMB and reduces the overestimation of the accumulation in comparison with MAR results without drifting snow.
Navigating the New Arctic: Trajectories of Change

Amanda Lynch¹ (amanda_lynch@brown.edu), Michael Goldstein²
¹Brown University, Institute at Brown for Environment and Society, Providence, United States, ²Babson College, Finance Division, Babson Park, United States

Because of Arctic amplification, the Arctic has been labeled the 'canary in the coal mine' or 'the frontline' of climate change. Rapid changes in temperature, ice and snow cover, and ecosystem distributions are leading to serious impacts on Arctic peoples. At the same time, these changes are inciting a "race for the North", with a range of industries showing increased interest the region. Low global oil prices, along with technological, geopolitical and security challenges, may render Arctic fossil fuel and mineral reserves economically nonviable for the foreseeable future, but industries such as freight, tourism and commercial fishing may benefit. Because of the high variability and concomitant low predictability of many components of the Arctic system in the near term, economic benefits have not accrued at the expected rate. Development trajectories remain highly contested. Safety and reliability concerns are ongoing. This confluence of opportunity and risk raises critical questions as to how well we understand the changing Arctic system on policy-relevant time scales. These questions will be explored through the lens of Arctic navigability.
Politics of Postcoloniality and Sustainability in the Arctic

Ulrik Pram Gad¹ (gad@cgs.aau.dk), Marc Jacobsen²
¹Aalborg University, Aalborg, Denmark, ²University of Copenhagen, Political Science, Copenhagen K., Denmark

In the Arctic as elsewhere, there is no overall agreement on what exactly ´sustainability´ or ´sustainable development´ refer to. However, received discourses of the Arctic as a special place, characterized by a nature at once hostile and fragile, has empowered a distinct constellation of actors in the Arctic. For NGOs, indigenous peoples´ organizations, states, and companies ´sustainability´ implies different sets of opportunities and precautions. The paper reports the findings of a collaborative research project mapping sustainability narratives in the Arctic and analyzing the political consequences of sustainability becoming pivotal for politics in the region. Analysing sustainability as a concept that re-orders the relationship between society (identity), development (time), and nature (space) we find that: First, presenting one´s venture as contributing to sustainability has indeed become a precondition for participation in the negotiation of Arctic development and governance. Second, when sustainability meets the Arctic it changes meaning from a universal concern with a global ecosphere to a particular concern with a series of more limited environments (natural, cultural, societal, economic). Third, in practical governance and pragmatic discourse, cultural and societal sustainabilities often crowd out environmental sustainabilities. Fourth, sustainability is undergoing a transformation of meaning from being a concept that limits development to one that allows development to take place in the Arctic. Fifth, the variety of postcolonial configurations is central for understanding both the overall dynamics of the politics of sustainability and the variation across the Arctic.

Keywords: Sustainability, Postcoloniality, Political Theory, Arctic
Ground-scale Socioecological Interactions and Arctic Environmental Governance

Nadia French1 (nadinfrench@gmail.com)
1University of Birmingham, Geography, Earth and Environmental Sciences, Birmingham, United Kingdom

The changing landscape and economic relevance of the Arctic present a unique opportunity to monitor the change in interactions between people and the arctic nature as well as to shed light onto the funnelling of the existing at different scales environmental governance regimes to the local level and vice versa.

The work done within this framework attempted to understand and map ground-scale interactions between human and non-human actants (individual and community-based behaviour that can impact the environment especially if multiplied) in a case study conducted in Mys Kamenny, Yamal district, Russia, in 2017. Yamal is a region of rapid socioeconomic development undergoing noticeable climatic and geomorphological shifts.

Individual and community level relationship with the environment especially of non-indigenous descent is often overlooked in assessments of environmental integrity, yet, it holds clues to the feedback loops between climate change, development and society.

The study found that using multiple tools to measure landscape change (e.g. GIS, interviews, fieldwork) relative to social and economic dynamics, individual behaviour and environmental regulation and enforcement can help better understand not only local but also generic ecological issues of the present day Arctic and draw insights from a close-up view to the environmental governance on a larger scale.
In my presentation, I argue that it is the resilience of the Antarctic Treaty legal system nurtured and strengthened by the very members of its system over the past six decades that would effectively control within its manageable confines any future “manifestation of territorial pressures”, “international power plays”, and the potential reviews after 2048 of the operation of the Madrid Protocol, which prohibits mineral resource activities in the Antarctica.

After recapitulating the systemic resilience of the Antarctic Treaty System, which consists of an intricate balance between a few fundamental principles of unchanging nature and its flexibilities in adapting to the changing political and environmental landscape surrounding the Antarctic (Shibata 2015), I will re-examine the legal, political and environmental contexts within which the 1988 Convention on the Regulation of Antarctic Mineral Resource Activities (CRAMRA) was negotiated, agreed, and, because of the two claimant states’ sudden change of policies, buried in oblivion. The external and internal accommodation the consultative parties at the time (1980s) endeavoured to achieve (and failed?) can serve as an interesting reference case when we consider the potential challenges the Antarctic Treaty System may face into the mid-21st century arising out of Antarctic resources.

Human Activity in the Ross Sea Region: A Temporal and Spatial Analysis

Fraser Morgan¹ (morganf@landcareresearch.co.nz), Thomas Robertson¹, Pierre Roudier², Daniela Liggett³, Neil Gilbert⁴

¹Landcare Research, Auckland, New Zealand, ²Landcare Research, Palmerston North, New Zealand, ³University of Canterbury, Gateway Antarctica, Christchurch, New Zealand, ⁴Constantia Consulting Ltd, Christchurch, New Zealand

With increasing human activity in Antarctica and the associated environmental pressures (such as non-native species incursions or protected area planning), there is a need to understand the scale of historic and current human activity on the continent.

Collating and harmonising data from various sources, we have developed a database of human activity within the Ross Sea region for the last 15 years. Data sources used to create the database account for tourism, science, and national operator activities within the region. This paper will utilise spatial analysis to explore how scientists, tourists, and base staff in Antarctica interact with the landscape. The paper will also highlight the various sources and methods used to access human activity data in the region.

We expect the database to enable the visualisation of the current and historic scale of human activity across the ice-free areas of the Ross Sea region and to assist in the management of the associated environmental pressures.
In the Footsteps of Visitors to the Ross Sea: Tracing Antarctic Tourism Patterns

Daniela Liggett¹ (daniela.liggett@canterbury.ac.nz), Neil Gilbert², Fraser Morgan³
¹University of Canterbury, Gateway Antarctica, Christchurch, New Zealand, ²Constantia Consulting Ltd, Christchurch, New Zealand, ³Landcare Research, Auckland, New Zealand

The last two decades have seen a rapid increase in Antarctic tourism numbers and a proliferation of Antarctic tourism research. Most of the growth in visitor numbers has occurred in the Antarctic Peninsula, which receives over 95% of all Antarctic tourists, and consequently much of the scholarly literature on Antarctic tourism focuses its attention to the particularities of tourism in this region. It is less well known that the Ross Sea region has been visited semi-regularly by commercial tour operators since the mid-1960s and annually since 1990. Tourism in the Ross Sea is concentrated on a dozen sites, out of just over 50 different visitor sites, and generally involves expedition cruising. While anecdotal accounts of tourism operations in the Ross Sea have shed some light on tourist experiences in this part of the world, no systematic analysis has been undertaken of tourism patterns in the Ross Sea over time.

In this paper, we present the results of a comprehensive study of tourism activities in the Ross Sea region and, using GIS-based analysis, discuss the changing footprint of Antarctic tourism in the Ross Sea over the last 50 years. This study forms one component of two larger integrated research programmes that aim at understanding the interconnected natural processes and human impacts that (re-)shape ecosystems in the Ross Sea in order to inform environmental management.
East Antarctic Ice Sheet Dynamics Inland of Shackleton and West Ice Shelves

Duanne White¹ (duanne.white@canberra.edu.au), Marcello Blaxell¹, Steven Phipps², Tobias Staal³, Alexandru Codilean³, David Fink⁴, Matt Jeromson¹, David Small⁵, Pippa Whitehouse⁵, Mike Bentley⁵, Matt King⁶

¹University of Canberra, Institute for Applied Ecology, Canberra, Australia, ²University of Tasmania / Institute for Marine and Antarctic Studies, Hobart, Australia, ³University of Wollongong, Wollongong, Australia, ⁴Australian Nuclear Science and Technology Organisation, Sydney, Australia, ⁵Durham University, Durham, United Kingdom, ⁶University of Tasmania, Hobart, Australia

Geological constraints of former ice extent are very limited in the interior of East Antarctica, particularly in areas near deep subglacial basins. Not surprisingly, the absence of empirical constraints mean these areas also contain some of the most divergent models of both modern Glacio-Isostatic Adjustment (GIA), and projections of future ice loss from the continent. To improve this situation, we have collected records of past ice sheet geometries along flowlines from inland to coast in the poorly explored regions inland of the Shackleton and West Ice Shelves. Here, isolated nunataks in the middle of subglacial basins, and mountain ranges flanking outlet glaciers draining deep basins provide a rare opportunity to improve our understanding of the influence of subglacial basins on past ice dynamics.

In this presentation we will detail results from field observations collected since 2015/16 and an initial tranche of ¹⁰Be exposure ages from inland outcrops in this area. Preliminary results suggest limited change in elevation during the LGM along the upper Denman Glacier, along with a substantive recent (potentially late Holocene) retreat close to the modern grounding line. We will discuss the significance of former ice sheet surface elevations in the context of existing models of GIA, present day ice loss, and the role of sub-glacial topography ice dynamics from a significant outlet of the Aurora Subglacial basin.
New Records of Holocene Glacial Fluctuations from Victoria Land, Antarctica

Ross Whitmore¹ (ross.whitmore@vuw.ac.nz), Andrew Mackintosh¹, Kevin Norton¹, Cliff Atkins¹, Jamey Stutz¹, Richard Jones²
¹Victoria University of Wellington, Wellington, New Zealand, ²Durham University, Durham, United Kingdom

Antarctic ice sheets represent the largest reservoir of melt water in a warming climate. Yet the most important and dynamic portions of these large systems have only been observed for ~50 years, since the beginning of the satellite era. Using geological dating techniques and focusing on outlet glaciers, the observational record can be extended 100-fold, from decades to millennia. By extending the observational range we can illuminate past changes in coupled ice-climate systems and infer their future response and related sea level change in a warming climate.

To more fully understand the nature of these important coupled ice-climate systems, surface-exposure dating of rocks adjacent to outlet glaciers can provide insight to the style and rate of change for outlet glacier surface-elevation through time. Sampling campaigns in Victoria Land have produced robust, high-resolution age-elevation transects for two glaciers draining East Antarctica along the Transantarctic Mountains. We present 33 new $^{10}$Be ages from Mawson and Tucker Glaciers. These new ice surface elevation chronologies directly constrain the style, rate, and magnitude of change for two outlet glaciers; and provide critical insight to Holocene ice-load history in Victoria Land. Both age-elevation profiles show rapid significant thinning of outlet glaciers during the Holocene. These data are critical analogues for modelling the response of present and future ice-climate systems in a warming world.
Deglacial History of the Western Ross Sea since the Last Glacial Maximum

Retreat of grounded ice in the Ross Sea since the LGM provides valuable insight into marine ice sheet stability and response to environmental change. Here, we present ¹⁰Be exposure ages from glacially transported erratics from South Victoria Land to gauge past extent and timing of retreat. Ages from Skelton Névé indicate the ice surface was between 50 and 106 m higher than present during the LGM. The ice surface elevation remained close to its maximum extent prior to 19.1 ka and lowered by at least 50 m since ~15.0 ka. These results suggest that ice sheet thinning in the Skelton Névé coincided with meltwater pulse 1A (MWP-1A). However, the thinning did not make a significant contribution at this time. Thinning continued after 9.7 ka at Skelton Glacier and data from southern McMurdo Sound reveals a late-glacial and Holocene deglaciation chronology. This is consistent with studies suggesting that EAIS outlet glaciers that drained into the western Ross Sea experienced most mass loss during the early to middle Holocene. This chronology coupled with sediment provenance define a two-stage ice flow scenario for McMurdo Sound. The thinning and pattern of retreat is likely to be in response to retreat of the grounded ice in the Ross Embayment causing a reduction in buffering of the Skelton Glacier and gravitational draw down into the Ross Sea.
Variability in Sediments Deposited at a Retreating ice Stream Grounding Line

Zoe Roseby1,2 (z.roseby@noc.soton.ac.uk), James Smith2, Matthieu Cartigny3, Claus-Dieter Hillenbrand2, Kelly Hogan2, Robert Larter2, Peter Talling3, Claire Allen2, Brad Rosenheim4, Werner Ehrmann5, Gerhard Kuhn6

Understanding the future response of ice streams and glaciers to climate change is of high importance but remains uncertain, due to the limited timescales over which we have recorded observational and satellite data. Sedimentary sequences, deposited on polar continental shelves during past episodes of ice sheet advance and retreat, can be used to improve our understanding of long term changes. Past studies on marine sediment cores have typically identified three sediment facies assemblages; sub-glacial, transitional and open marine. Transitional sediment facies, deposited proximal to the ice stream grounding line, have the potential to capture the ice-proximal environment and processes taking place during deglaciation; thus providing an insight into the cause and style of ice stream retreat. Despite the development of depositional models to help explain the processes occurring at grounding lines, there is still uncertainty about the variability in sediments deposited in this environment. Here we use a multi-proxy approach on marine sediment cores recovered from the Anvers-Hugo Palaeo-Ice Stream Trough, western Antarctic Peninsula shelf, to identify the variability in transitional sediment facies deposited along and across the trough. Our data reveal systematic variability in the types and volume of transitional sediments, resulting from changes in retreat rate, bathymetry, thermal regime, grounding line oscillations and the evolving nature of the ice margin over deglaciation.
Retreats of Ice Sheet/Ice Shelf Driven by Warm Water Incursions in the Ross Sea

Zhihua Chen¹23 (chenzia@fio.org.cn), Mengshan Ju¹, Shulan Ge¹, Zheng Tang¹, Yuanhui Huang¹, Renjie Zhao¹, Ralf Tiedemann³, Lester Lembke-Jene³
¹Key Laboratory of Marine Sedimentology and Environmental Geology, First Institute of Oceanography, State Oceanic Administration, Qingdao, China, ²Laboratory for Marine Geology, Qingdao National Laboratory for Marine Science and Technology, Qingdao, China, ³Alfred-Wegener-Institut für Polar- und Meeresforschung, Bremerhaven, Germany

The stratigraphic data provide direct evidences and opportunities to address questions concerning retreat history of the Ross Ice Sheet and Ice Shelf, but there are significant uncertainties in the chronologies and interpretation. Here, we present and compare stratigraphic records of several sediment cores dredged from the continental shelf and slope of the Ross Sea. The sedimentological and geochemical records reveal the Circumpolar Deep Water (CDW) upwelled, mixed with more surface waters and contained higher oxygen since the Last Glacial Maximum (LGM), while sedimentary facies and paleoenvironmental proxies indicate synchronous and rapid retreats of (ice sheet) grounding-line and (ice shelf front) calving line occurred on the continental shelf especially during Holocene. The stability of marine-based margins of the Antarctic Ice Sheet was evidently controlled by postglacial warm deep-water incursions onto the shelf in the past. Thus, it can be inferred that the ice sheet and ice shelf in the Ross Embayment will melt and retreat faster, or even disastrously collapse and disappear in the future with more incursions of much warmer water in a continuously warming world.

Keywords: Ross Sea, continental shelf and slope, paleo-records, retreats of ice sheet and ice shelf, warm water incursions, since the Last Glacial Maximum
Ice Sheet Instability in the Western Ross Sea during the Last Glacial Maximum

Jae Il Lee1 (leeji@kopri.re.kr), Cristina Subt2, Brad Rosenheim2, Eugene Domack2, Min Kyung Lee1, Kyu-Cheul Yoo1, Heung Soo Moon1, Young-Suk Bak3

1Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of, 2University of South Florida, St. Petersburg, United States, 3Chonbuk National University, Jeonju, Korea, Republic of

Last Glacial Maximum (LGM) deposit in the western Ross Sea is represented by glacial diamicton facies, and with an absence of sediment facies other than diamicton, it has been assumed that thick ice sheet was extended to the outer shelf and was grounded to the sea floor during the LGM. However, we cannot preclude the possibility that the ice sheet did not remain stable in the western Ross Sea, considering the unstable nature of a marine-based ice sheet, presence of deep Drygalski Trough that makes warm water-intrusion easier, and sporadic warm climate events such as AIM2 during the LGM.

Here we show that diatomaceous mud layers underlie diamicton in cores collected from the Southern Drygalski Trough (SDT), indicating there was an open marine environment prior to the latest glacial event in the western Ross Sea. Ramped PyrOx (RP) 14C dating on the diatomaceous mud revealed that ice sheet on the western Ross Sea retreated at ~26.6 ky BP (all ages here are uncorrected 14C), and the SDT remained ungrounded until the latest ice sheet advanced at ~20.8 ky BP. The latest ice sheet retreated from the SDT at ~8.7 ky BP. This chronology is remarkably consistent with previous RP 14C ages on glacial and deglacial successions from condensed sections on the open Ross Sea. Combined with a result from the eastern Ross Sea implying an earlier retreat of ice sheet prior to the LGM, it is possible that large areas of the Ross Embayment remained ungrounded during the global LGM period.
Regional Geology Mapping Using Satellite-Based Remote Sensing Data in Antarctica

Amin Beiranvand Pour¹ (amin.beiranvand@kopri.re.kr), Yongcheol Park¹, Jong Kuk Hong¹, Jusun Woo², Tae-Yoon Park¹

Satellite remote sensing imagery is especially useful for geological investigations in Antarctica because of its remoteness and extreme environmental conditions that constrain direct geological survey. The highest percentage of exposed rocks and soils in Antarctica occurs in Northern Victoria Land (NVL). Exposed Rocks in NVL were part of the paleo-Pacific margin of East Gondwana during the Paleozoic time. This investigation provides a satellite-based remote sensing approach for regional geological mapping in the NVL, Antarctica, focusing on the Bowers terrane with high potential for hosting orogenic gold mineralization. The Landsat-8 and the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) datasets were used to extract lithological-structural and mineralogical information. Several new spectral-band ratio indices were developed using Landsat-8 and ASTER bands and proposed for Antarctic environments to map spectral signatures of snow/ice, iron oxide/hydroxide minerals, Al-OH-bearing and Fe, Mg-O-H and CO₃ mineral zones, and quartz-rich felsic and mafic-to-ultramafic lithological units. The new spectral-band ratio indices were tested and implemented to Level 1 terrain-corrected (L1T) products of Landsat-8 and ASTER datasets covering the NVL. The new spectral-band ratio indices are especially useful for geological investigations in inaccessible locations and poorly exposed lithological units in Antarctica environments.
Application of Navigation System for the Vessels Sailing in the Sea Ice Area

Jian Liu\(^1\) (liujian@pric.org.cn)
\(^1\)Polar Research Institute of China, Shanghai, China

Sea ice is an important factor affecting vessels navigation in the polar ocean. The University of Bremen, NSIDC and other agencies released the sea ice concentration and thickness of products etc. In addition, such as visible light, SAR remote sensing data can provide data support for vessel navigation. So, how to apply these data in the best way to provide navigation guidance for vessels in the sea ice area? We use the combination of GIS, remote sensing and big data technology to realize the application of sea ice data in the vessel terminal. At the same time, the path planning of vessel sailing is realized by using visible light, SAR and other data. China Snow Dragon vessel equipped with a satellite receiver system, it can receive real-time data, such as MODIS and HY-2A remote sensing data. These data can be used to provide remote sensing monitoring products and wind products for the vessel, so as to ensure the navigation safety of vessel in the sea ice area.
Late Winter Snow Thickness Estimation from Early Summer Melt Pond Fraction

Saroat Ramjan¹ (saroat.ramjan@ucalgary.ca), Torsten Geldsetzer¹, Randall Scharien², John Yackel¹
¹University of Calgary, Geography, Calgary, Canada, ²University of Victoria, Geography, Victoria, Canada

It is of great interest to understand the snow thickness variability in the Arctic to understand the geophysical properties at the ocean-seaice-atmosphere interface. The radiative and thermal properties of snow significantly affect the sea ice growth and decay. Moreover, presence of snow cover on sea ice plays a crucial role in satellite-based sea ice thickness retrievals. Prior research reported that, during summer melt, thin snow cover leads to dominant surface flooding (larger pond fraction), whereas thick snow cover leads to a greater fraction of snow patches (smaller pond fraction). Thus, summer measurements of melt pond fraction can be utilized as a proxy to estimate relative winter snow thickness. In order to quantify regional-scale melt pond fraction, aerial photography surveys were conducted in 2012, near Cornwallis Island, Nunavut. Polarimetric parameters and polarimetric texture parameters of winter RADARSAT-2 SAR fine quad-pol images were analyzed at different incidence angles, to estimate the relationship between the winter backscatter from snow cover on first year sea ice and early summer melt pond fraction, to predict late winter snow thickness. Our results indicate that the regression models derived from the most significant polarimetric and texture parameters provide better prediction to estimate the winter snow thickness variability and snow topography.
Comprehensive Monitoring of Polar Land Ice by Sentinel-1

Jan Wuite¹ (jan.wuite@enveo.at), Thomas Nagler¹, Markus Hetzenecker¹, Stefan Scheiblauer¹, Helmut Rott¹
¹ENVEO IT GmbH, Innsbruck, Austria

The Sentinel-1 acquisition planning for polar regions provides nearly uninterrupted observations of the Greenland Ice Sheet margin, key regions in Antarctica and other polar ice masses. The dual satellite constellation has thereby changed the landscape for satellite earth observation entirely, providing excellent opportunities for operational monitoring of key climate variables like ice velocity (IV) and glacier discharge. Continuous coverage is now extended to include most of the Antarctic margin, allowing retrieval of dense time series of ice flow for major outlet glaciers hitherto only sparsely observed. We developed a system for IV retrieval and discharge monitoring, applying advanced iterative offset tracking, utilizing repeat pass Sentinel-1 SAR. Generated IV maps compare well with those derived from other high-resolution sensors and provide detailed coverage even in regions with high accumulation and fast flow. Combined with ice thickness from RES, the maps form the basis for studying glacier dynamics, ice discharge and mass balance.

Including the latest observational data, we present IV maps of Greenland, Antarctica and smaller ice caps highlighting time series of IV fluctuations of major outlet glaciers. We demonstrate how IV and discharge varies over time scales ranging from days to years and between adjacent basins. Continuous monitoring of the polar regions, exploiting both satellites, is ongoing to detect changes of ice flow as indicators of climate change.
Satellite images provide the opportunity to differentiate different ice units in and around the Terra Nova Bay Polynya (TNBP) in the Ross Sea (Antarctica) on different spatial scales. However, at a first stage, the separation of units is usually be carried out in terms of radar signature variations, i.e. the result are “radar units” with statistically significant signature differences. In a second step, the radar units have to be linked to observations in the field in order to enable a geophysical interpretation of the stage of polynya development and the sea ice conditions around the polynya. In this specific analysis we focus on the first step. The radar imagery acquired over the TNBP comprises data from TerraSAR-X strip-map dual-polarization (HH, VV) mode, TerraSAR-X ScanSAR mode (HH-polarization), Sentinel-1 extra wide-swath mode (HH and HV polarization), and Sentinel-1 interferometric wide-swath mode (HH-polarization). Dependent on the temporal gap between image acquisitions it is possible in some cases to produce layer stacks including different imaging modes. We use different segmentation methods (such as e.g. Support Vector Machine) to arrive at a map of different radar units with only small overlaps of their radar signatures (i.e. significant discernibility). The goal is to generate a temporal sequence of radar unit maps, which in the second step in collaboration with the PIPERS team can be related to ground data gathered in the field.
Increasing surface melting on the Greenland ice sheet and rising sea level have heightened the need for understanding the complex pathways transporting meltwater from the ice sheet surface to the ice edge and the ocean. Supraglacial streams abundantly cover the western ablation zone throughout the melt season, transporting large volumes of meltwater into moulins and to englacial and subglacial networks before entering the ocean. However, current regional and global model projections of meltwater runoff from the GrIS do not incorporate this hydrological process. This knowledge gap is due to the lack of observations of meltwater transport off the surface of the ice sheet and into the ocean. Furthermore, current ice sheet watershed models lack the ability to determine actual flow paths on the ice because terrain-modeled networks cannot account for the presence of moulins without observations from satellite imagery. In this study, we map supraglacial stream networks and moulin termination points using high-resolution WorldView-1/2/3 satellite imagery from 2012 and 2015. These image-extracted features are also combined with a high-resolution digital elevation model (ArcticDEM) to model ice sheet watersheds.
Climate-driven changes of sea ice habitats are impacting large parts of the Southern Ocean and virtually the entire Arctic Ocean. At the same time, we have only just begun understanding the importance of sea ice for the functioning of Polar ecosystems. Within the Iceflux project, we analysed the structure of ice-associated and planktonic communities in Arctic and Antarctic ecosystems in relation to habitat properties. Using isotopic and biochemical trophic marker analysis, the dependency of sea-ice fauna and zooplankton on ice algae-produced carbon was estimated. Our results show that sea ice properties were a key driver of community structure in both Polar Oceans. Certain abundant metazoan species were highly dependent on ice algae-produced carbon. Based on the consumption rates of these species, differences in the proportional trophic carbon flux from sea ice into the pelagic food web were investigated between the Arctic Ocean and the Southern Ocean. Effects of declining sea-ice habitats on the food web structure in both Polar Oceans will vary seasonally and regionally, with winners who can adapt to new carbon sources and losers facing increasing difficulties to obtain resources and complete their life cycles. Due to the close linkage of central carbon transmitters with sea ice (polar cod in the Arctic and Antarctic krill in the Southern Ocean), sea ice decline may lead to disruptions of ecosystems until a new equilibrium is found.
The Role of Mixotrophic Algae in Sea Ice Ecosystems

Tobias Vonnahme¹ (tobias.vonnahme@uit.no), Ulrike Dietrich², Brandon Hassett², Rolf Gradinger²

¹UiT The Arctic University of Norway, Arctic Marine System Ecology, Tromsø, Norway, ²UiT The Arctic University of Norway in Tromsø, Tromsø, Norway

The finding of heterotrophic carbon uptake in diatoms has challenged the representation of algae as pure autotrophs in current ecosystem models. Mixotrophy as adaptation to nutrient or light limitations, both typical conditions in sea ice ecosystems, have been described. Thus, it is not surprising to find living algae in the polar night, but the survival strategies remain speculative. For describing the importance of mixotrophy in sea ice algae, a variety of methods are applied. Multiple omics approaches are used for a molecular understanding of the metabolic processes involved. Metagenomics and Metatranscriptomics data are integrated and the potential for organic matter degradation in diatoms explored. Stable isotope probing experiments are used to estimate fluxes of dissolved organic matter uptake in algae under varying light conditions. The potential for phagotrophy is explored via fluorescent in situ hybridisations and feeding experiments with fluorescently labelled sea ice bacteria. All data will be integrated into a dynamic phytoplankton growth and photoacclimation model and the implications for bacteria-algae interactions and higher trophic levels discussed.
Changes in the Arctic icescape include higher light availability for primary producers due to declining and thinning ice pack. In addition, the increasing dynamics of the thinner ice pack may result in higher ice deformation rates and more open water areas (leads) covered by new thin ice with higher light transmittance. Both the detailed light climate and the algal response to it require further studies. During the Norwegian young sea ICE expedition (N-ICE2015) in spring 2015 we studied the implications of thinner ice in leads, which enabled development of a phytoplankton bloom beneath the otherwise opaque ice cover - transmittance through the snow-covered thick ice was < 0.3 %, whereas up to 40 % of incoming light penetrated through the studied refrozen lead. Yet, ice algal biomass in the lead ice did not exceed that of the surrounding thicker and older ice over the lifetime (1 month) of the lead, suggesting that ice algal growth was not only a function of increased light availability. We discuss potential controlling factors, including high-light acclimation indicated by high concentrations of ultraviolet-protecting mycosporine-like amino acids (MAAs), and time needed for recruitment. The ice algal community shifted from dominance of flagellates towards dominance of pennate, ice-adapted diatom species. In summary, our results suggest that high-light environments like young ice benefit under-ice phytoplankton blooms but might not boost ice algal production per unit area.
Phaeocystis versus Diatoms Blooms in the Ice Covered European Arctic

Paris 6)-CNRS-IRD-MNHN, Paris, France, 7IOPAS - Institute of Oceanology Polish Academy of Sciences, Sopot, Poland, 8Department of Fisheries and Oceans Canada, Manitoba, Canada, 9AquaBiota Water Research, Stockholm, Sweden

The Arctic Ocean is one of the key regions where the effects of climate change are most pronounced. Massive reductions in sea ice thickness and extent are anticipated to cause large changes in the Arctic ecosystem. Two comprehensive expeditions in 2015, the Norwegian young sea ICE expedition (N-ICE2015) from January-June and the Transitions in the Arctic Seasonal Sea Ice Zone (TRANSISIZ) cruise from May-June carried out ecological and biogeochemical process studies during ice floe drift experiments and shelf-to-basin sampling across the European Arctic margin and on the Yermak Plateau. As previously reported, a Phaeocystis under-ice bloom was observed over the south-eastern Yermak Plateau, while the north-western Yermak Plateau was characterized by deep mixed layers associated with low standing phytoplankton stocks and weak productivity. In contrast, a large diatom bloom dominated by various Thalassiosira and Chaetoceros species, was observed over the continental slope further east. The diatom bloom was found above the core of the Atlantic water boundary current, concurrent with enhanced dissipation and large diapycnal heat fluxes into the mixed layer. Highlights from these contrasting bloom scenarios will help to improve our understanding of ecosystem functioning and predictions of the potential annual primary production in a rapidly changing Arctic Ocean.
Impact of Ice Algae and under-ice Phytoplankton on the Marine Carbonate System

Brent Else¹ (belse@ucalgary.ca), Jeremy Whitehead¹, Virginie Galindo², C.J. Mundy², Soren Rysgaard², Joannie Ferland¹, Marcel Babin³

¹University of Calgary, Geography, Calgary, Canada, ²University of Manitoba, CEOS, Winnipeg, Canada, ³Laval University and CNRS, Takuvik, Quebec, Canada

Past research has suggested that ice algae play a role in reducing surface water dissolved inorganic carbon (DIC) during spring, pre-conditioning surface waters to low dissolved CO₂ (pCO₂sw) and uptake of atmospheric CO₂ during the ice free season. The potential role of under-ice phytoplankton blooms in this seasonal cycle has generally not been considered. The objective of this study was to look at trends in the inorganic carbon system in the upper water column under sea ice from early spring to ice melt onset near Qikiqtarjuaq, NU. Sample collection started midway through an ice algae bloom, and continued until the early stages of an under-ice phytoplankton bloom. During most of the ice algae bloom period we observed a slight increase in DIC and pCO₂sw in the top 5m of the water column, as opposed to the expected reduction in those parameters. Although it is possible that substantial pCO₂sw/DIC drawdown was missed at the initiation of the ice algae bloom, biomass calculations show that previous studies may have overestimated the role of ice algae, and that this null result may be widely applicable. Following the formation of melt ponds, we observed a rapid phytoplankton bloom in the upper 25 m of the water column that did dramatically reduce DIC and pCO₂sw. We conclude that under-ice phytoplankton blooms may be the most important biological mechanism predisposing the Arctic surface mixed layer to act as a CO₂ sink in the open water season.
The Dependence of Sea Ice Algal Production on Conditions of Sample Melt

Karley Campbell1, C.J. Mundy1, Andrew Juhl2, Laura Dalman1, Christine Michel1,3, R Galley1, B E Else4, Nicolas-Xavier Gelfius1, Soren Rysgaard1,5,6
1University of Manitoba, Centre for Earth Observation Science, Winnipeg, Canada, 2Colombia University, Lamont Doherty Earth Observatory, New York, United States, 3Fisheries and Oceans Canada, Freshwater Institute, Winnipeg, Canada, 4University of Calgary, Department of Geography, Calgary, Canada, 5University of Aarhus, Biosciences, Aarhus, Denmark, 6Greenland Institute of Natural Resources, Nuuk, Greenland

The influence of algae on sea ice biogeochemical conditions is a significant aspect of sea ice flux and ecosystem modeling. Accurate estimates of sea ice algal productivity and responses to environmental change are particularly important in light of shifting Arctic sea ice conditions. The foundation of production estimates in such studies historically, and at present, often relies on the melt of ice samples prior to incubation. The specific procedure varies between studies, particularly the duration of melt and whether samples are buffered for changes in salinity. In this study we combine field and laboratory measurements to comprehensively investigate the impact of melt procedure on the gross production and photophysiology of sea ice algae, and demonstrate the potential for scientific protocols to contribute to variability of estimates reported across the Arctic. We found that estimates of productivity are likely artificially enhanced or reduced in individual studies depending on melt conditions, including: duration of melt, volume of filtered seawater added, and temperature. Recommendations for best practices in melting ice samples for biogeochemical studies is provided.
Determining robust trends in Arctic snow cover with quantitative uncertainty estimates is required to better constrain impacts on the climate system, the freshwater budget of the Arctic, and impacts of changing snow cover on vegetation, biogeochemical activity, exchanges of carbon dioxide and trace gases, and ecosystem services. In this study, we determine the spread in Arctic seasonal snow cover extent (SCE) and snow water equivalent (SWE) trends from multiple sources. The NOAA snow chart Climate Data Record (NOAA-CDR), dating back to 1967, shows dramatic reductions in Arctic spring SCE, particularly since 2005, and a positive trend in fall SCE. Trends derived from five other sources of snow information, including surface observations, passive microwave satellite data and land surface models (with snow schemes of varying complexity) driven by modern era reanalyses (from various reanalysis centres) identify weaker reductions in spring SCE compared to NOAA-CDR, along with a loss of fall analysis. SCE trend sensitivity to surface temperature forcing is anomalous for the NOAA-CDR compared to other data sets for the months of October, November, May, and June, and so should be interpreted with caution in these months. Trends in maximum pre-melt SWE over the 1981 - 2016 period are negative when the Arctic is considered as a whole, but considerable regional and inter-dataset variability in the spatial patterns of change limit the confidence in these trends.
Arctic Snowfall from CloudSat Observations and Reanalyses

Léo Edel¹ (leo.edel@lmd.polytechnique.fr), Chantal Claud², Christophe Genthon²
¹Laboratoire de Météorologie Dynamique, Ecole Polytechnique, Palaiseau, France, ²Institut des Géosciences de l’Environnement, Grenoble, France

While snowfall likely has a major contribution to the Arctic amplification, available state-of-the-art climatologies still significantly disagree. We will present a satellite-based characterization of snowfall in the Arctic using CloudSat data, and compare with and between various other climatologies. First, we examine the frequency, phase and rate of snowfall from CloudSat over 2007-2010. Then we compare with ECMWF (European Center for Medium Range Weather Forecast) Interim reanalysis (ERA-I), Arctic System Reanalysis (ASR) and Global Precipitation Climatology Center Monitoring Product (GPCC MP). Similar general patterns are observed in all datasets. Yet, significant mean snowfall rates differences are found over continents between 58° and 82°N between ERA-I (155 mm/an), ASR (197), GPCC MP (156) and CloudSat (210). These differences are larger between CloudSat (317 mm/an) and GPCC MP (181 mm/an), and larger overall over Greenland. In spite of its limitations, CloudSat clearly contributes to a better characterization of snowfall in the Arctic.
Snow accumulation patterns are determined by many different processes from ice crystal nucleation in clouds to snow redistribution by wind and avalanches. In between, snow precipitation undergoes different dynamical and microphysical processes, such as ice crystal growth, aggregation and riming, which determine the growth of particles and thereby influence the intensity and structure of the snowfall event. In alpine terrain the interaction of different processes and the topography may lead to orographic enhancement and preferential deposition of precipitation.

To better understand the relative importance of different pre-depositional processes on snow precipitation we analyze three snowfall events between January and March 2016 in Davos (CH). Snow precipitation patterns from MeteoSwiss operational weather radar measurements on Weissfluhgipfel and very high resolution Weather Research and Forecasting (WRF) model simulations show reasonable agreement with measurements from automatic weather stations. Overall, radar precipitation patterns show higher small scale variability compared to WRF simulations. Two-dimensional autocorrelation maps and variograms of precipitation patterns reveal a strong dependence of radar and WRF precipitation on topography and the prevailing wind direction, which emphasizes the importance of large-scale orographic enhancement on regional scales and small-scale topography-wind interactions on a mountain ridge scale.
The Required Model Resolution for Resolving the SMB of the Greenland Ice Sheet

Willem Jan van de Berg¹ (w.j.vandeberg@uu.nl), Erik van Meijgaard², Bert van Ulft²
¹Utrecht University, Faculty of Science, Department of Physics, Institute for Marine and Atmospheric Research (IMAU), Utrecht, Netherlands, ²KNMI, De Bilt, Netherlands

For reliable estimates of past, current and projected mass changes of the Greenland Ice Sheet and its peripheral glaciers and ice caps, the surface mass balance (SMB) must be determined with sufficient spatial detail, which could be carried out with a global or regional climate model or statistical downscaling. This raises a number of questions: Which resolution is sufficient? Which method is appropriate for the SMB refinement at this resolution? Can we assess which method is most accurate?

In order to answer these questions, the regional climate model RACMO2.3 is run at 4 different resolutions ranging from 2.2 to 60 km for South Greenland. The results of these runs are statistically downscaled. Analysis of the downscaled products from various model resolutions shows that statistical downscaling improves the estimates of runoff and hence of SMB compared to interpolation, but has no beneficial effect on the other SMB components. From the comparison with observations it can be concluded that 20 km resolution is sufficient to represent the ice sheet accumulation zone. In the ablation zone, RCMs outperform statistical downscaling although the performance gain per grid refinement factor decreases for finer resolutions. Furthermore, we show that for RCMs run at resolutions finer than 20 km, snow pack initialization, snow model tuning and cloud physics are of equal importance for the quality of model results as resolution.
Despite the increasing importance of ice sheet surface ablation in Greenland's sea-level contribution, a quantitative inter-comparison between modeled and measured meltwater discharge across multiple drainage basins is conspicuously lacking. Here we investigate the accuracy of model discharge estimates from the Modèle Atmosphérique Régionale (MAR) regional climate model by comparison with in situ proglacial river discharge measurements at three West Greenland drainage basins - North River (Thule), Watson River (Kangerlussuaq), and Naujat Kuat River (Nuuk). At each basin, we:
1) determine optimal drainage basin delineations;
2) evaluate MAR at daily, 5-, 10- and 20-day time scales; and
3) identify potential sources for model-observation discrepancies by analyzing model bias relative to data from automatic weather stations.

Our results reveal that daily discharge is best captured by MAR across the Watson basin, whilst there is lower correspondence between modeled and observed discharge at the Thule and Nuuk basins. Model agreement with observed is reduced during periods of peak discharge, but is improved at the Thule and Nuuk basins over longer time scales. Our study highlights the importance of reducing MAR overestimation of surface albedo and warm bias in near surface air temperature, underestimation of cloud cover representation, and adding more realistic runoff delay functions to reduce model error and to improve prediction of Greenland's contribution to sea level rise.

From Slope-scale Snow Processes to Hydrologic Response: A Validation of Alpine3D

Tristan Brauchli¹ (tristan.brauchli@epfl.ch), Ernesto Trujillo¹, Hendrik Huwald¹, Michael Lehning¹,²
¹Ecole Polytechnique Fédérale de Lausanne (EPFL), School of Architecture, Civil and Environmental Engineering, Lausanne, Switzerland, ²WSL Institute for Snow and Avalanche Research, SLF, Davos, Switzerland

Snow modeling in mountainous areas remains a challenge because of the numerous processes affecting the mass and energy balance. In this study, we examine the influence of snowmelt on the hydrological response of the Dischma river basin, a high-alpine catchment of 43.2 km² in Switzerland. Based on recent developments in Alpine3D, we study the influence of snow distribution and liquid water transport within the snowpack on runoff dynamics. We show the added value of a more realistic snow distribution by comparing our results with multi-scale observations (snow lysimeter, distributed snow depths and streamflow). At the plot scale, snowpack runoff is well simulated when the initial (peak of snow season) mass balance errors are small, which is achieved with a precipitation scaling approach. At the sub-basin scale, a more realistic snowpack leads to a faster runoff pulse originated in the shallower areas while the melting period is extended by a month with snowmelt coming from deeper areas. The hydrological response at the basin scale is also enhanced by the more realistic snowpack, even though calibration processes smoothen the differences. The added value of a more complex liquid water transport scheme is obvious at the site scale but decreases at larger scales. Our results highlight not only the importance but also the difficulty of getting a realistic snowpack distribution even in a well-instrumented area and present a model validation from multi-scale observations.
Arctic Freshwater Plankton Response to Environmental Stressors

Heather Mariash\(^1\) (h.l.mariash@uu.nl), Ann Kristin Schartau\(^2\), Kirsten Christoffersen\(^3\)
\(^1\)Utrecht University, Utrecht, Netherlands, \(^2\)Norwegian Institute for Nature Research, Oslo, Norway, \(^3\)University of Copenhagen, Copenhagen, Denmark

Arctic freshwaters are facing a number of environmental pressures, including rapid climate change that affects both the formation and loss of surface waters, along with changing biogeochemistry of these waters. Freshwater plankton assemblages are expected to reflect the impacts of these stressors through shifts in productivity and species composition. This paper examines spatial and contemporary trends in phytoplankton and zooplankton biodiversity throughout the circumpolar Arctic. We have analyzed contemporary (1950-present) data of abiotic variables and plankton diversity collected from more than 400 Arctic and subarctic lakes in USA, Canada, Greenland, Iceland, Faroe Islands, Norway, Sweden, Finland and Russia using various univariate and multivariate analysis techniques. Based on our findings we will establish contemporary baselines for future comparisons of plankton communities in the Arctic region. We will evaluate patterns in biodiversity and environmental stressors to allow discussion of current and future responses to environmental pressures on Arctic plankton communities. We will also discuss the implications our findings have for the future monitoring.
Exploring Patterns of Diatom Assemblages from Circumpolar Arctic Lakes & Streams

The assessment of spatial and temporal trends in Arctic freshwater biota and their physical and biogeochemical habitat in response to a warming climate requires a large-scale harmonized monitoring program. The presented work, performed by the freshwater group of the Circumpolar Biodiversity Monitoring Plan (Arctic Council: Conservation of Arctic Flora and Fauna), is one of the first steps towards such a harmonized monitoring program. Using circum-Arctic diatom assemblage data, specific goals of this study include:

1) establishing current and pre-industrial environmental conditions as reference points to guide future environmental monitoring programs, and
2) understanding the historical context of diatom distributions.

Large-scale assessments of diatom distributions in Arctic regions are currently scarce, and detailed taxonomic studies tracking species compositional changes in both lakes and streams have yet to be undertaken. We used contemporary stream and lake data from ongoing monitoring programs, spot data from research projects, as well as surface sediment (modern) diatoms from paleolimnological studies to provide a spatial assessment of species distributions of the circum-Arctic region. Additionally, we analysed a large set of dated and “top-bottom” paleolimnological records to better describe historical background conditions on a circum-Arctic scale.
Landscape Filters as Drivers of Arctic Benthic Macroinvertebrate Biodiversity

The concept of landscape filters allows us to test hypotheses about environmental driver-biological response relationships by examining the relative importance of drivers at different spatial scales. Across the Arctic, differences in warming rates, human development, and biogeography may be expected to contribute to differences in the relative importance of variables at different spatial scales. For example, in regions where large-scale variables, such as climate, have already had an effect on community structure: Are regional patterns of benthic assemblages more strongly associated with small-scale structuring variables such as water chemistry and substrate? This paper explores driver-response relationships across different spatial scales (i.e., both latitudinal and longitudinal) to determine whether similar patterns are evident among the sub-, low-, and high-Arctic across the circumpolar region. Specifically, the response of benthic macroinvertebrate assemblages to landscape filters across latitudinal gradients is used as a proxy for predicting shifts in biological pattern as a result of climate change. Moreover, longitudinal contrasts with respect to the importance of climate-related variables on biological pattern has implications for the importance of warming history across the circumpolar region, particularly when projecting risk for those areas that have experienced less warming.
Trends in Biodiversity and Environmental Estressors in Fennoscandian Arctic Lakes

Willem Goedkoop¹ (willem.goedkoop@slu.se), Danny Lau², Jennifer Lento³

¹Swedish University of Agricultural Sciences (SLU), Aquatic Sciences and Assessment, Uppsala, Sweden, ²Umeå University, Umeå, Sweden, ³University of New Brunswick, Fredericton, Canada

Arctic lakes in Fennoscandia are experiencing rapid environmental changes resulting from human activities, large-scale oligotrophication, and climate change. These stressors are expected to alter both abiotic variables and biodiversity, i.e. communities of benthic invertebrates, algae, zooplankton, water plants, and fish. We compiled a data set for 74 selected Arctic/alpine lakes in Norway, Sweden and Finland and analyzed their spatiotemporal trends using both univariate and multivariate analyses. Multiple indicators will be used to assess biodiversity trends that are hypothesized to associate with spatial and temporal abiotic changes, and to identify regional biodiversity hotspots. Findings from this study will provide the basis for regional impact assessments for Fennoscandian Arctic lakes and establish contemporary abiotic and biotic baselines for future comparisons. The work is done in the framework of the Circumpolar Biodiversity Monitoring Group under the Convention of Arctic Flora and Fauna (CAFF).
Aquatic Ecosystem Change in High Arctic Catchments due to Permafrost Change

Scott Lamoureux¹ (scott.lamoureux@queensu.ca), Kaitlyn Roberts¹, Amanda Schevers¹, Melissa Lafreniere¹, Derek Muir², Anna Pienkowski³,⁴

¹Queen’s University, Geography and Planning, Kingston, Canada, ²Environment and Climate Change Canada, Aquatic Contaminants Research Division, Burlington, Canada, ³MacEwan University, Physical Sciences, Edmonton, Canada, ⁴Bangor University, School of Ocean and Natural Sciences, Anglesey, United Kingdom

Understanding how climate-induced permafrost changes will alter riverine and lacustrine environments is critical to develop accurate predictions of how aquatic ecosystems will respond. We assess the impact of recent climate and permafrost perturbation on the hydrochemistry, nutrient transport and downstream aquatic ecosystem in paired catchments at the Cape Bounty Arctic Watershed Observatory (75°N, 109°W; CBAWO) in the Canadian High Arctic between 2003-2017.

There has been a sharp increase in solutes in the lakes at CBAWO, and sulfate has notably increased 380-500%. River fluxes have similarly increased, exemplified by dissolved inorganic nitrogen fluxes. These hydrochemical and nutrient fluxes are interpreted to be associated with deep thaw and mobilization from the upper permafrost. Fish condition factor has improved steadily during the observation period and otolith analysis indicates that fish show abrupt geochemical changes associated with solute loading. Diatoms show a shift to small planktonic species in the past decade, suggesting primary productivity has responded to climate amelioration, ice cover, and river fluxes.

Our results from CBAWO indicate that climate-induced permafrost changes can impart rapid changes on High Arctic aquatic systems, and indicate that an integrated approach to predicting aquatic responses to environmental forcings will be necessary to predict future changes.
Effects of Environmental Change on Signy Island Terrestrial Algae Diversity

Faradina Merican1 (faradina@usm.my), Peter Convey2, Paul Broady3, Japareng Lalung4, Wan Maznah Wan Omar4
1Universiti Sains Malaysia, School of Biological Sciences, Penang, Malaysia, 2British Antarctic Survey, Cambridge, United Kingdom, 3University of Canterbury, School of Biological Sciences, Christchurch, New Zealand, 4Universiti Sains Malaysia, School of Industrial Technology, Penang, Malaysia

The terrestrial algal microflora of Signy Island (lat. 60° 43'S) has been sporadically studied since the 1960s. The first extensive report is that of Broady, investigating the microalgae diversity in the late 1970s from 122 samples including two Signy Island Reference Sites. The island has changed markedly since then under the influence of trends of rapid regional climate change. In 2016 we re-visited and re-examined in detail the diversity of the terrestrial microalgae at locations on Signy Island previously studied by Broady. Polyphasic assessments conducted to date indicate changes in the microflora community over the four decades between surveys. Morphological features observed in the new material suggest either the presence of species/strains not previously recorded at specific sites, or the expression of phenotypic plasticity in response to the environmental changes experienced. We also found morphospecies that were absent from previous records to be present in a number of sites, in some cases with high abundance. Increased understanding of past and present diversity and distribution of microalgae on Signy Island will support conservation of the indigenous biota and aid future research on ecological processes, including consequences of environmental change.
A Critical Evaluation of NorESM1 to Understand Aerosol Effects on Arctic Climate

Tanja N. Dallafior\(^1\), Srinath Krishnan\(^2\), Anna Lewinschal\(^2\), Ilona Riipinen\(^1\), Hans-Christen Hansson\(^1\), Annica M. L. Ekman\(^2\) (annica@misu.su.se)

\(^1\)Stockholm University, Department of Environmental Sciences and Analytical Chemistry, Stockholm, Sweden, \(^2\)Stockholm University, Department of Meteorology and Bolin Centre for Climate Research, Stockholm, Sweden

Previous studies using the earth system model NorESM1 show that changing SO\(_2\) emissions in various regions in the northern hemisphere mid-latitudes result in significant temperature responses in the Arctic. Evidence so far suggests that in NorESM1, amplified Arctic surface temperature response is obtained despite a weak sea-ice albedo feedback and without significant aerosol-induced changes in cloud properties in the Arctic.

This work aims at gaining a process understanding of the Arctic temperature response to mid-latitude emission changes both in the real world and in the model. To this end, we evaluate aerosol size distributions, cloud properties, and other entities in NorESM1 against remote and in-situ observations at high latitudes. Furthermore, results are compared to a newer version of NorESM1 including improvements of the sea ice model, convective transport and nucleation of aerosols to identify critical processes affecting Arctic climate. A preliminary comparison between the NorESM1 output and in-situ measurements of aerosol size-distributions show that the model underestimates particle sizes, which is of direct importance to cloud droplet activation. Furthermore, a comparison with aerosol optical depths obtained from the CALIOP satellite suggests that the model overestimates aerosol transported to the Arctic through the free troposphere which implies that the modeled aerosol impacts on high-latitude low-level clouds are underestimated in NorESM1.
Characteristics of Biogenically-derived Aerosols in the Amundsen Sea, Antarctica

Jinyoung Jung, Sang-Bum Hong, Meilian Chen, Jin Hur, Liping Jiao, SangHoon Lee

1Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of, 2Sejong University, Department of Environment & Energy, Seoul, Korea, Republic of, 3Third Institute of Oceanography, SOA, Xiamen, China, 4Korea Polar Research Institute (KOPRI), Incheon, China

Atmospheric concentrations of ionic species, water-soluble organic carbon (WSOC), total organic carbon (TOC), and total carbon (TC) were measured over the Southern Ocean and the Amundsen Sea, Antarctica between 43°S and 75°S during the ANA06B cruise conducted in the austral summer of 2016 on board the Korean icebreaker IBR/V Araon, in order to investigate abundance of biogenically-derived aerosol species and source of organic carbon. During the cruise, mean concentrations of non-sea-salt sulfate (nss-SO$_4^{2-}$) and methanesulfonic acid (MSA) in bulk aerosols were $0.61 \pm 0.17 \mu g \ m^{-3}$ and $0.22 \pm 0.13 \mu g \ m^{-3}$, respectively. In the Amundsen Sea Polynya, MSA concentration increased from $0.35 \mu g \ m^{-3}$ up to $0.57 \mu g \ m^{-3}$, and it showed a positive relationship with dimethyl sulfide (DMS) in sea surface water, showing significant influences of marine biological activities. Estimate using the MSA/nss-SO$_4^{2-}$ ratio measured in Antarctica revealed that mean contribution of biogenic nss-SO$_4^{2-}$ accounted for $69 \pm 34\%$ of total nss-SO$_4^{2-}$. Atmospheric TOC concentration varied from $0.16$-$0.65 \mu g \ m^{-3}$, of which $16$-$47\%$ was WSOC, showing that water-insoluble OC was dominant organic carbon species. Excitation emission matrix (EEM) analysis revealed that protein-like WSOC was dominant WSOC type (46-98%). This result suggests that most WSOC was derived from marine biological processes, and that biogenic WSOC as well as sulfur species could be a important source of cloud condensations nuclei in the Amundsen Sea.
Sea-salt Aerosol from Blowing Snow on Sea Ice: A New CCN Source in Polar Regions

Xin Yang¹ (xinyang55@bas.ac.uk), Markus Frey¹, Rachael Rhodes², Sara Norris³, Ian Brooks³, Philip Anderson⁴, Kouichi Nishimura⁵, Anna Jones¹, Eric Wolff²

¹British Antarctic Survey, Cambridge, United Kingdom, ²University of Cambridge, Department of Earth Sciences, Cambridge, United Kingdom, ³University of Leeds, School of Earth and Environment, Leeds, United Kingdom, ⁴Scottish Association for Marine Science, Oban, United Kingdom, ⁵Nagoya University, Graduate School of Environmental Studies, Nagoya, Japan

Using winter cruise data collected within in the Weddell Sea during June-August 2013, for the first time, we are able to carry out a systematic examination to the parameterization of sea salt aerosol (SSA) production from blowing snow as proposed by Yang et al. [2008]. Aerosol elevation events have been frequently observed within the sea ice zone, which, however, could not be solely explained by the sea spray. When the SSA production scheme from blowing snow is implemented in to the model, further constrained by the campaign data, the model could reproduce well many of the elevation events. In addition, modelled SSA size spectrum generally matches the observations at size range of ~0.4-10 µm strongly indicating that the SSA production scheme implemented is working and the micro-physical process involved in the parameterization could be reasonable.

Moreover, the widely observed winter peaks of SSA in mass in polar regions can be reproduced by the model. Model also predicts that the total number density of SSA (down to size of 0.2 µm) over the sea ice zone can be larger than that in the marine boundary layer by about one order of magnitude, indicating blowing snow is favorable of producing sub-micron sized SSA compared to sea spray. These small SSA are not limited within the sea ice zone and can be long distance transported. Therefore they could potentially act as a source of CCN in high latitudes.
Atmospheric new particle formation and growth significantly influences climate by supplying new seeds for cloud condensation and brightness. Currently, there is a lack of understanding of whether and how marine biota emissions affect aerosol-cloud-climate interactions in the Arctic. Here, the aerosol population was categorised via cluster analysis of aerosol size distributions taken at Mt Zeppelin (Svalbard) during a 11 year record (2000-2010) and at Station Nord (Greenland) during a 7 year period (2010-2016). Air mass trajectory analysis and atmospheric nitrogen and sulphur tracers link these frequent nucleation events to biogenic precursors released by open water and melting sea ice regions. The occurrence of such events across both temporal periods (2000-2010 and 2010-2016) are anti-correlated with sea ice extent.
Details of Secondary Aerosol Formation in the Polar Atmosphere

Lisa Beck¹ (lisa.beck@helsinki.fi), Clémence Rose¹, Ella-Maria Duplissy¹, Matthieu Riva¹, Federico Bianchi¹, Heikki Junninen¹,², Olga Garmash¹, Yee Jun Tham¹, Clara Hoppe³, Alexander Schulz⁴, Angelo Viola⁵, Vito Vitale⁶, Mauro Mazzola⁶, David Cappelletti⁶,⁷, Markku Kulmala¹, Veli-Matti Kerminen¹, Mikko Sipilä¹

¹University of Helsinki, Helsinki, Finland, ²University of Tartu, Tartu, Estonia, ³Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, ⁴Alfred Wegener Institute, Potsdam, Germany, ⁵Institute of Atmospheric Sciences and Climate - CNR, Rome, Italy, ⁶Institute of Atmospheric Sciences and Climate - CNR, Bologna, Italy, ⁷University of Perugia, Perugia, Italy

Secondary aerosol formation is globally contributing about 50% of cloud condensation nuclei. With increasing temperature, the emission of gases from the different spheres is changing, and therefore, the molecular composition of the atmosphere is changing as well.

For understanding to which extent the temperature rise and sea ice loss might contribute to future cloud formation and the radiation feedback, the mechanisms of secondary aerosol formation must be known. Therefore, we conducted a field campaign from March to August 2017 in Ny Ålesund, Svalbard. The key instrumentation included mass spectrometers for solving the molecular mechanism of particle formation. The known contributing gases to secondary aerosol formation in polar regions are sulphuric acid and iodic acid - detailed mechanisms are still only vaguely known. Changes in the phytoplankton dynamics, and sea ice extent will have an important effect on aerosol formation in those regions. To understand the effect of temperature change on secondary aerosol formation, all different spheres have to be taken into account. This study tries to combine all the components related to gas-to-particle conversion necessary for predicting the future behaviour of arctic clouds and climate.
Global warming of climate is connected to ecosystem change, especially in the Arctic ocean. Biogenic emissions of dimethylsulfide (DMS) are the main biogenic source of sulfate aerosols to the marine atmosphere and may make a rapid change in the Arctic due to the massive melting ice. Here we simulate DMS distributions and sea-to-air fluxes in the Barents Sea (30°W-40°E and 70°N-80°N) and Greenland Sea (20°W-10°E and 70°N-80°N) for the period 2003-2005. A genetic algorithm (GA) is used to calibrate the key parameters in the DMS model for both regions. Due to limitation of DMS observations in the Arctic Ocean, multiple data sources were used. Parameter sensitivity analysis were studied using a limit method. CMIP5 global model is used for obtaining the forcings for 4 CO2 conditions. DMS flux under quadrupled CO2 increases much more compared to late 20thC levels (1 CO2). The reason for the increase in DMS flux under 4 CO2 conditions is due to changes in sea surface temperature (SST), the sea ice melting and shoaling of the mixed layer depth (MLD). The double or tripling of DMS fluxes indicates that warming in the Arctic could be slowed through the controlling of greenhouse gases and changing of radiative budget associated with DMS derived aerosols.
A dominant Antarctic ecological paradigm suggests that winter sea ice is the feeding ground for larval Antarctic krill. Results from a late winter study in the northern Weddell Sea in combination with previous findings contradict this view and present the first evidence that although there’s abundant food in winter sea ice, it is not accessible for larval krill compared to food supply in neighbouring open water regions. Despite high biomass in winter sea ice, the growth rates of larval krill are constant low in winter pack ice regions. We found that complex under ice habitats are vital for larval krill, providing shelter from currents. During daytime the larvae feed on the sparse ice-associated food but after sunset, they migrate down into the water below the ice. This behaviour increases food uptake in a patchy food environment and ensures transport of larvae to spring feeding grounds in the Scotia Sea. Our study shows the first mechanistic linkage between larval krill and winter sea ice.
Long Dark Winters Thwart the Borealization of High Arctic Plankton Communities

Janne E. Søreide¹ (janne.soreide@unis.no), Tove M. Gabrielsen¹, Anna Vader¹, Ragnheid Skogseth², Malin Daase³, Jørgen Berge³, Kjetil Lygre⁴, Kasia Dmoch⁵, Katarzyna Blachowiak-Samolyk⁵, Ksenia Kosobokova⁶, Elena Druzhkova⁷, Igor Berchenko⁷, Pavel Makarevich⁷, Denis Moiseev⁷

Isfjorden Marine Observatory Svalbard (IMOS) is a long-term plankton time series from the largest fjord system in Svalbard, with data dating partly 20 years back. Hydrography, protist - and mesozooplankton are regularly sampled along a climate gradient from the ice-free outer fjord with Atlantic water influence to the seasonal ice covered inner fjord where local cold water of Arctic characteristics prevails. The high seasonal resolution of this time series makes it possible to disentangle natural variability in the plankton community from persistent changes caused by climate warming.

Microbial eukaryotes (0.45-10 µm size) display strong seasonality in community composition with rapid shifts during spring and summer, when also inter-annual differences are most apparent. In contrast, highly similar and stable communities are found during winter, suggesting a high degree of resilience in the system. The mesozooplankton community consists of a mix of boreal and Arctic species with a growing share of boreal ones towards the outer part of the fjord. The seasonal variability in community structure is higher than the inter-annual variability. While boreal species may be prominent during summer and autumn, the zooplankton community resets to a more Arctic community each winter. The long dark winter likely represent a bottleneck for survival of more temperate species. This may potentially thwart the Atlantification of the plankton community in the European Arctic.
Sensitivity and Adaptability of Antarctic Krill to a Warming Southern Ocean

Katharina Michael¹ (katharina.michael@uol.de), Wiebke Wessels¹, Rob King², So Kawaguchi², Bettina Meyer¹,3
¹Carl-von-Ossietzky University of Oldenburg, Institute for Chemistry and Biology of the Marine Environment, Oldenburg, Germany, ²Australian Antarctic Division, Kingston, Tasmania, Australia, ³Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany

Antarctic krill (Euphausia superba) is a key species in the marine Antarctic ecosystem due to its central position in the food web. As the krill's life cycle is characterized by a strong interplay between endogenous physiological processes and seasonal environmental factors, it is crucial to understand how increasing water temperatures affect these processes. However, physiological studies providing insights on the performance of Antarctic krill under climate-induced environmental changes are scarce. By combining physiological performance indicators with transcriptomic approaches, we aimed to identify effective mechanisms determining sensitivity as well as adaptability of this species to a warming Southern Ocean. The seasonal transcriptome of E. superba was compared to a de novo seasonal transcriptome of the closely related Northern krill (Meganyctiphanes norvegica). Furthermore, long-term acclimation of E. superba at different temperature scenarios during austral summer provided insights into the effects of elevated ambient temperatures on Antarctic krill physiology, enabling a first estimate of putative effects on whole animal energy status when facing upcoming winter season. Therefore, our data do not only provide a more detailed insight into krill thermal physiology but also determine the capacity of E. superba to cope with Southern Ocean warming.
Energetic Value of Zooplankton and Nekton of the Southern Ocean: A Review

Fokje L. Schaafsma1, Yves Cherel2, Hauke Flores3, Jan A. van Franeker1, Mary-Anne Lea4, Ben Raymond4,5, Rowan Treblico6, Andrea Walters4, Anton P. Van de Putte7 (anton.vandeputte@kuleuven.be)
1Wageningen Marine Research, Den Helder, Netherlands, 2Centre d’Etudes Biologiques de Chizé, Villiers-en-Bois, France, 3Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, 4Institute for Marine and Antarctic Studies, University of Tasmania, Hobart, Australia, 5Australian Antarctic Division, Kingston, Australia, 6Antarctic Climate and Ecosystems Cooperative Research Centre, University of Tasmania, Hobart, Australia, 7Royal Belgian Institute for Natural Sciences, Brussels, Belgium

The energy content of different prey items is an important factor in structuring food webs and relationships between species. Information on the energetic value of prey can be a key predictor of the behaviour and population dynamics of predators, trophic interactions between species and of energy flow through trophic levels. The Southern Ocean (SO) represents approximately 10% of the earth’s surface and is home to a variety of top predators such as birds, seals and whales, which forage on zooplankton and nekton species. The strong seasonality occurring in the SO, in combination with regional differences in environmental properties caused by latitude, currents and/or fronts, cause variations in the energetic density within a single species or between ecologically equivalent species. Here we present the results of a review on available energetic data that contributed to the Southern Ocean Diet and Energetics Database. This database is a product of the Expert Group on Antarctic Biodiversity Informatics (EG-ABI). Data that contributed to the review include summary data as published in scientific literature as well as individual measurements kindly provided by the authors on request. The data on individual measurements can help to better assess possible ontogenetic, spatial and temporal patterns. Furthermore, we provide an overview of knowledge gaps, possible uses of the data in larger ecosystem studies and consider implications for models.
Genomic Basis of Adaptation of the Southern Ocean Salp, *Salpa thompsoni*

Ann Bucklin¹ (ann.bucklin@uconn.edu), Kate Divito², Paola Batta-Lona³, Peter H. Wiebe⁴, Jennifer M. Questel⁵, Rachel J. O'Neill⁶

¹University of Connecticut, Marine Sciences, Groton, United States, ²University of Connecticut, Molecular and Cell Biology, Institute for Systems Genomics, Storrs, United States, ³CISESE, Biotecnologia Marina, Ensenada, Mexico, ⁴Woods Hole Oceanographic Institution, Biology, Woods Hole, United States, ⁵University of Connecticut, Marine Sciences, Groton CT, United States, ⁶University of Connecticut, Molecular and Cell Biology, Institute for Systems Genomics, Storrs, United States

The Antarctic salp, *Salpa thompsoni*, is an increasingly important player in the vulnerable Southern Ocean pelagic ecosystem. Field studies have documented rapid population growth resulting in dense blooms of salps that can displace other species, including the keystone Antarctic krill (*Euphausia superba*), and significantly perturb the pelagic ecosystem. We are developing new genomic resources, including a comprehensive reference genome, for the Antarctic salp to enable identification of genes and gene networks underlying physiological responses, including bloom formation. Our comparative genomic analysis is focused on novel aspects of genomic evolution found only in the invertebrate Class Tunicata and detailed characterization of genome evolution of *S. thompsoni*. We are examining evidence that rapid evolution of *S. thompsoni* orthologs (genes of the same function that share a common ancestor) is driven by positive selection, and that these genes and associated gene networks provide the basis for adaptation of the Antarctic salp to environmental conditions. Our results build upon our previously-published genomic resources and comparative transcriptomic data for this species, including de novo genome assembly, de novo transcriptome assembly, and small RNA analyses. Our results are yielding new understanding of the genomic basis of adaptation to environmental variation associated with climate change for the Antarctic salp.
Origin of CDW Intruding onto the Amundsen and Bellingshausen Sea Shelves

Yoshihiro Nakayama¹ (yoshihiro.nakayama@jpl.nasa.gov), Dimitris Menemenlis¹, Michael Schodlok¹², Eric Rignot¹³

¹Jet Propulsion Laboratory, California Institute of Technology, Pasadena, United States, ²University of California Los Angeles, Los Angeles, United States, ³University of California Irvine, Irvine, United States

The ice shelves and glaciers of the West Antarctic Ice Sheet are thinning rapidly, which is mainly caused by Circumpolar Deep Water (CDW) intruding onto the Amundsen and Bellingshausen Seas (ABS) continental shelves. Despite existing works on cross-shelf and on-shelf CDW transports, CDW pathways onto the ABS originating from further offshore have never been investigated. Here, we show that simulated CDW from the World Ocean Circulation Experiment (WOCE) S04P section (67ºS) circulates along the Antarctic Circumpolar Current (ACC) and Ross Gyre and travels into the ABS after 3-5 years. Simulated CDW warming off the ABS continental shelves in 2009-2014, consistent with limited observations available, is associated with different CDW pathways due to the strengthened Ross Gyre circulation and warmer temperature at the northern model boundary. Although wind over shelf and shelf-break areas has been commonly considered to control CDW intrusion, we conclude that the far field ocean properties and circulation control more than half of the off-shelf CDW warming in our model simulations, demonstrating a dominant link between large-scale atmospheric forcing and off-shelf CDW properties. Given the trend towards positive Southern Annular Mode causing a southern shift of the westerlies, the proposed mechanism may exert a dominant control on the on-shelf CDW intrusion and thus accelerate the retreat of West Antarctic glaciers and its impact on global sea level rise.
Impact of Glacial Meltwater on Ocean Warming and Antarctic Bottom Water

Alessandro Silvano1 (alessandro.silvano@utas.edu.au), Steve Rintoul2, Beatriz Pena-Molino3, Will Hobbs3, Esmeer Van Wijk2, Guy Williams1, Shigeru Aoki4, Takeshi Tamura5

1University of Tasmania / Institute for Marine and Antarctic Studies, Hobart, Australia, 2CSIRO Oceans & Atmosphere, Hobart, Australia, 3ACE CRC, Hobart, Australia, 4Hokkaido University, Sapporo, Australia, 5National Institute of Polar Research, Tachikawa, Japan

Strong heat loss and brine release during sea-ice formation in coastal polynyas act to cool and salinify waters on the Antarctic continental shelf. Polynya activity thus both limits the ocean heat flux to the Antarctic Ice Sheet and promotes formation of Dense Shelf Water (DSW), the precursor to Antarctic Bottom Water. However, despite the presence of strong polynyas, DSW is not formed on the Sabrina Coast in East Antarctica and in the Amundsen Sea in West Antarctica. Using a simple ocean model driven by observed forcing, we show that freshwater input from basal melt of ice shelves partially offsets the salt flux by sea-ice formation in polynyas found in both regions, preventing full-depth convection and formation of DSW. In the absence of deep convection, warm waters from the Southern Ocean can spread across the continental shelf at depth and reach the ice-shelf cavities to drive the rapid basal melt observed at the Totten Ice Shelf on the Sabrina Coast and at the Dotson and Getz ice shelves in the Amundsen Sea. Our results suggest that increased glacial-meltwater input in a warming climate will both reduce Antarctic Bottom Water formation and trigger increased mass loss from the Antarctic Ice Sheet, with consequences for the global overturning circulation and sea-level rise.
Large gyre systems are prominent features of the polar Southern Ocean. They form elongated cyclonic features south of the eastward-flowing Antarctic Circumpolar Current, and provide pathways between the World ocean basins and the main global production sites of abyssal water. The subpolar gyre intensity therefore plays a key role in climate as a “dam” that ultimately controls the rate of Antarctic Bottom Water entering the world’s ocean overturning circulation. Despite their potential key control on the Southern Ocean circulation, on water-mass pathway, and on the global overturning circulation, very little is known about Southern Ocean subpolar gyre. Here we use a novel observation database to investigate extent and seasonal variability of subpolar gyres in the Southern Ocean. We investigate the dynamics that sets their extent and variability using a combination of observation, as well as realistic and idealised models. Interestingly, the presence of sea-ice plays both a dynamical role in shaping the subpolar gyre structure, and thermodynamical role in driving seasonal variability of its strength. Variability and long-term change of sea-ice associated with a shift in wind regime might change strength, vertical structure, and extent of Southern Ocean subpolar gyres, with important consequences for the large-scale water-mass circulation.
Circulation Beneath Filchner-Ronne Ice Shelf and Exchange with Open Ocean

Tore Hattermann1,2 (tore.hattermann@awi.de), Peter Davis3, Keith W. Nicholls3, Svein Østerhus4, Elin Darelius5, Hartmut Hellmer6
1Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, 2Akvaplan-niva AS, Tromsø, Norway, 3British Antarctic Survey, Cambridge, United Kingdom, 4Uni Research, Bergen, Norway, 5University of Bergen, Bergen, Norway, 6Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

During the austral summer 2015/16 and 2016/17, seven oceanographic moorings were deployed through hot-water-drill holes located over the Filchner Trough east of Berkner Island. The aim was to investigate and monitor the processes determining the access of ocean heat to the ice base. The vertical structure beneath the southern part of the ice shelf is dominated by tidal mixing, and the water mass properties are related to the densest High Salinity Shelf Water (HSSW), which is known to be produced in front of the Ronne Ice Shelf. This water mass is observed to exit the cavity along the western flank of the Filchner Trough during parts of the year. In contrast, the northeastern part of the cavity is filled with HSSW and its Ice Shelf Water derivatives that have a local origin, in front of Filchner Ice Shelf. The preliminary time series shows that this less dense HSSW enters the cavity on the eastern side of the Filchner Trough during parts of the year, but seems to be trapped in the deep trough where it interacts laterally with derivatives of the Ronne-sourced HSSW; there is no evidence that it can penetrate to the deep southern grounding lines. The link of these two circulation regimes to different regions of dense water formation on the continental shelf needs to be taken into account, when investigating whether an inflow of warmer water in front of the Filchner Ice Shelf is important for basal melting today, and how that might change in a future climate.
Flow Paths of the Arctic Halocline and Atlantic Layer Derived from Tracer Data

Angelica Pasqualini¹ (ap@ldeo.columbia.edu), Peter Schlosser¹,²,³, Robert Newton³, Tobias N. Koffman³, Ronny Friedrich⁴

¹Columbia University, Department of Earth and Environmental Engineering, New York, United States, ²Columbia University, The Earth Institute of Columbia University, New York, United States, ³Columbia University, Lamont Doherty Earth Observatory, Palisades, United States, ⁴Curt-Engelhorn-Centre Archaeometry gGmbH, Mannheim, Germany

We present ³H/³He age and hydrographic data from 21 expeditions spanning 25 years of Arctic Ocean section work (1987 and 2013) to independently estimate spreading velocities, flow paths, and stability of upper and lower halocline waters (UHW and LHW), as well as the Atlantic Water branches on a pan-Arctic scale. Our results corroborate and add a time dimension to previously established circulation schemes. Tracer data confirm the presence of a well-organized boundary current that cyclonically flows along the continental slope and add insights into the other, typically topographically steered, circulation branches for the LHW and Atlantic layers. The circulation scheme for the UHW still shows similarities to those of the Atlantic layer but differs significantly in certain regions of the Arctic Ocean. Tracer data show that within the limits of our method the current system has been stable over the 25 years of observation. The results are discussed in the context of the temporal stability of the circulation in the Arctic Ocean, as well as regional variability of spreading velocities along individual branches of the circulation pattern due to topographic and dynamic forcing.
Polar Ocean State Estimation around the Greenland Ice Sheet

Ian Fenty¹ (ian.fenty@jpl.nasa.gov)
²NASA Jet Propulsion Laboratory, Pasadena, United States

Four-dimensional (space and time) ocean and ice data assimilation allows for the synthesis of diverse and temporally and spatially heterogeneous observational data with a numerical model to create a coherent representation of the coupled ocean, sea ice, and ice sheet system. This coherent representation of the time-evolving system, referred to a state estimate, is a dynamically-consistent reconstruction that is constrained to observations and their uncertainties in a least squares sense. In this talk I will describe recent progress, outstanding challenges, and future prospects of using four-dimensional data assimilation to reconstruct decadal changes in ocean circulation, temperature and salinity around the Greenland Ice Sheet with the goal of understanding the causes of increasing submarine melting of its tidewater glaciers. This effort supported by NASA’s Estimating the Circulation and Climate of the Oceans (ECCO) project and its Oceans Melting Greenland (OMG) mission.
Perturbations on the Stratosphere Due to Intense Geomagnetic Storms: Study Cases

Viviana Elisa López, Adriana Maria Gulisano, Sergio Dasso
Servicio Meteorológico Nacional, Ciudad Autónoma de Buenos Aires, Argentina, IAA/DNA, IAFA (UBA-CONICET), Depto de Física FCEyN UBA, Atmospheric Sciences Department, Vicente Lopez, BsAs, Argentina, IAFE (UBA-CONICET), DCAO FCEyN UBA, Depto de Física, Ciudad Autónoma de Buenos Aires, Argentina

We analyzed balloon sounding data gathered at the Argentinean Marambio Antarctic station from 1998 to 2016 (inclusive) by the National Meteorological Service of Argentina, in order to study the atmospheric profiles with height of temperature and pressure variables. During the study, and taking into account seasonality, we have found the associated climatology at Marambio station in order to compare the same profiles during 5 cases of intense geomagnetic storms (GS) where the balloon measurements where available. We compute the temperature anomalies for the day of the GS, and 14 days after the event at different height levels. The knowledge of the deviation of the seasonal profile during a geomagnetic storm will help to assess the possible deviation from the expected cosmic ray flux at the station during these GS events. The atmospheric profile with height is necessary to perform the Monte Carlo simulations of secondary cosmic rays showers, so this kind of study will help to improve them.

Temperature Variations of Polar Ionosphere during Stratospheric Sudden Warming

Yasunobu Ogawa1 (yogawa@nipr.ac.jp), Satonori Nozawa2, Masaki Tsutsumi1, Chris Hall3, Ingemar Haggstrom4

1National Institute of Polar Research / SOKENDAI, Tokyo, Japan, 2ISEE, Nagoya University, Nagoya, Japan, 3UiT The Arctic University of Norway, Tromso, Norway, 4EISCAT Scientific Association, Kiruna, Sweden

We analyzed ion temperature and velocity observed by the European Incoherent Scatter (EISCAT) UHF radar at Tromsoe (69.6°N, 19.2°E) during a stratospheric sudden warming (SSW) that occurred in January-February 2017. The zonal ion velocities at 85-100 km height reversed approximately 8 days earlier than the zonal wind reversal in the upper stratosphere and the ion temperature at 85-95 km decreased simultaneously with the zonal ion velocity reversal at the same altitude. We found that the time variations of ion temperature in the daytime are close to those of ambipolar diffusion coefficients derived from the Nippon/Norway Tromso Meteor Radar (NTMR) data at the same altitude even when geomagnetic activity is moderate. This suggests that the D- and lower E-region ion temperature in the daytime is a good proxy for neutral temperature at the same altitude. We will explain the reliable ion temperature derivation in the D-region and its limitation, and also discuss relationship between ion temperature and vertical ion velocity variations at 85-95 km measured with the EISCAT UHF radar.
Ionospheric Scintillation Climatology at Ny-Ålesund across Solar Cycle 23 and 24

Lucilla Alfonsi1 (lucilla.alfonsi@ingv.it), Luca Spogli2,3, Claudio Cesaroni2, Vincenzo Romano2,4, Ingrid Hunstad2, Giorgiana De Franceschi2
1Istituto Nazionale di Geofisica e Vulcanologia, Environment, Rome, Italy, 2Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy, 3Space Physics Laboratory, Earth Technology, Rome, Italy, 4SpacEarth Technology, Rome, Italy

INGV operates a network of GNSS receivers acquiring data at 50 Hz incorporating a firmware especially modified to provide several parameters useful to monitor the perturbations of the high latitudes upper atmosphere. In particular, the first GPS receiver was installed in 2003 at Ny-Ålesund (Svalbard Island, 78°55’N 11°55’E). Currently, three receivers are operating at Ny-Ålesund, recording GPS, GLONASS, Galileo signals. The analysis exploits the scintillation parameters (S4 and sf), TEC and its rate of change (ROT) measured by INGV receivers to study the behaviour of the high latitudes ionosphere during the different phase of a solar cycle. The analysis is supported by the climatological reconstruction of the probability of the scintillation occurrence sorted also according different conditions of the geospace and of the geomagnetic field. This would enable to infer the relationship between the physical processes ruling the morphology of the high latitudes ionosphere and the amplitude and phase scintillations on GNSS signals. The knowledge of such relationship is necessary in view of a long term forecasting of the disruptive effects of the ionosphere on the L-band signals affecting the applications based on GNSS such as precise positioning and navigation. Moreover, a climatology of the scintillation over Galileo signals is here provided for the first time in the high latitude European sector.
Energetic particle precipitation generates perturbations in the abundance of various neutral and ionic species in the polar mesosphere-lower thermosphere, partly through a complex ion cluster chemistry. In particular, mesospheric polar nitric acid enhancements have been attributed to energetic electron precipitation (EEP). We investigate such nitric acid enhancements following a series of EEP events during April and May 2010 with WACCM-D, a recently developed variant of the Whole Atmosphere Community Climate Model (WACCM) that includes a sophisticated ion chemistry of the D-layer of the ionosphere (50-90 km). Whereas the standard WACCM includes only 5 positive ions, WACCM-D comprises 21 negative ions and 20 positive ions. Using the specified-dynamics mode, we perform a one-year long simulation and contrast WACCM-D with the standard WACCM. Both simulations are performed with and without a forcing by medium-to-high energy electrons. We demonstrate the effects of the EEP events on nitric acid and on key ion cluster species, as well as other key species of the nitrogen family. The one-year long simulation allows placing the event-related changes in key neutral and ionic species in the context of their annual cycle. We especially highlight the important role played by medium-to-high energy electrons in triggering ion cluster chemistry in the mesosphere and lower thermosphere, leading to the production of nitric acid through the ion-ion recombinations.
Surveys of 557.7/630.0-nm Dayside Auroral Emissions in Arctic and Antarctica

Zejun Hu1 (huzejun@pric.org.cn), Huigen Yang1, Hongqiao Hu1, Beichen Zhang1
1Polar Research Institute of China, SOA Key Laboratory for Polar Science, Shanghai, China

The synoptic distributions of dayside aurora in the Northern and Southern Hemispheres, acquired from all-sky imagers at Yellow River Station in Arctic and South Pole Station in Antarctica, respectively, present the same two-peak structure, namely, the prenoon 09:00 MLT and postnoon 14:00-15:00 MLT peaks. The auroral intensity presents a hemispheric asymmetry, i.e., the postnoon intensity is less than the prenoon intensity in the Southern Hemisphere but more in the Northern Hemisphere. The hemispheric asymmetry is not changed with the change of IMF’s polarity. We suggested that 1) the two-peak structure in the dayside oval are predominantly related with the prenoon/postnoon antiparallel reconnection in high-latitude magnetopause produced to the prenoon and postnoon peaks; 2) the IMF By should modulate the dayside aurora through the inter-hemispheric current, which is produced by a north-south oriented electric field, and changing the distribution of midday R0-R1 current; 3) the opposite prenoon-postnoon asymmetries of dayside auroral distributions in the two hemispheres are the combined effect of the prenoon-postnoon variations of the magnetosheath density and the variation of the local ionospheric conductivity in the two ground-based observatories.
Unusual Amplitude Scintillation on GNSS Signals Recorded in Antarctica

Giulia D’Angelo¹ (giu.dangelo8@gmail.com), Mirko Piersanti²,³, Lucilla Alfonsi⁴, Luca Spogli⁴,⁵, Claudio Cesaroni⁶, Lasse Boy Novock Clausen⁶, Ingrid Hunstad⁴, Vincenzo Romano⁴,⁵, Pierre Cilliers⁷

¹Roma Tre University, Mathematics and Physics Department, ROMA, Italy, ²Università di L’Aquila, Dipartimento di Scienze Fisiche e Chimiche, L’Aquila, Italy, ³Università di L’Aquila, Consorzio Area di Ricerca in Astrogeofisica, L’Aquila, Italy, ⁴Istituto Nazionale di Geofisica e Vulcanologia, Roma, Italy, ⁵SpacEarth Technology, Roma, Italy, ⁶University of Oslo, Department of Physics, Oslo, Norway, ⁷South African National Space Agency, Hermanus, South Africa

The storm onset on September 7, 2017 triggered several electron density fluctuations in the ionosphere causing severe phase scintillations at polar latitudes in both hemispheres. Concurrently, unusual amplitude scintillations were also recorded in Antarctica. At high latitudes, indeed, scintillations on the GNSS signal phase are expected to be more frequent than those on the amplitude. This is due to the higher reaction of the GNSS signal phase to the complex plasma dynamics caused by the coupling between the Interplanetary Magnetic Field (IMF) and the Earth’s magnetic field, which directly exposes the high latitude ionosphere to the solar wind variability. This work investigates the physical mechanisms triggering the observed amplitude scintillations. In particular, leveraging on observations provided by receivers located at Concordia (75.10°S, 123.35°E), Mario Zucchelli (74.41°S, 164.10°E) and SANAE (71.68°S, 2.83°O) stations, supported by ancillary data, we reconstruct the scenario in which irregularities form, move and trigger both amplitude and phase scintillation. Our study includes scintillations derived from GPS, GLONASS and Galileo data.
Environmentally Adaptive Acoustic Navigation and Communication in the New Arctic

Henrik Schmidt1 (henrik@mit.edu)
1Massachusetts Institute of Technology, Mechanical Engineering, Cambridge, United States

The climate change induced enhancement of the “Beaufort Lens”, a warm water layer penetrating from the Bering Strait, has severe implications for under-ice acoustic sensing, communication and navigation. As part of the ICEX16 US Navy Exercise, an AUV with a towed hydrophone array was used for assessing the associated changes to the undersea ambient noise environment. The AUV operation depended on navigation updates from the submarine tracking range being communicated to the vehicle for fusion with the onboard inertial navigation. However, the tracking performance was severely deteriorated compared earlier deployments, to the presence of the warm layer, which creates a double duct environment with severe shadow zones for shallow sources and receivers. In addition, the dominant ice mechanical sources for the ambient noise has dramatically changed due to the reduced average thickness and the associated ice mechanics. As a combined effect of these environmental changes, the spatial and temporal signal/noise budget is fundamentally changed, characterized by robust environmental features that may be exploited by unmanned underwater vehicles. This paper describes the environmental effects observed and discusses how robust acoustic connectivity in requires manned or unmanned under-ice platforms to be capable of using their mobility to adapt to the environment for reliable sensing, communication and navigation [Work supported by ONR and DARPA].
A Decade of Under-ice Operations by Long-endurance Seagliders

Craig M. Lee¹ (craig@apl.washington.edu), Jason Gobat¹, Luc Rainville¹
¹University of Washington, Applied Physics Laboratory, Seattle, United States

Over the past decade, the long-endurance, buoyancy-driven autonomous underwater vehicle Seaglider has successfully completed a range of Arctic and Antarctic science missions that have included extended, multi-month operation beneath ice. Early developments began in 2004, targeting year-round operation in the seasonally ice-covered Davis Strait, a critical gateway connecting the Arctic with the Subpolar North Atlantic. Seaglider capabilities were augmented with enhanced autonomy, ice detection and avoidance, and real-time acoustic navigation. First-generation ice-capable Seagliders geolocated by multi-lateration from an array of 780-Hz RAFOS acoustic sources. Seaglider’s first extended (hundreds of kilometers) under-ice transits occurred in 2008, followed by year-round occupation of Davis Strait and a multi-day transit, without acoustic navigation, under the ice bridge separating the Ross ice self from the Ross Sea Polynya in 2010. Continued development has included enhanced autonomy and navigation, and integration of a broadband acoustic source capable of encoding information onto the navigation signal. These advances opened new operational possibilities, including a 2014 experiment that employed four Seagliders to sample the marginal ice zone of the Beaufort Sea. This presentation will review the history of Seaglider missions under ice and the technological developments undertaken to enable them, and discuss ongoing missions and future plans for ice-capable Seagliders.
The Polar-ARV Unmanned Underwater Vehicle and Investigation of Sea Ice in Arctic

Shuo Li1 (shuoli@sia.cn), Junbao Zeng1, Yuangui Tang1, Yiping Li1
1Shenyang Institute of Automation, Chinese Academy of Sciences, Shenyang, China

Pole-ARV is a UUV used for observation under sea ice in Arctic, it has both the characteristics of AUV and ROV with onboard power and optical fiber technology, its scientific payloads include radiometer, CTD, altimeter, cameras and pressure sensor. Pole-ARV has been deployed in the Chinese Arctic expedition for three times since it was developed in 2008. The vehicle's maiden sub-ice voyage occurred during the summer of 2008 and the control system and sub-ice navigation system was tested. In 2010 the Polar-ARV was launched and recovered from an ice hole in the ice station, and collected a lot of scientific data, include ice thickness, spectral irradiance, video, photo, conductivity, temperature, pressure etc. Its volume and weight of the vehicle was reduced for field application after this deployment. In 2014, Polar-ARV was deployed in the 6th Chinese Arctic expedition. It surveyed under designated ice area for three times and got a detail ice draft based on the ice thickness and 3D spatial distribution of spectral irradiance. Recently we are just upgrading the Polar-ARV, and are now preparing for a 2018 deployment in Arctic to test the acoustic system and perform sub-ice investigation mission. The acoustic system includes a long range homing system, short range localization system and acoustic propagation system. In future, we plan to expand the operating range of Polar-ARV, and equip more sensors on it, such as multi-beam sonar.
The West Spitsbergen Current in summer 2017

Marie-Noelle Houssais¹ (mnh@locean-ipsl.upmc.fr), Agnieszka Beszczynska-Möller², Christophe Herbaut¹, Pierre Testor¹, Laurent Mortier¹, Jean-Luc Fuda³, Jeanne Melkonian³, Hassane BenabdelMoumene¹, Pierrette Dufoventelle⁴

¹UPMC/LOCEAN, Paris, France, ²Polish Academy of Sciences/Institute of Oceanology, Sopot, Poland, ³CNRS/Division Technique INSU, La Seyne sur Mer, France, ⁴IFREMER/Centre Méditerranée, La Seyne sur Mer, France

The flow of Atlantic Water through Fram Strait is the main provider of heat to the Arctic Ocean. The poleward transport in the strait is achieved mostly by the West Spitsbergen Current, which flows as a slope current over the Svalbard shelf and slope. Repeat glider sections were carried out in July-September 2017 across the eastern Fram Strait as part of the EU-H2020 INTAROS project. These measurements aimed at monitoring the cross-slope structure of the West Spitsbergen Current and identifying possible mesoscale features and recirculation. Combining the glider data with results from a high-resolution sea ice-ocean model allows us to characterize the time-space structure of the eddies and to estimate their contribution to the flow of Atlantic Water which is diverted westward and possibly recirculates southward in the strait. The variability of the recirculated transport will be analyzed in relation to the interannual variability of the volume and heat transports, which eventually enters the Arctic Ocean through Fram Strait.
The Southern Ocean’s surface boundary layer plays a key role in the exchange of heat and carbon between the atmosphere and the ocean interior. Submesoscale motions strongly impact mixed layer depths and vertical velocities, but observations that resolve these scales in the Antarctic Circumpolar Current (ACC) are extremely limited. We present observations from multiple glider deployments in Drake Passage for both summer (December 2014 - March 2015) and winter (May - August 2016) periods. The gliders provided persistent measurements of the ACC’s frontal structure over the shelf and slope in southern Drake Passage, and completed multiple crossing of the Polar Front during the 2016 deployment. These observations provide a comprehensive view of surface and bottom boundary layer variability in this region. This presentation will summarize the major results of the project, which include:

(i) observations of strong eddy-induced subduction of shelf properties across the continental shelf break that sustains an off-shore subsurface chlorophyll maximum;
(ii) abrupt spatial transitions, modulated by topography, in how submesoscale motions influence mixed layer depths;
(iii) strong turbulent mixing and water mass modification arising from submesoscale symmetric instability in bottom boundary layers over the continental slope;
(iv) seasonal variations in submesoscale eddy mixing lengths and subduction properties at the Southern ACC Front (SACCF) and Polar Front.
Marginal ice zones (MIzs) are characterized by the complex and dynamic interaction between the atmosphere, the ice, and the ocean. These high dynamics put MIzs among the - biologically - most productive regions of the world ocean and make them an ideal place to investigate the coupling between physics and ecology. Fostered by the last decades’ technological progress in robotics and sensor technology, marine sciences are increasingly able to investigate these processes, which occur on very small scales - both temporal and spatial. The Alfred Wegener Institute (AWI) has regularly operated its Autonomous Underwater Vehicle (AUV) “PAUL” in the Arctic and especially in the MIZ of the Fram Strait since 2009. Starting in 2011 / 2012 AWI has also used Unmanned Aerial Vehicles (UAVs) to support AUV operations and gather a holistic picture of the investigated area. In our talk we will give an overview on the equipment and infrastructure used to support our AUV dives including an UAV for operations at high latitudes. We will present technical details of our vehicle’s scientific payload which is specifically designed to study the physical dynamics of the marginal ice zone and its ecological response.
Effects of Snow Grain Shape on Climate Simulations with NorESM

Petri Räisänen\textsuperscript{1} (petri.raisanen@fmi.fi), Risto Makkonen\textsuperscript{2}, Alf Kirkevåg\textsuperscript{3}, Jens B. Debernard\textsuperscript{3}
\textsuperscript{1}Finnish Meteorological Institute, Helsinki, Finland, \textsuperscript{2}University of Helsinki, Dept. of Physics, Helsinki, Finland, \textsuperscript{3}Norwegian Meteorological Institute, Oslo, Norway

Snow consists of non-spherical grains of various shapes and sizes. Still, in climate model snow albedo calculations and many other radiative transfer applications, snow grains are often treated as spherical. We evaluate the effects of snow grain shape on climate simulated by the Norwegian Earth System Model (NorESM) in a slab ocean configuration of the model. An experiment with spherical snow grains (SPH) is compared with another (NONSPH) in which the snow shortwave single-scattering properties are based on a combination of three non-spherical snow grain shapes, optimized using measurements of angular scattering by blowing snow. The key difference between these treatments is that the asymmetry parameter is smaller in the non-spherical case (0.77-0.78 in the visible region) than in the spherical case (0.89). Therefore, for a given snow grain size, the use of non-spherical snow grains leads to a higher snow broadband albedo, typically by 0.02-0.03. Considering the spherical case as the baseline, this results in an instantaneous negative change in net shortwave radiation, with a global-mean top-of-the-model value of -0.22 Wm\textsuperscript{-2}. The effects on climate simulated by NorESM are, however, larger than what one would expect based on the global-mean radiative effect. The global annual-mean 2-m air temperature in NONSPH is 1.17 K lower than in SPH, with substantially larger differences at high latitudes. The climatic response is amplified by strong snow and sea ice feedbacks.
Dual Frequency Radar Altimetry - Measuring Greenland Firn Properties from Space

Sebastian B. Simonsen¹ (ssim@space.dtu.dk), Louise Sandberg Sørensen¹, Lars Stenseng², Rene Forsberg¹
¹DTU Space - National Space Institute, Geodynamics, Kongens Lyngby, Denmark, ²DTU Space - National Space Institute, Geodesy, Kongens Lyngby, Denmark

For the last seven years the ESA CryoSat-2 Ku-band radar altimeter has been measuring the elevation of the Greenland Ice Sheet. Ku-band enables surface penetration at firn covered areas, which hampers the direct interpretation of surface elevation change from Cryosat-2 and other Ku-band altimeters. However, mapping the changes in penetration depth can provide information on firn stratigraphy. If the physical surface (snow/air interface) of the ice sheet can be determined from an independent source, the differences in the two surfaces may directly be linked to the penetration depth of Ku-band radar altimetry, and hence to the temperature and density of the upper firn.

Here, we use independent estimates of the surface elevation changes from the Ka-band radar altimeter (AltiKa) operated onboard the French/Indian satellite SARAL. The higher frequency of Ka-band reduces surface penetration to a minimum and combining the records from both Ku- and Ka-band satellites is the key to utilizing the full potential of CryoSat-2. Hence, providing both high spatial-resolution surface elevation change and insights into changes in firn properties. The interpretation of dual-frequency altimetry is supported by firn modeling. The model has previously been applied to gain mass balance from ICESat, and is now updated with a conceptual model for Ku-band radar penetration.

Ultimately, a dual-band radar altimeter operating from space may provide ice sheet wide measurements of firn densities.
Snow-air Exchange and its Influence on Preservation of Climate Signals in Ice

Abigail Thayer\textsuperscript{1}, Hans Christian Steen-Larsen\textsuperscript{2} (hans.christian.steen-larsen@uib.no), Maria Hörhold\textsuperscript{3}, Sepp Kipfstuhl\textsuperscript{3}, Bruce Vaughn\textsuperscript{1}, James White\textsuperscript{1}

\textsuperscript{1}University of Colorado Boulder, Institute of Arctic and Alpine Research, Boulder, United States, \textsuperscript{2}University of Copenhagen, Center for Ice and Climate, Copenhagen, Denmark, \textsuperscript{3}Alfred Wegener Institute, Bremerhaven, Germany

Water isotopes in ice cores have been used for decades as a temperature proxy in Greenland and Antarctica to provide information about past climate. However, there are still deficiencies in our knowledge about how post-depositional processes influence the recorded water isotope signal. It is unclear why water isotopes reflect continuous temperature changes when depositional snow events have a seasonal bias and can be separated by weeks or months. Recent studies have shown that surface snow isotopes exhibit intra-day to inter-day variations in parallel with near-surface atmospheric water vapor isotopes, suggesting that the snowpack is more closely tracking atmospheric conditions such as near-surface temperatures.

A study at the EGRIP field camp (North-East Greenland) in July 2017 showed that over a 40-hour period, surface snow experienced sublimation and interaction with near-surface atmospheric water vapor, changing the snow isotopic composition. A series of lab experiments conducted in a controlled environment in Fall 2017 will better quantify the acting processes, by filling a sealed chamber with homogeneous snow and an inflow of isotopically- and humidity-controlled vapor. Continuous laser-based measurements of water vapor are used to monitor changes in the air, and snow samples are measured over the duration of multiple-day periods. Effects such as wind and thermal gradients in the snow can be simulated to better understand natural processes taking place on the ice sheet.
Measurement and Modelling of Tundra Snowpack Structure

Richard Essery¹ (richard.essery@ed.ac.uk), Nick Rutter²
¹University of Edinburgh, School of GeoSciences, Edinburgh, United Kingdom, ²Northumbria University, Newcastle, United Kingdom

Shallow tundra snowpacks subject to strong winds and strong vertical temperature gradients have distinctive structures, with basal layers of large faceted grains overlain by hard fine-grained slabs. The physical properties of these layers differ greatly in how they control, amongst other processes, conduction of heat and scattering of microwave radiation; these are important for determining the amount of snow on the ground by remote sensing and the influence of that snow on ground - atmosphere heat exchanges for numerical weather prediction. Even the most sophisticated current snow physics models, which have largely been developed for alpine applications, are known to perform poorly in reproducing tundra snowpack structures. A Year of Polar Prediction / UK-Canada Arctic Partnership experiment will be conducted in the Canadian Northwest Territories during March 2018 to combine ground measurements of vertical microstructure and horizontal topographic variations in snow with airborne microwave measurements. Preliminary measurement and modelling results will be presented.
Evolution in Geometry of Firn in Ice Sheets Detected by Dielectric Anisotropy

Shuji Fujita¹ (sfujita@nipr.ac.jp), Koaro Fukui², Motohiro Hirabayashi³, Yoshinori Iizuka⁴, Sumito Matoba⁴, Atsushi Miyamoto⁵, Hideaki Motoyama¹, Takeshi Saito⁶, Toshitaka Suzuki⁶
¹National Institute for Polar Research / SOKENDAI, Tachikawa, Japan, ²Tateyama Caldera Sabo Museum, Tateyama-machi, Japan, ³National Institute for Polar Research, Tachikawa, Japan, ⁴Institute of Low Temperature Science, Hokkaido University, Sapporo, Japan, ⁵Institute for the Advancement of Higher Education, Hokkaido University, Sapporo, Japan, ⁶Yamagata University, Yamagata, Japan

Ice in polar ice sheets once experience a state of firn at near-surface depths. Therefore, it is important to understand physical processes of firn formation, metamorphism and deformation for ice core studies. We investigated firn through measurement of tensorial values of the dielectric permittivity at microwave and millimeter-wave frequencies. This method can detect presence and strength of anisotropic structure in the geometry of pore spaces and ice matrix. We applied the method to many firn cores drilled at both ice sheets. We find that firn that have shorter residence time at the near-surface depths does not form strong vertical anisotropy that is caused by vertical movement of moistures. In contrast, firn that have longer residence time at the near-surface depths tend to form vertical anisotropy. When density exceeds more than ~600 kg/m³, a common feature of firn at many polar sites is that there are evolution of vertically elongated features of pore spaces in firn despite growth of vertical compression. We hypothesize an explanation as follows. As firn becomes denser, air within firn needs to "escape" to upward directions as compared to sinking firn. In firn, porous structure tends to have vertically elongated structure because of this vertical escape movement of air. The observed phenomena of the growth of the vertical dielectric anisotropy can be understood by this vertical movement of the air within firn.
Long-term monitoring of the subsurface processes taking place in snow and firn presents a significant technological challenge. Many in situ observational studies cover only short time intervals, or rely on sensors connected to surface dataloggers. Wired sensors connected to the surface may impact the physical processes within the firn, resulting in altered percolation pathways and the potential formation of artificial ice pipes or ice lenses. Here, we present results from a measurement campaign conducted with a suite of small (50 mm diameter) wireless sensors (ETracer+) that continuously transmit information on temperature, pressure and electrical conductivity (as a proxy for meltwater presence and solute content). The tested sensor platforms are small, robust and low cost, and communicate data via a very high frequency (VHF) radio link to surface receivers. The sensors can accurately log subsurface temperatures, and transmit the recorded data through up to 150 m firn.

The sensors were deployed in the upper 15 cm snow layer at the East Greenland Ice Core Project campsite in northeastern Greenland. Tests demonstrated that the sensors are capable of prolonged operation in low temperature environments, accurate measurement of subsurface temperatures, and of detecting meltwater pulses within otherwise dry firn. Our results show that wireless sensors have great potential for long term monitoring of sub-surface processes in firn.
New Arctic Straits and Islands and their Potential Influence on Human Activity

Wieslaw Ziaja¹ (wieslaw.ziaja@uj.edu.pl), Krzysztof Ostafin²
¹Jagiellonian University, Institute of Geography and Spatial Management, Krakow, Poland

32 new islands (each above 0.5 km²) appeared due to recession of Arctic glaciers under climate warming since the 1960s. Analysis of satellite images was a basic method of recognizing them. The islands' origin is a final stage of a process which began in the 20th century. They appear in the coasts where bedrock elevations above the sea are surrounded by depressions below its level, filled (at least from a land-side) with glaciers. Their recession leads to flooding the depressions by sea water and thus origin of new straits separating them from a mainland. Such new islands appear in Greenland and the European Arctic. Their ecosystems accommodate to new environmental conditions. In the nearest future, this process will be: - intensified in a case of further warming, - continued if climate will stabilize, - stopped after light cooling, - reversed after heavy cooling. All the new straits will become new sea-ways. Most of them will be of a local significance for an off-shore coastal traffic. However, a few new straits may become important for a state or international traffic, shortening important Arctic sea-ways. Such a new potential strait across the today's southern Spitsbergen - which may appear due to connection of the Hornsund and Hambergbukta fjords - would be of a great political-economic and ecological importance. It would become a useful way for ships going from west to the Barents Sea (to the eastern Spitsbergen coast, eastern Svalbard islands, Franz Josef Land, etc.).
Engaging Youth to Envision and Advance Sustainability in Arctic Russia

Andrey Petrov¹ (andrey.petrov@uni.edu), Tatiana Vlasova², V Volkov², Nikita Kaplin³, Varvara Korkina¹, Diane Hirshberg⁴, Joan Nymand Larsen⁵

¹University of Northern Iowa, Cedar Falls, United States, ²Russian Academy of Science, Moscow, Russian Federation, ³ARUN- Evenki Municipal District, Tura, Russian Federation, ⁴University of Alaska Anchorage, Anchorage, United States, ⁵Stefansson Arctic Institute, Akureyri, Iceland

In order to ensure that the perspectives of youth are included in the investigation of sustainability issues, it is critical to involve youth directly in the research process. Involving youth as co-researchers ensures true participation and a ‘voice’ in both identifying relevant issues and determining appropriate solutions. The ability to manage and control social-ecological processes with active participation of young people is a key factor in achieving social-ecological resilience and sustainability. This paper presents the results of a youth engagement project to explore youth perspectives on these processes, using multiple methods including semi-structured interviews, quantitative data on key sustainability indicators and scenario planning. The project includes young people aged 15-29 from different regions of the Russian Arctic: Evenkia, Murmansk, Yakutia, and Chukotka. These regions and communities differ in terms of status (capital/regional center, village) natural-climatic conditions) and most importantly, access to transport and communication infrastructure, and thus provide good examples for comparing the relations between perceived quality of life and regional Arctic specific. The analysis helps to identify key indicators to monitor issues of the Arctic social-ecological sustainability facing Arctic youth and important steps for their solution.
How Does Change Actually Affect Arctic Communities?

Henry Huntington\(^1\) (hph@alaska.net)  
\(^1\)Huntington Consulting, Eagle River, AK, United States

We know that Arctic communities are experiencing rapid and far-reaching social, cultural, economic, environmental, and climatic changes. These changes in turn have had many effects on the communities and their residents, and are predicted to have many more. The closer we look at cause-and-effect relationships, however, the less clear the picture becomes. Using Arctic Alaska as one example, there is no evidence of demographic effects from climate change or other notable shocks to the social-ecological system. To the contrary, despite high reliance on traditional hunting and fishing, human outcomes appear de-coupled from environmental influences. Among the possible explanations are robust innovation that creates new opportunities, suffering that is not apparent in standard demographic metrics, and the use of reserves or subsidies as a buffer against negative effects. Each explanation has distinct implications for policies and practices aimed at achieving sustainability or resilience, a topic worthy of further study. We cannot rely on innovation, but neither can we expect communities to respond to change in mechanical and inevitable ways. Hidden suffering needs to be recognized to avoid undermining long-term sustainability. Buffers, too, need to be understood for what they are, so that they are used effectively rather than exhausted before long-term changes are made. This presentation will use examples from recent research to explore these ideas.
Socio-economic Changes in Mining Communities of Murmansk Region, Arctic Russia

Yulia Zaika1 (yzaika@inbox.ru)

1Lomonosov Moscow State University, Faculty of Geography, Khibiny Research Station, Kirovsk, Russian Federation

Murmansk region is the part of Arctic zone of Russian Federation; and is one of the most heavily industrialized. Among other Arctic territories of Russia, region holds the first place by number of single-industry cities. At present 1/3 of region’s urban population live and work in single-industry cities and set up the greatest industrial potential for socioeconomic development of this area. The most part of regions’ single-industry cities has a mining profile allocating several “industry big-player” companies. Along with its resource role Murmansk region is also perceived by the government as the model territory for the current socio-economic and more innovative way of development. Moreover it plays an international role as well by being the part of the Barents Euro-Arctic region. Even though there are a lot of positive changes in the state regulatory system and mechanisms such as development of regional and municipal territories with special financial regimes for investment projects, there are also some uncertainties and factors which deepen the disparity of socio-economic development within region. One of the ways to overcome this can be spatial development of territory. The most dramatic trend of the past 10 years in Murmansk region is depopulation which leads to the compression of socioeconomic and demographic space of the region. Nevertheless, such a compression can force the consolidation of social and economic resources which will be discussed during the conference.
An Arctic Village Facing New Socio-economic Transformations: Teriberka, Russia

Gleb Kraev¹ (kraevg@gmail.com), Jessica Graybill², Andrey Petrov³
¹Russian Academy of Sciences, Center of Forest Ecology and Productivity, Moscow, Russian Federation, ²Colgate University, Hamilton, Hamilton, United States, ³University of Northern Iowa/IASSA, Cedar Falls, United States

This study documents and analyzes recent socio-economic and socio-ecological transformations of the coastal village of Teriberka in the Barents region of Russia. Teriberka is undergoing rapid and potentially radical change due to external pressures generated by various outside interests. Since the mid-20th century it experienced a number of boom and bust cycles: the rise and fall of shipyards and the fishing industry, construction and operation of hydropower facilities, and infrastructure development for the now-frozen Shtokman gas project. Since 2014, after the award-winning film "Leviathan" was produced there, the village has become an International tourist attraction, bringing thousands of visitors annually and building new hotels and restaurants. In 2016 it was designated as a priority development settlement meaning the regional government decides what investments are “appropriate” and how the settlement should look like. The local people are to be displaced and resettled while the region benefits from touristic, and bioresources processing development. Disappointed and clustered local commune quietly disavows the changes, but cannot make an offer of any alternative. Is “Leviathan” script being literally reproduced this time? Our socio-ecological study, employing interview, focus group, and environmental science methods, and community meeting allowed introduction of changes to the new area development plan.
Svalbard is at a historical crossroads, with five former coalmining settlements in states of transition simultaneously. The Norwegian government’s 2017-2018 budget proposition for Svalbard calls for the de facto end of coalmining, which has been Norway’s primary means of effective occupation for over 100 years. Following a 2016 white paper, which signaled such a direction for Svalbard policy, the proposed budget entails the abandonment of Sveagruva, major changes in the socio-economic foundation of Longyearbyen and significant reorganization in Ny-Ålesund. Similarly, the Russian coalmining settlements at Svalbard are in different stages of transition to post-mining. In future visions for Barentsburg and Pyramiden, scientific research, tourism and cultural heritage are cornerstones. The process underway on Svalbard provides a point of departure for exploring how areas based on resource extraction in the Arctic can transition to post-extraction futures. To analyze this process, we draw upon research on the sustainable development of former Arctic mining communities within the Mistra Arctic Sustainable Development program and the Nordic Centre of Excellence REXSAC—Resource Extraction and Sustainable Arctic Communities. Research has included document analysis, interviews and contemporary archeological fieldwork on Svalbard and other Arctic locations. The paper provides an overarching analysis of Svalbard’s post-coal future, built on five case studies of settlements in transition.
Paleoclimate records of climate change from northeast Arctic Russia (Lake El'gygytgyn) and Antarctica over the past 3-4 Million years provide a new opportunity for understanding the sensitivity of the polar regions to forcings involving natural greenhouse gas variability, changing orbital configurations and associated feedbacks. While geography and transient atmospheric CO2 in excess of preindustrial levels can explain most of the Pliocene warming, the occurrence of Arctic super interglacials without clear pacing documented over the past 2.78 Myrs requires additional explanation. We hypothesize that super interglacials in the Arctic correspond with extremes in insolation leading to the demise of the WAIS. During MIS 11c, 31, 49, 55, 77, 87, 91, and 93 Milankovitch forcing coinciding with extreme lows in eccentricity and high obliquity likely preconditioned the Earth system to synchronize summer melt intensity and duration to produce bipolar warming. This warming likely led to the demise of the WAIS in the Southern Hemisphere and super interglacials in the Arctic Northern Hemisphere. Diatomite layers in the ANDRILL AND-1B record coincide reasonably well super interglacials (Melles et al, 2012) but unconformities in the AND-1B cores prevent direct correlation. The challenge has been to understand how these high latitude sites are linked with changes in ocean circulation and heat transport.
A Transantarctic View of the Plio-Pleistocene East Antarctic Ice Sheet
Rachel Bertram¹, Tina van de Flierdt², Richard Levy³ (r.levy@gns.cri.nz), Rob McKay⁴
¹Imperial College London, London, United Kingdom, ²Imperial College London, Earth Science and Engineering, London, United Kingdom, ³GNS Science, Wellington, New Zealand, ⁴Victoria University of Wellington, Wellington, New Zealand

The East Antarctic Ice Sheet likely underwent some prominent changes as a result of global cooling from the mid- to late-Pliocene, yet direct evidence from the Antarctic ice margin is sparse. We here present new geochemical provenance analyses on Plio-Pleistocene marine sediment from the CIROS-2 drill site at the mouth of the Ferrar Glacier in the Transantarctic Mountains. Stratigraphic and sedimentological analysis revealed alternating sequences of diamictites and mudstones, interpreted as glacial and interglacial deposits respectively. New radiogenic isotope analyses show distinct provenance variations between these units, which can be directly compared to exposed bedrock samples from the vicinity of the Ferrar Glacier valley. Diamictites are characterised by locally-sourced material throughout the core, while mudstones from the early- to mid-Pliocene show an integrated provenance signature representative of additional lithologies located upstream within the Ferrar Glacier valley. We observe a fundamental shift in the provenance of the interglacial mudstones at ~3 Ma. A more local erosional source in younger sediments may indicate that the ice sheet margin became increasingly stable in the late Pliocene. Comparison of this new CIROS-2 record with other sites in the vicinity (e.g. ANDRILL, IODP Sites U1361 and 1165) will help to build a spatial understanding of the East Antarctic ice sheet at this crucial climate transition.
The mid Pliocene (3.3 -3 Ma) has long been considered an analogue for future warming scenarios with climate conditions of 400 ppm pCO2, temperatures 2-3 °C higher-than-present and a lack of large-scale ice sheets in the Northern Hemisphere. We present a direct and continuous sea-level record, from a shallow marine margin, Whanganui Basin, New Zealand, derived from a newly developed grainsize water-depth relationship. An integrated age model, independent of the global benthic δ18O stack, was developed from paleomagnetostratigraphy, tephrochronology and biostratigraphy. Following back-stripping to remove effects of subsidence, our relative sea-level record characterises glacial-interglacial precession-paced fluctuations of 15±5m during the mid Pliocene, and obliquity-paced cycles of 23±5m for the Late Pliocene, not registered to present-day sea-level. Four paleomagnetic reversals allow correlation to orbital time-series, demonstrating sea-level in phase with 65°S summer insolation. We conclude an Antarctic dominated meltwater source eustatic sea-level for the mid Pliocene. An Antarctic ice-rafted debris record also suggest the marine based margins of the Antarctic ice sheets continue to be paced by local insolation (precession) through the Late Pliocene. The emergence of obliquity in the record is driven by developing northern hemisphere ice sheets. Glacio-isostatic adjustment modelling for the mid Pliocene suggests the Whanganui site approximates eustatic sea-level.
A Framework for Understanding the Long-term Landscape Evolution of Antarctica

David Sugden1, Stewart Jamieson2 (stewart.jamieson@durham.ac.uk)
1University of Edinburgh, School of GeoSciences, Edinburgh, United Kingdom, 2Durham University, Dept. of Geography, Durham, United Kingdom

The subglacial landscape of Antarctica is less well known than that of the moon or Mars. Much of our understanding of its evolution derives from land exposed at the coast, but the geomorphological record that lies beneath the ice holds significant potential for understanding changes in the Antarctic. As knowledge of modern bed topography increases yearly, we present a framework for using it to test hypotheses of interactions between plate movement, tectonics, surface processes and glacial erosion. We suggest that the landscape evolution of Greenhouse Antarctica before ca.34 Ma, has analogues with typical passive margin evolution (e.g. Australia), displaying feedbacks between base-level change, fluvial erosion, scarp retreat and marginal uplift. Intense weathering would occur under the warm conditions, and flat regions near the coast would form via surface wash. In Icehouse Antarctica, we propose that expansion and contraction of ice produced waves of warm-based erosion which were most effective where flow directions were maintained regardless of ice sheet scale, and where pre-glacial topography steers ice. There may be thresholds of glacial behaviour whereby topography controls significant jumps in ice volume between mountain icefields and ice sheet glaciation. Glacial erosion occurs over long timescales so marine-based beds continually deepen and become more reverse-sloped. We therefore suggest the modern ice sheet is more sensitive to climate changes than in the past.
Reconstructions of the bedrock topography of Antarctica since the Eocene-Oligocene Boundary (ca. 34 Ma) provide an important boundary condition for modelling past Antarctic ice sheets. This is particularly vital in regions where the bedrock presently lies below sea level, since these sectors are thought to be most vulnerable to future change. Here we use 3D flexural modelling to reconstruct the evolution of the topography of the Wilkes Subglacial Basin and Transantarctic Mountains, which are situated beneath the East Antarctic Ice Sheet.

We estimate the spatial distribution of glacial erosion and restore this material to the topography, which is also adjusted for the associated flexural isostatic responses. We constrain our erosion estimates and the pace of landscape evolution since 34 Ma using offshore sediment stratigraphy. In our reconstructions, the 2 km-deep troughs within the Wilkes Subglacial Basin were much shallower at the Eocene-Oligocene Boundary due to the restoration of selectively eroded material. Our models provide a better-defined boundary condition for modelling early ice sheets, and show that the majority of glacial erosion and landscape evolution occurred prior to 14 Ma, which we interpret to reflect a more dynamic and erosive early East Antarctic Ice Sheet. Our flexural modelling shows that the inherited (pre-34 Ma) topography is consistent with long-wavelength elastic plate flexure and influenced by the inherited crustal structure.
Glacial Geomorphic Features: West Antarctic Seafloor and Subsurface Barents Sea

Julia Wellner¹ (jwellner@uh.edu), Janet Kong¹, Yuribia Munoz¹
¹University of Houston, Houston, United States

Analysis of subsurface geomorphic features, found beneath the modern-day seafloor, can illustrate past ice-sheet characteristics from before the last glacial maximum. Such analysis is not possible in the Antarctic but petroleum industry 3-D seismic data from Arctic Norway allow such subsurface mapping at a scale comparable to low-resolution multibeam swath bathymetry grids. This study uses detailed interpretation from 3-D seismic data from the Barents Sea to identify glacial features formed following the onset of glaciation across the region, around 1 Ma. A series of parallel, evenly spaced glacial lineations ranging from 0.5-10 km long, minimum length, and trending northwest-southeast, has been identified. The seafloor surface picked on 3-D seismic shows evidence of iceberg scours carved by drifting icebergs that formed following ice-sheet retreat after the LGM. In our data, iceberg scours have only been identified on the seafloor, and glacial lineations found only in the subsurface. Comparison of glacial features from multiple layers in the subsurface allows examination of the history of ice flow through multiple periods over the last several glacial cycles, with slight reorganization of flow direction between each glacial readvance. We compare the subsurface Barents Sea geomorphology to seafloor geomorphology from multibeam data collected in West Antarctica, where flow direction reorganization is mapped throughout the deglacial period.
New Enhanced-resolution Passive Microwave Climate Record for Historical Analysis

Mary J. Brodzik¹ (brodzik@nsidc.org), David G. Long², Molly A. Hardman¹, Joan M. Ramage³, Richard L. Armstrong¹

¹NSIDC/CtRES/Univ of Colorado, Boulder, United States, ²Brigham Young University, Provo, United States, ³Lehigh University, Bethlehem, United States

Since 1978, satellite sensors have observed Earth passive microwave emissions. Collected globally both day and night and able to see through most clouds, passive microwave measurements are used to derive significant and meaningful cryospheric climate records at high latitudes and high elevations, including sea ice concentrations, snow water equivalent and snow and ice melt onset. Until now, spatial resolution of historical products has been relatively coarse. Historical gridded passive microwave data sets did not meet many requirements of climate data records, most notably in intersensor calibration and consistent processing methods. Original gridding techniques for these data were relatively primitive, produced on 25 km grids using the original EASE-Grid definition that is not easily accommodated in modern software packages. Funded by NASA MEaSUREs, we have processed SMMR, SSM/I-SSMIS and AMSR-E (1978-2016) as gridded Earth System Data Records using state-of-the-art image reconstruction methods. The improved spatial resolution, enhanced to 3 km for the highest-frequency channels, is enabling new analysis of the sea ice concentration and SWE records, especially in mountainous regions that had not previously been possible. We will summarize the methods used to improve spatial resolution and include examples of melt onset detection and melt onset variability in the high-relief Upper Indus Hunza basin (13,000 sq. km, at 36N, 74E).
Thermodynamic Technique for Estimating Ice Thickness from a Moving Icebreaker

Ola Persson¹ (ola.persson@colorado.edu), Byron Blomquist¹, Blake Weissling², Stephen Ackley², Christopher Fairall³
¹University of Colorado/CIRES/NOAA/ESRL/PSD, Boulder, United States, ²University of Texas at San Antonio, San Antonio, United States, ³NOAA/Earth System Research Laboratory/PSD, Boulder, United States

Ice thickness is a crucial parameter for coupled modeling on many time scales, for understanding ice evolution, and for the increasing polar operational maritime navigation. Correct ice thickness initialization has been recently identified as having the greatest impact on seasonal sea-ice forecasting, and even on seasonal terrestrial temperature anomalies. The proposed thermodynamic technique has previously been used with satellite measurements, but its use from an icebreaker allows elimination of some key assumptions and derived quantities to be directly measured. Measurements of the surface temperature over sea-ice in combination with measurements of surface energy budget terms allows the retrieval of ice thickness through inversion of a thermodynamic model. High temporal-resolution data, including the surface energy budget, from the Sea State research cruise in autumn 2015 are used for the ice thickness retrieval and validation. This cruise provides three other sources of independent measurements/estimates of ice thickness to be used as validation, including 1 Hz data from an electromagnetic device. The resultant 1 Hz ice thickness data set provides a resolution of approximately 3 m along the track of the ship. Ice statistics parameters, such as ice concentration, derived from the thicknesses have a nominal resolution of 2 km. This provides a unique data set with numerous scientific uses, a few of which will be illustrated.

An New Algorithm to Detect Blowing Snow from Ceilometers in East Antarctica

Alexandra Gossart¹ (alexandra.gossart@hotmail.com), Niels Souverijns¹, Irina V. Gorodetskaya², Stef Lhermitte³, Jan T.M. Lenaerts⁴, Stephen P. Palm⁵, Nicole P.M. van Lipzig¹

¹KU Leuven, Department of Earth and Environmental Sciences, Leuven, Belgium, ²University of Aveiro, Centre for Environmental and Marine Studies, Aveiro, Portugal, ³TU Delft, Department of Geoscience and Remote Sensing, Delft, Netherlands, ⁴University of Colorado Boulder, Department of Atmospheric and Oceanic Sciences, Boulder, United States, ⁵Science Systems Applications Inc., Maryland, United States

Surface mass balance (SMB) strongly controls spatial and temporal variations in the Antarctic Ice Sheet (AIS) and its contribution to sea level rise. The current scarcity of observational data and the challenges of climate modelling over the ice sheet limit our understanding of the processes controlling AIS SMB. Particularly, the impact of blowing snow (BS) on local SMB is not yet constrained and is subject to large uncertainties.

To assess the impact of BS on local SMB, we investigate the backscatter profiles from ceilometers at two East Antarctic locations in Dronning Maud Land. In addition to the traditional cloud base height and vertical structure retrievals, these instruments also provide information on the particles present in the boundary layer.

We developed a new algorithm to detect BS from the ceilometer attenuated backscatter.

BS detection is also possible by satellite imagery: the near-surface BS layers are apparent in CALYPSO lidar backscatter profiles and enable BS events detection. However, the remote sensing detection of these events is limited to minimal BS layers thicknesses of 20-30 m. In addition, thick clouds, mostly occurring during winter storms, can impede BS detection from satellite products while the algorithm indicates that the majority of these events occur together or shortly after a storm. We will compare both ceilometer and satellite detections of BS, and present case studies focusing on the days when concurrent and divergent retrieval occur.
Cryospheric applications of radar altimetry are hampered by spatiotemporal variability of signal penetration into snow, and uncertainties in the location of the Point of Closest Approach over sloping glaciers, ice caps, and ice sheet margins. The SARIn mode of the SIRAL instrument onboard ESA’s CryoSat-2 allows Doppler and Interferometric processing, overcoming the latter limitation, and providing spatially extensive measurements of ice elevation. However, strong backscatter from within the snowpack, as well as underlying firn and glacial ice has the potential to lead to a ‘radar elevation’ which is below the physical surface. Airborne and field-based calibration and validation campaigns are necessary to assess this bias, allowing more precise calculation of elevation change and mass balance. Here, we present results from the ‘Radar altimetry for ice mass balance - impact of melting and refreezing in the snowpack’ project, which aims to derive optimum techniques for elevation change estimation over glaciers and ice caps in different climatic regimes, using Austfonna, Svalbard as an analogue for melt-affected snowpacks in the Arctic, and ice rises on Fimbulisen, Antarctica, as an analogue for dry snowpacks. In particular, we focus on bias estimation through the comparison of radar elevations with co-located GPS and Airborne Laser Scanner elevations from Svalbard and Antarctica. Additionally, we highlight glaciological results from Svalbard and Dronning Maud Land, Antarctica.
A Decade of Changes of Glacier Facies Extents on Hansbreen (Svalbard)

Barbara Barzycka¹ (bbarzycka@us.edu.pl), Mariusz Grabiec¹, Małgorzata Błaszczyk¹, Dariusz Ignatiuk¹, Jacek Jania¹
¹University of Silesia, Department of Geomorphology, Sosnowiec, Poland

Extents of glaciers facies can facilitate estimations of glaciers mass balance and assessment of their drainage systems. In addition, changes in facies spatial distribution in time are indicative of glaciers response to the warming climate of the Arctic. Especially advantageous for distinguishing glaciers facies are Synthetic Aperture Radar (SAR) satellite sensors, which are sensitive on surface characteristic and independent on sunlight. However, due to complexity of SAR data, in situ measurements are recommended for their validation. For verification of glaciers facies determination both Ground Penetrating Radar (GPR) and shallow ice cores are very valuable source of information.

In our study, we analysed both SAR and in situ data in order to distinguish extends of facies of Hansbreen during last 10 years. Analysis included both simple classification of single- and dual-polarisation SAR data (thresholding, unsupervised classifications) and advanced analysis of fully-polarimetric images (H-α segmentation). For validation purposes we visually interpreted GPR data and applied Internal Reflection Energy (IRE) coefficient, sensitive on glacier’s subsurface characteristic. Shallow ice cores provided additional information on the thickness and character of the facies and helped to assess the GPR visual interpretation. As a result, we present changes of Hansbreen’s facies during last 10 years with a description of advantages and limitations of SAR sensors and methods of analysis.
UAV Multispectral Remote Sensing of Sub-arctic Ponds (Nunavik, Canada)

Pedro Freitas¹, Goncalo Vieira²,³ (vieira@campus.ul.pt), Simone Girst¹, Carla Mora², João Canário⁴, Warwick F. Vincent³
¹IGOT - Universidade de Lisboa, Lisboa, Portugal, ²CEG/IGOT - Universidade de Lisboa, Lisboa, Portugal, ³Centre d'Etudes Nordiques, Université Laval, Quebec, Canada, ⁴CQE, Instituto Superior Técnico, Universidade de Lisboa, Lisboa, Portugal

Thaw ponds are frequent features in Arctic and Sub-Arctic wetlands associated with degrading ice-rich permafrost. They show strong biogeochemical dynamics and are important players in the carbon cycle. Arctic warming is accelerating thaw, affecting whole landscapes and influencing hydrology and soils, generating new conditions for ecosystems and human activities. Significant changes have been affecting the tundra-forest boundary, with a marked increase in both tree and shrub formations.

Identifying small ponds using remote sensing is an important challenge for quantifying the processes affecting polar wetlands. The launch of Sentinel 2-A in 2015 and Sentinel 2-B in 2017 (S2 - 10 m resolution), that followed Landsat 8 (L8 - 30 m resolution) in 2013, offering revisiting times of a few days, opened a new breadth of possibilities for monitoring and advancing the understanding of remote Arctic and Sub-Arctic regions. Two field surveying missions were conducted in the summers of 2015 and 2017 in the sporadic and discontinuous permafrost zones (Kuujjuarapik and Umiujaq, Nunavik) using an Unmanned Aerial Vehicle (UAV) and a multispectral camera. The high spatial resolution (ci 15 cm) and spectral quality of the imagery provides ground truthing and allows assessing the quality of Landsat-8 and Sentinel-2 imagery and their accuracy for regional assessments of landcover, including lake colour.
Sea-ice Phenology in a Warmer Arctic

Letizia Tedesco¹ (letizia.tedesco@environment.fi), Marcello Vichi², Enrico Scoccimarro³
¹Finnish Environment Institute, Marine Research Centre, Helsinki, Finland, ²University of Cape Town, Cape Town, South Africa, ³Euro-Mediterranean Center on Climate Change, Bologna, Italy

Future projections of Arctic sea-ice changes are alarming, but the response of the ice-associated biological community is still uncertain. Here we investigate future changes in timing and intensity of primary production in Arctic first-year ice using a combination of climate and sea-ice biogeochemistry models. Overall, model results suggest a general increase in sea-ice primary production at all latitudes during this century. However, the projected phenological changes are not as quasi-monotonic as the changes in physical drivers. Three latitudinal clusters are identified and distinctly explained by snow cover thinning at the lowest latitudes, biological time windows narrowing in the mid latitudes, and ice seasons advancing towards more favourable photoperiods at the highest latitudes. When considering the changes in ice extent, the increase in sea-ice production at the highest latitudes is boosted due to significant first-year ice expansion at the expense of multiyear ice. The projected changes in sea-ice primary production suggest potential far-reaching consequences for the whole Arctic marine food web.
Sea ice provides a stable environment for algae growth and survival. In the Arctic Ocean, ice associated algae guarantee a food source for sympagic and pelagic biota. The rapid decline of Arctic sea ice and the changes in its physical structure will lead to a new biological environment causing shifts in sea-ice algae dependent ecosystems. The impact of these changes on ice algae distribution and production can be quantified on large scales by sea ice numerical models. These models need data for calibration, comparison and parameterization of processes. Due to the high variability of sea-ice physical, chemical and biological properties, field sampling and representative model output of ice algae are challenging. In this work we present data from a 2-weeks ice station in the Arctic Ocean in spring 2017. Sea-ice algal chl $\alpha$ has been sampled at different spatial scales to assess its variability, and to determine any relationship of sea ice algae distribution with the variability of physical and chemical sea ice properties in spring. In addition, this work focuses on the study of ridged and deformed ice. We present a characterization of the biophysical environment of ridges in terms of temperature, salinity, nutrients, biomass. The results are used to assess the importance of ridges for the total biomass. We upscale the along-transect variability of sea-ice algae on a floe scale and on the average grid length of sea-ice-ocean numerical models to compare with recent model results.
We will summarize recent progress in coupling sympagic (ice-associated) and pelagic ecosystems using 1-D and 3-D model approaches. The 1-D model studies highlight processes relevant to adequately represent ice algal growth, as well as carbon and sulfur fluxes. Important processes include ecosystem productivity, ice growth (via brine transport) and melt, and air sea exchange. 3-D model studies highlight gaps and issues when transferring parameterisations from 1-D to 3-D as well as preliminary results with respect to ice algal and pelagic primary production and air-ice-sea sulfur and carbon exchanges.
Winter to Summer CO₂ Chemistry in Antarctic Sea Ice

Elizabeth Jones¹,²,³ (elizabeth.jones@imr.no), Mairi Fenton⁴, Jacqueline Stefels¹, Maria van Leeuwe², Sharyn Ossebaar³, Hein de Baar²,³
¹Institute of Marine Research, Tromsø, Norway, ²University of Groningen, Groningen, Netherlands, ³Royal Netherlands Institute for Sea Research, Den Burg, Netherlands, ⁴British Antarctic Survey, Cambridge, United Kingdom

The west Antarctic Peninsula is a highly productive ecosystem where sea ice plays an important role in biological processes and the biogeochemical cycling of carbon and other elements. Carbon dioxide (CO₂) chemistry in sea ice and under-ice water was investigated to examine ice-ocean exchanges from austral winter to summer in the Antarctic coastal zone. Algal production and CO₂ uptake reduced winter concentrations of inorganic carbon (CT) to less than 200 µmol/kg within the ice pack. Sea ice total alkalinity (AT) reached lowest values (< 100 µmol/kg) during melting of the sea ice. Processes in the sea ice such as brine rejection and carbonate (CaCO₃) mineral precipitation also affected the carbon chemistry, increasing the AT-CT ratio in the ice to >1.5 from winter to summer. Nitrate concentrations at the ice-water boundary were enriched compared to bulk ice by late summer, likely resulting from re-supply from underlying ocean waters and sustaining ice-algal CT uptake. Biological production and CaCO₃ dissolution during sea ice melt increased the AT-CT ratio in the under-ice water by late summer. Concomitant reduction in sea surface CO₂ enhanced CO₂ uptake upon retreat of the ice pack. Wintertime remineralisation of organic matter contributed to enhanced inorganic carbon and nitrogen in the snow-capped sea ice. This study reveals intense biogeochemical cycling in Antarctic sea ice to help to further elucidate the role of sea ice and ice-ocean interactions in a changing climate.
Seasonal Evolution of Light Transmission through Central Arctic Sea Ice

Christian Katlein1, Stefanie Arndt1, H. Jakob Belter1, Marcel Nicolaus1 (marcel.nicolaus@awi.de)
1Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Bremerhaven, Germany

Light transmission through sea ice has been identified as a critical process for energy partitioning at the polar atmosphere-ice-ocean boundary. Transmission of sunlight influences direct sea ice melting by absorption, heat deposition in the upper ocean, and in particular primary productivity. The recent years have seen an increase in spatially distributed light measurements underneath sea ice using remotely operated vehicles. These measurements allow us to reconstruct the seasonal evolution of the spatial variability in light transmission. Here we present measurements of sea ice light transmittance from 6 years of polar ROV operations. The dataset covers the entire melt cycle of Central Arctic sea ice. This data from multiple years is combined into a pseudo timeseries describing the seasonal evolution of the changing spatial variability of sea ice optical properties. Snow melt in spring increases light transmission continuously, until a secondary mode originating from translucent melt-ponds appears in the histograms of light transmittance. This secondary mode persists long into autumn, before snow fall reduces overall light levels again. Comparison to several autonomous time series measurements from single locations confirms the detected general patterns of the seasonal evolution of light transmittance variability. These results will allow further insights on the validity of radiation transfer parameterization used in ice-ocean models.
As a part of the new Norwegian research project “Nansen Legacy”, involving eight Norwegian governmental and two private research institutions (https://site.uit.no/nansenlegacy/), a scientific review about the status and changes in the Barents Sea System is developed. We will present first results from this synthesis, focusing on the physical, biological and biogeochemical systems. The review is based on recent peer-review publications about the region, with additional use of publically available longterm monitoring data, such as satellite-based sea ice extent. The Barents Sea represents both geographically and temporarily a gateway to a changing Arctic: It is connected to the Arctic Basin in the central Arctic and ocean currents, sea ice drift and ship traffic illustrate this connection. One question scientists work with is to what extent the Barents Sea can be seen as a sentinel for current changes that in a similar way could happen in the future in other Arctic regions. The Barents Sea is highly relevant as a part of the climate system, as a habitat, and within socio-economics. It is exposed to natural forcing and direct or indirect human impacts, and it is is changing relatively fast, compared with other Arctic regions. We will present examples of such changes and relevant processes, including results from numerical modelling.
Global-scale Hydrological Response to Future Glacier Mass Loss

Matthias Huss¹,² (huss@vaw.baug.ethz.ch), Regine Hock³,⁴
¹ETH Zurich, Laboratory of Hydraulics, Hydrology and Glaciology (VAW), Zurich, Switzerland, ²University of Fribourg, Department of Geosciences, Fribourg, Switzerland, ³University of Alaska Fairbanks, Geophysical Institute, Fairbanks, United States, ⁴Uppsala University, Department of Earth Sciences, Uppsala, Sweden

Worldwide glacier retreat and associated future runoff changes raise major concerns over the sustainability of global water resources, but global-scale assessments of glacier decline and resulting hydrological consequences are scarce. Here, we compute global glacier runoff changes until 2100 for three greenhouse gas emission scenarios and analyze the glacial impact on streamflow for 56 large-scale glacierized drainage basins on Earth. In roughly half of the investigated basins modelled annual glacier runoff continues to rise until a maximum (‘peak water’) is reached, beyond which runoff steadily declines, while in the remaining basins this tipping point has already been passed. Peak water occurs later in basins with larger glaciers, higher ice-cover fractions, and at higher latitudes. Most basins experience future glacier runoff increases in early summer but decreases in late summer. Although most of the 56 basins have below 2% ice coverage, by 2100 one third of them might experience runoff decreases greater than 10% in at least one melt season month due to glacier mass loss. The reductions are largest in central Asia and the Andes, hence exacerbating future water stress in these regions. We conclude that even in large-scale basins with minimal ice-cover fraction, the downstream hydrological effects of continued glacier wastage can be substantial, but magnitudes vary greatly among basins and throughout the melt season.
Tibetan Plateau and its surrounding areas are known as the earth’s Third Pole (TP). Major environmental changes are taking place on the TP characterized by complex interactions of atmospheric, cryospheric, hydrological, geological and environmental processes. We identified three modes of the modern westerlies-monsoon interaction system based on variation patterns of precipitation stable isotopes on the TP: Indian monsoon mode, westerlies mode and transition mode. The three modes directly affect environmental changes on the TP. We found the largest retreat of glaciers in the monsoon mode on southern TP, moderate retreat in the transition mode on central TP, and the least retreat, or even slight advance in the westerlies mode on northwestern TP. Further study shows that the enhancing westerlies against the weakening summer monsoon is the major driver of regional differences in environmental changes on the TP.

As TP research goes further, the Third Pole environment is not isolated, interacting with the changes in the Northern hemisphere and even the Arctic and Antarctic. The new program, called Pan-TPE, works to characterize the scenarios of monsoon-westerly interaction and its implications, the water-ecosystem interaction and oasis sustainability, as well as human and disaster impact on environment and consequent uncertainties, regarding earth system behavior in Pan-TP. It endeavors to map out a coordinated strategy for regional sustainable development with scientific vision.

Impact of a Global Temperature Rise of 1.5 °C on Asia’s Glaciers

Philip D.A. Kraaijenbrink1 (p.d.a.kraaijenbrink@gmail.com), Marc F.P. Bierkens1,2, Arthur F. Lutz3, Walter W. Immerzeel1,4
1Utrecht University, Physical Geography, Utrecht, Netherlands, 2Deltares, Utrecht, Netherlands, 3FutureWater, Wageningen, Netherlands, 4International Centre for Integrated Mountain Development, Kathmandu, Nepal

Glaciers in the high mountains of Asia (HMA) play a substantial role in regional water resources. In general, these glaciers have been losing mass over the last decades, a trend that is most likely to persist in the future. In 2015, 195 nations signed the “Paris Agreement” and agreed on efforts to limit the global temperature rise to 1.5 °C. It is unknown, however, how much of Asia’s ice will be lost under a 1.5 °C temperature increase, or under more extreme temperature scenarios. To determine this, we modelled all individual glaciers in HMA larger than 0.4 km² transiently up to 2100 using the entire CMIP5 ensemble within a Monte Carlo framework to account for parameter uncertainty. Only a handful of the climate models project a global temperature rise of 1.5 °C. Under such a scenario HMA warms stronger than the global average (2.1±0.1 °C). By the end of the 21st century, the 1.5 °C scenario results in a 36±7% mass loss relative to the present-day ice mass. Mass losses projected by RCP4.5, RCP6.0 and RCP8.5 ensembles are considerably higher with 49±7%, 51±6% and 65±6%, respectively. Results also show large regional differences, which are primarily caused by differences in debris cover, ice mass, observed mass balance, and glacier sensitivity to climate perturbations. We conclude that even under the ambitious 1.5 °C scenario over one third of HMA’s glacier mass will be lost by the end of century, and that the difference with more likely scenarios is considerable.
Fate of Glaciers on the Tibetan Plateau by 2100

Keqin Duan¹ (kqduan@snnu.edu.cn), Tangdong Yao²
¹Shaanxi Normal University, Xi’an, China, ²Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China

As the third polar on the Earth, the Tibetan plateau holds more than 40,000 glaciers which have experienced a rapid retreat in recent decades. Glacier loss has increased concern for water resources around the Tibetan plateau. The variability of equilibrium line altitude (ELA) indicates expansion and wastage of glacier directly. Here we simulated the ELA variability in the Tibetan Plateau based on a full surface energy and mass balance model. The simulation results are agreement with the observations. The ELAs have risen at a rate of 2-8m/a since 1970 throughout the Plateau, especially in the Qilian Mountain and the southeastern Plateau where the ELAs have risen to or over the top altitude of glacier, indicating the glaciers are accelerating to melting over there. Then the future ELA variability on the Tibetan plateau are forecasted in the scenarios of RCP2.6, RCP4.5 and RCP 8.5 given by IPCC. The results show the ELAs of most glaciers will arrive to its maximum in around 2040 in RCP2.6. While the ELAs will be over the top altitude of glaciers in the eastern Plateau in 2040-2050 in RCP4.5 and RCP8.5, suggesting most of the glaciers on the Tibetan Plateau will accelerate to melt until to disappear by the end of 2100.
Possible Impacts of Black Carbon on Water Cycle Pattern over the Third Pole

Baiqing Xu1 (baiqing@itpcas.ac.cn), Mo Wang1
1Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China

Water cycle pattern over the Third Pole has been changed apparently since the early-1990s. Stabilization even advance of glaciers and expansion of lakes accompanied with an increase of precipitation were found in the northwest Third Pole dominated by westerlies, in contrast to an accelerated decline of glaciers and lakes led by a decrease of precipitation in the south and east controlled by Indian monsoons. Despite its far-reaching influence on regional water supply, the reason is unknown. Here, we propose black carbon (BC) may have a dominating contribution to the different water cycle patterns in the Third Pole, demonstrated by 8 sequences of BC concentration for the last 150 years documented in ice cores. We found BC concentration has decreased by half since the early-1990s in westerly domain, while doubled in Indian monsoon region due to an increased emission in South Asia. It indicates BC effect on glacier melt has been greatly reduced in westerly domain, but increased in monsoon region, as well as its effect on rainfall suppression by interacting with clouds, especially an effect called “cloud-top gathering BC” in our new finding. The opposite trends of BC content in both glacier and atmosphere can explain the different water cycle patterns in the same background of global warming. We suggest reducing BC emission in South Asia can effectively mitigate glacier melting and increase precipitation in Indian monsoon region as happened in the westerly domain.
Changes in terrestrial vegetation could modulate the water cycle, with direct impacts on changes in soil moisture, evapotranspiration, streamflow and regional precipitation. The pan-Third pole vegetation has witnessed significant variations over the past several decades. However, analyses of the impacts of vegetation changes on the water cycle has so far been lacking over this region. Here we examined consequences of the two contrasting scenarios of vegetation changes (vegetation restoration and degradation) on the water cycle. The first case is to quantify the impact of large-scale ecological restoration program implemented in the headstream region of Yangtze River since 2000. Our analyses showed that grassland restoration in the headstream reduces the streamflow and increased evapotranspiration (ET), which improves local soil water conditions but undercuts any gain in downstream water resources associated with precipitation increases. The second case is to understand the role of deforestation in driving the long-lasting drying trend that is widely observed in the South Asian monsoon region of the pan-Third pole. We indicate that deforestation is the second primer driver of summer drying trend over the 20th century, while increasing aerosol emissions primarily contribute to this drying trend. Our results from these two case studies highlighted the importance of vegetation changes in understanding the past and future evolution of the water cycle over the pan-Third Pole.
Causes of Multi-decadal Environmental Change near Toolik Lake, Arctic Alaska

George Kling¹ (gwk@umich.edu), Gaius Shaver², John Hobbie², Anne Giblin², Vladimir Romanovsky³, Edward Rastetter²
¹University of Michigan, Ecology and Evolutionary Biology, Ann Arbor, United States, ²Marine Biological Laboratory, Woods Hole, United States, ³University of Alaska - Fairbanks, Fairbanks, United States

Long-term data near the Arctic LTER site in arctic Alaska show 40 years of environmental change on land and in surface waters. While some changes have been substantial (e.g., a doubling of alkalinity in Toolik Lake and an increase in permafrost temperatures and NDVI), other changes are small or undetectable. In addition, changes in the drivers of these trends, e.g., increases in air temperature or mean catchment thaw depth, have been muted. Clearly these terrestrial and aquatic ecosystems are vulnerable to change, and the stressors causing the changes are either undiscovered or hidden from our ability for detection. One hypothesis to explain the variability in ecosystem response is that certain changes are integrating the effects of a climate signal on multi-year to decadal time scales, acting as a medium-pass filter of climate that reduces the signal variability yet allows the effects of long-term warming to emerge, as seen in the alkalinity, NDVI, and permafrost temperature records. Other likely effects of climate change on the landscape are seen in dramatic land-surface disturbances such as thermokarst failures and tundra fires, which have the potential to rapidly alter land and water biogeochemistry and may result in larger transformations than will the steady trends of climate change. Similar environmental changes may be occurring in unmonitored regions of the Arctic, even when the obvious drivers of climate have changed little over time.
Groundwater Exchanges on the Land Surface Control Stream Chemistry in Permafrost

Bethany Neilson¹, M. Bayani Cardenas² (cardenas@jsg.utexas.edu), Michael O’Connor², Mitchell Rasmussen³, Tyler King¹, George Kling³
¹Utah State University, Civil and Environmental Engineering, Logan, United States, ²University of Texas at Austin, Geological Sciences, Austin, United States, ³University of Michigan, Ecology and Evolutionary Biology, Ann Arbor, United States

The mechanisms for export of dissolved carbon (C) and nitrogen (N) from land to rivers and lakes are poorly understood in arctic landscapes. In watersheds with continuous permafrost, overland flow at high discharge is thought to dominate export. We show here that surface microtopography drives overland flow into the ground, where surface water exchanges with soil waters having higher C and N concentrations. These surface-subsurface exchanges in the seasonal shallow aquifer control dissolved organic C and N export, regardless of whether the landscape is saturated or inundated by overland flow. Combined with rapid leaching of organic matter in shallow soils, these vertical exchanges explain the relatively constant dissolved C and N stream concentrations observed across a wide range of stream discharge. The dominance of groundwater influence on surface water C and N export, and the response of these transport and exchange mechanisms to ongoing permafrost thaw, is key to the fate of organic C and N stored in arctic soils.
How Do CO₂ and CH₄ Effluxes from Toolik Lake Change with Climate Change?

Werner Eugster¹ (werner.eugster@usys.ethz.ch), Tonya DelSontro², Gaius R. Shaver³, George W. Kling⁴
¹ETH Zurich, Department of Environmental Systems Science, Zurich, Switzerland, ²Université du Québec à Montréal, Département des Sciences Biologiques, Montréal, Canada, ³Marine Biological Laboratory, Ecosystems Center, Woods Hole, United States, ⁴University of Michigan, Department of Ecology & Evolutionary Biology, Ann Arbor, United States

Effluxes of CO₂ and CH₄ from Toolik lake, northern Alaska, during the ice-free season were measured from 2010 to 2015 using the eddy covariance technique. Measurements were made on a floating platform ca. 400 m from the lake shore. Our measurements are thus representative of the open water where the lake is deep enough to show a distinct thermal stratification throughout most of the ice-free season (typically end of June to mid-September). We analyzed the relationship between daily aggregated CO₂ and CH₄ fluxes and lake level height, hypothesizing that a low lake level would increase gas evasion from the lake and thus enhance the fluxes of these two greenhouse gases. Our measurements however showed that (a) ebullition of gases from bottom sediments was not detectable with a sonar device, thus indicating that diffusive fluxes are dominating total efflux; that there is a significant increase of (b) daily CO₂ effluxes with increasing lake level (p=0.029); and (c) of CH₄ fluxes with increasing lake level (p=0.005). Over the 28 years of continuous lake level measurements a significantly decreasing trend of 1.0 ± 0.2 cm per year was observed (except for the annual maximum lake level), which suggests that CO₂ and CH₄ effluxes should slightly decrease over time if this trend continues. This actual trend is in contrast to predicted increases in precipitation by 2100, which should increase rather than decrease the lake level, thereby increasing CO₂ and CH₄ effluxes.
Variability of Ecosystem Connectivity in the McMurdo Dry Valleys, Antarctica

Michael Gooseff1 (michael.gooseff@colorado.edu), Byron Adams2, Jeb Barrett3, Shawn Devlin4, Peter Doran5, Adrian Howkins6, Diane McKnight1, Rachael Morgan-Kiss7, John Priscu8, Cristina Takacs-Vesbach9
1University of Colorado, INSTAAR, Boulder, United States, 2Brigham Young University, Biology Department, Provo, United States, 3Virginia Tech, Biological Sciences, Blacksburg, United States, 4University of Montana, Flathead Lake Biological Station, Polson, United States, 5Louisiana State University, Geological Sciences, Baton Rouge, United States, 6University of Bristol, Environmental History, Bristol, United Kingdom, 7University of Miami, Department of Microbiology, Miami, United States, 8Montana State University, Land, Resources, and Environmental Sciences Department, Bozeman, United States, 9University of New Mexico, Biology Department, Albuquerque, United States

The McMurdo Dry Valleys are the largest ice-free area of Antarctica, made up of exposed soils, glaciers, streams, and ice-covered closed-basin lakes. The connections among these landscape units facilitate the movement of energy, mass, and biota - largely driven by physical processes of glacier melt water transport and aeolian transport. Glacial melt occurs during a 6-10 week period in the austral summer, with significant interannual variability. Aeolian transport, however, typically occurs during strong foehn events, which are most common during the austral winter. Despite these two primary modes of transport being out of phase, their impacts are most significant during the austral summer, when biological activity is the highest. Here we explore the ecosystem impacts of these differential connections.
The Ecology of Small Glacier Animals: A Case Study from the Arctic

Marie Sabacka¹ (sabacka.marie@gmail.com), Tobias Vonnahme², Karel Janko³, Krzysztof Zawierucha², Miloslav Devetter⁴, Josef Elster¹

¹University of South Bohemia, Centre for Polar Ecology, Ceske Budejovice, Czech Republic, ²The Arctic University of Norway, Department of Arctic and Marine Biology, Tromso, Norway, ³Institute of Animal Physiology and Genetics, Libechov, Czech Republic, ⁴Institute of Soil Biology AS CR, Ceske Budejovice, Czech Republic

Unique freshwater environments, called cryoconite holes, occur globally on the surface of glaciers. They are predominantly water filled and frozen throughout the winter and can cover up to 10% of the ablation zone of a glacier. These microhabitats host diverse viral, prokaryotic and eukaryotic life forms and are among the most productive ecosystems in the Polar Regions. The organisms living within the holes are able to cope with cold, dryness, strong winds and low levels of nutrients, and include small grazing animals such as rotifers and tardigrades. Whilst the autotrophic and bacterial communities have received considerable attention over the past decade, the grazing predators and their role on the cryoconite community composition and productivity remains an enigma.

These small animals occur in high numbers in cryoconite holes in Petuniabukta glaciers, Svalbard, and are likely to play a key role in recycling of nutrients, which is extremely important in sustaining the physiological functioning of the autotrophic and bacterial communities. The aim of this project is to understand the role of small grazing predators (rotifers and tardigrades) on the ecology of the cryoconite holes by assessing their effect on biogeochemical cycling and ecosystem production within the cryoconite communities.

Initial findings showed that nutrient levels related to recycling of limiting nutrients are the main factor driving variation in the community structure of microalgae and grazers.
Understanding the dynamics of heat transfer in arctic rivers is critical for forecasting the effects of climate change on river temperatures. Building on the collection of five years of data throughout the Kuparuk River basin in Alaska, USA, spanning dry to wet summer seasons, we have adapted a dynamic river temperature model to quantify heat fluxes during varied hydrologic conditions in order to understand drivers of thermal change in arctic systems. We have identified hydrologic conditions where the dominant heat fluxes shift from lateral inflows, to solar radiation, to hyporheic exchange. We found that accounting for the mass contribution of lateral inflows throughout the basin was critical during high flow periods. However, the lower order portion of the basin is more sensitive to the temperatures assigned to these inflows. Under lower flow conditions, temperatures in the lower order portion of the basin also shift from a high dependence on lateral inflows to one relying primarily on air-water or surface heat exchanges. During the lowest flow conditions, the system is still dependent on these surface heat fluxes, but the heat transfer with the bed sediments, primarily via hyporheic exchange, rivals their influence and significantly buffers instream temperatures. Together the data and modeling results provide insight into the potential influences of the changing climate and the associated hydrologic shifts in areas of continuous permafrost.

Arctic Cloud Residual and Ambient Aerosol Properties Measured during A CLOUD

Stephan Mertes1 (mertes@tropos.de), Udo Kästner1, Oliver Eppers2,3, Marco Zanatta4, Johannes Schneider2, Heiko Bozem3, Emma Järvinen5, Olivier Jourdan6, Andreas Herber4
1Leibniz Institute for Tropospheric Research, Leipzig, Germany, 2Max Planck Institute for Chemistry, Mainz, Germany, 3Institute for Atmospheric Physics, University of Mainz, Germany, 4Alfred Wegner Institute, Bremerhaven, Germany, 5Karlsruhe Institute of Technology, Karlsruhe, Germany, 6Laboratoire de Météorologie Physique, Université Clermont Auvergne, Clermont Ferrand, France

Supercooled or mixed-phase clouds are suspected to contribute considerably to the amplified warming of the Arctic. Thus, it is studied which arctic aerosol particles are involved in their formation during the aircraft-based field campaign A CLOUD, part of the German arctic research project (AC)3. In May/June 2017 cloud particles of low and mid-level clouds were sampled by means of a Counterflow Virtual Impactor inlet (CVI) aboard the Polar 6 aircraft in order to characterize their cloud particle residues (CPR), which are closely related to the original cloud condensation and ice nuclei. Number density, size distribution, chemical composition and mixing state of the CPR are determined to derive which aerosol particles form the arctic clouds. A case study reveals that all particles larger 150 nm are activated and that the 50% activation diameter is around 115 nm.

Beside these in-cloud investigations, it is of great importance to infer the origin of the cloud forming particles (natural vs anthropogenic, local vs long range transported) by measuring the vertical profiles of the same aerosol parameters from below cloud inside the boundary layer across the inversion up to the free troposphere operating the CVI as aerosol inlet. First results show particle number accumulation at the lower inversion, depletion above the cloud layer and a strong increase in long-range transported pollution layers. Absolute values of the BC mass concentration are found to be in the order of 50 ng m$^{-3}$. 
ACE-SPACE: Overview of Southern Ocean Aerosol and Trace Gases Measurements

Julia Schmale1 (julia.schmale@psi.ch), Silvia Henning2, Andrea Baccarini3, Conor Bolas4, Katrianne Lehtipalo5, Markus Hartmann2, Andre Welti2, Fiona Tummon6, Iris Thurnherr7, Franziska Aemisegger7, Heini Wernli7, Daniel Rosenfeld8, Leighton Regayre9, Neil Harris10, Pascal Graf7, Irina Gorodetskaya11, Martin Schnaiter12, Frank Stratmann2, Urs Baltensperger13, Josef Dommen4, Ken Carslaw9, Martin Gysel3

1Paul Scherrer Institute, ENE, Villigen, Switzerland, 2Leibniz Institute for Tropospheric Research, Leipzig, Germany, 3Paul Scherrer Institute, Villigen, Switzerland, 4University of Cambridge, Cambridge, United Kingdom, 5University of Helsinki, Helsinki, Finland, 6University of Tromso, Tromso, Norway, 7ETH Zurich, Institute for Atmospheric and Climate Science, Zurich, Switzerland, 8Hebrew University of Jerusalem, Jerusalem, Israel, 9University of Leeds, Leeds, United Kingdom, 10University of Cranfield, Cranfield, United Kingdom, 11University of Aveiro, Centre for Environmental and Marine Studies, Aveiro, Portugal, 12Karlsruhe Institute of Technology, Karlsruhe, Germany

The main purpose of the 'Study of Preindustrial-like-Aerosol Climate Effects' (SPACE) was to conduct a comprehensive aerosol and trace gas characterization during the Antarctic Circumnavigation Expedition (ACE) from December 2016 to March 2017 in partly unexplored areas of the Southern Ocean. The data are not only of interest to understand atmospheric processes under pristine conditions, but also particularly to validate satellite retrievals of aerosol properties and model simulations, which are both essentially unconstrained in that region.

Here, we will present aerosol microphysical and chemical characteristics, discuss particle origin and trace gas correlations. Important factors influencing aerosol properties were different meteorological conditions, the thermodynamic structure of the boundary layer and ocean microbial regimes. For example, the leg between South Africa and Australia experienced a series of low-pressure systems characterized by a large fraction of Aitken mode particles, hinting at downward mixing of particles processed in the free troposphere. Near the west Antarctic coast larger particles were found and associated with Antarctic air masses and potentially cloud processing. They also contained methane-sulfonic acid. First results of a model-measurement intercomparison will be shown as well.

Note, there will be two more ACE-SPACE contributions on cloud condensation nuclei and new particle formation specifically.
Aerosol and Surface Snow Chemical Composition at Dome C from 10-yr Long Records

Rita Traversi¹ (rita.traversi@unifi.it), Silvia Becagli¹, Laura Caiazzo¹, Maurizio Busetto¹, Francesco Calzolari², Paolo Cristofanelli², Boyan Petkov², Mirko Severi¹
¹University of Florence, Chemistry Dept. 'Ugo Schiff', Sesto F.no, Italy, ²CNR-ISAC, Bologna, Italy

Chemical composition and the physical parameters of the atmospheric aerosol in the Antarctic plateau provide basic information on the main natural inputs, tropospheric transformation and long-range transport processes of the aerosol components. In addition, chemical and physical processes occurring at the atmosphere-snow interface are yet not fully understood and work is needed to assess the impact of atmospheric chemistry on snow composition and to better interpret ice core records there retrieved.

Thus, simultaneous aerosol and surface snow sampling was set up and run at Dome C station (75° 06' S; 123° 20' E, 3233 m a.s.l) all year-round over 2004-2013. Aerosol and snow samples were analyzed for main and trace ion markers, in order to study the extent and timing of main aerosol sources as sea salt (open ocean/frost flowers/blowing snow), biogenic production, crustal input, as well as transport (e.g. free troposphere, stratosphere-troposphere exchange) and atmospheric reaction processes (e.g. neutralization, chemical fractionation).

A comparison with ozone and solar irradiance measurements, carried out continuously over the same time period, is also attempted to better constrain the atmospheric processes involving the atmosphere-snow exchanges of N-cycle species.

Moreover, preliminary results achieved in the framework of a PNRA project (LTCPAA), started in 2016 and continuing the previous 10-yr long sampling and direct measurement activity, are presented.
Full System Characterization of a Summer to Winter Transition

Taneil Uttal¹ (taneil.uttal@noaa.gov), Alexander Makshtas², Andrey Grachev³, Tuomas Laurila⁴, Christopher Cox⁴, Sara Morris³, Vasily Kustov², Eija Asmi⁴, John Backman⁴
¹NOAA Earth System Research Laboratory, Physical Science Division, Boulder, United States, ²Arctic and Antarctic Research Institute of Roshydromet (AARI), St Petersburg, Russian Federation, ³Cooperative Institute for Research in Environmental Sciences, NOAA/ESRL/PSD, Boulder, United States, ⁴Finnish Meteorological Institute, Helsinki, Finland

Measurements of turbulent and radiation fluxes, CO2, equivalent black carbon, aerosol sizes/concentrations, meteorology and surface and near-surface temperatures are presented for a period during the fall freeze-up period in 2013 at Tiksi, Russia. The measurements are assessed in the context of cloud forcing, the first snow accumulations, and more winter-like, synoptic transport patterns and aerosol transports for expected and unexpected correlations and dependencies. Four episodes of precipitation occurred, one synoptically driven warming event, and 3 clear sky events which clearly impacted the timing of freeze up. The snow that accumulated on the ground during the precipitation periods was important as it acted as an insulator and essentially shut off communication between some atmosphere and surface for processes such as turbulent, radiative and CO2 fluxes. For some components of the system the primary control was advection from either local or remote source regions. One elevated equivalent black carbon (eBC) event was likely the result of long-range transport while two shorter eBC events were due to contamination from the town of Tiksi (north of the observatory site). Ozone values were impacted by bromine sources from the open ocean - as the adjacent bay froze, ozone levels began to rise to higher winter values. The forcers, responders and feedbacks in the system are evaluated.
Airborne Measurements in the Polar Boundary Layer over Sea Ice during ACloud

Christof Lüpkes¹ (christof.luepkes@awi.de), Dmitry Chechin¹, Andre Ehrlich⁷, Manfred Wendisch²
¹ Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Climate Sciences, Bremerhaven, Germany, ² University Leipzig, Leipzig, Germany

In May/June 2017 the aircraft campaign ACloud (Arctic Cloud Observations Using airborne measurements during polar Day) has been carried out in the framework of the project (AC)³ over the Fram Strait close to Svalbard. Two polar aircraft of the German Alfred Wegener Institute (AWI) were used during this joint project of the universities Leipzig, Köln, and Bremen, of the AWI, and of the Leibniz Institute for tropospheric research (TROPOS). The aircraft were equipped with a large suite of instruments measuring mean and turbulent meteorological quantities as well as cloud particles and aerosol. We show first results of four flight missions that were mainly focusing on the boundary layer over sea ice. We discuss especially the turbulence measurements carried out with both aircraft which have been equipped with identical turbulence probes. It is shown that in general the turbulent fluxes were small as usual during Arctic summer conditions, but that both strongly stable conditions occurred with bulk Richardson numbers up to 0.26 and slightly unstable conditions with upward fluxes. We discuss especially the strong variability (intermittent and wave-like character) of the high resolution wind and temperature data during horizontal flight legs in strongly stable conditions. We further show that vertical flux profiles were nonlinear in the weakly convective boundary layer as a consequence of cloud cover.
In situ aerosol measurements have been conducted at the Concordia station at Dome C (75°S, 123°E) on the upper plateau at about 3200 m amsl since December 2007. Part of these measurements have been continuous since then, part of them only for shorter periods. The size distributions in the size range 10 - 600 nm have been measured with a differential mobility particle sizer (DMPS) and with a Grimm Model 1.108 optical particle counter in the size range 0.3 - 15 μm. Air Ion Spectrometer (AIS), that measures charged particle size distributions in the size range of about 0.8 - 40 nm, was operated for almost a year. Light absorption by aerosols was measured with a 3-wavelength PSAP. There was no nephelometer so scattering was calculated from the size distributions using a Mie code. In addition to calculating scattering coefficients from the DMPS data it was calculated from PM1 and PM10 mass concentrations. A comparison of the aerosol scattering at Dome C and at the South Pole Observatory (SPO) was conducted for 6 consecutive years. Despite being separated by approximately 1400 km some prominent features are visible at both stations at the same time, lasting from some days to a week. FLEXPART simulations show that the BC aerosols observed on the Antarctic upper plateau often have travelled more than 30 days from the sources in the surrounding continents South America, Africa and Australia.
The phenology of Arctic algal blooms in sea ice and water is determined largely by their environment. The Arctic has been changing rapidly during the past decades with a decreasing sea ice cover affecting light availability and ocean stratification. Further, ocean acidification poses physiological challenges that may lead to changes in species composition exacerbated by temperate species being transported towards the Arctic by ocean currents. The FAABulous project (Future Arctic Algae Blooms - and their role in the context of climate change) aims to improve our understanding of how these multiple stressors may affect the timing, species composition and productivity of future algae blooms in the Arctic. It has utilized two model arctic fjord systems with contrasting oceanic and ice characteristics. In a multidisciplinary approach we combined seasonal field observations with high temporal resolution, with experiments and modelling.

First results show that the extent of Atlantic water advection determines the temperature regime and nutrient supply in the two different systems, resulting in large differences in bloom scenarios. Furthermore, experimental work shows a clear physiological response by dominating sea ice diatoms to future stress scenarios that differs fundamentally from their pelagic counterparts. We therefore anticipate profound changes in bloom phenology in the Arctic with cascading implications for higher trophic levels.
Controls on Primary Productivity and Nitrogen Fixation in Arctic Waters

Allison Fong¹ (allison.fong@awi.de), Eric Raes¹, Anya Waite¹

¹Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Polar Biological Oceanography, Bremerhaven, Germany

In recent years, new studies demonstrate that biological nitrogen fixation (BNF) is an unresolved process in Arctic marine ecosystems. Low BNF rates have been measured in the shallow shelves of the Chukchi Sea and areas of the Canadian basin, and nifH genes have been recovered from widespread areas across the Arctic Ocean. However, there remains little to no evidence of BNF activity from offshore Arctic waters. Previous studies suggest that diazotrophic assemblages are potentially dominated by heterotrophic bacteria in Arctic marine waters, and not by photosynthetic cyanobacteria as is common in (sub)tropical oceans. This could imply decoupling between primary productivity and BNF in the photic zone. In the summer of 2017, experiments were conducted during an ice drift campaign in the Atlantic sector of the Arctic Ocean (~82N), north of Svalbard, to test controls on primary productivity and BNF activity. Natural, whole seawater microbial assemblages were amended with glucose and subjected to simple alterations in incoming irradiance to test how these variables may induce or suppress Arctic BNF activity and alter primary productivity. Experimental bottles were incubated in situ on an under-ice mooring line. Together, these experiments aim to elucidate plankton assemblage responses to variations in light and measure stimulations of BNF rates in the Arctic Ocean.
Impacts of Light and Nutrients on Simulated Under-ice Phytoplankton Blooms

Aurélie Delaforge1 (delafora@myumanitoba.ca), Joannie Ferland2, Virginie Galindo1, Patrick Raimbaud3, Marcel Babin5, Søren Rysgaard4,5, C.J. Mundy1
1University of Manitoba, Centre for Earth Observation Science, Winnipeg, Canada, 2Laval University, Takuvik Joint International Laboratory, Québec, Canada, 3Centre d’Océanologie de Marseille, Laboratoire d’Océanographie et de Biogéochimie, Marseille, France, 4University of Aarhus, Arctic Research Centre, Aarhus, Denmark, 5Greenland Institute of Natural Resources, Greenland Climate Research Centre, Nuuk, Greenland

The warming Arctic Ocean and increasing first-year ice cover (FYI) has helped fuel recent attention on under-ice phytoplankton blooms. Here we focus on the response of under-ice phytoplankton growth and taxonomic composition to varying light and nutrient conditions. This study will allow to better understand potential responses of a developing bloom. Experiments were carried out during the 2016 Green Edge ice camp, near Qikiqtarjuaq (Baffin Island, Canada). The experiment included mimic of three light regimes (light availability underneath FYI, open water, and open water with an UV-blocking filter) and two nutrient conditions (ambient and doubled ambient concentrations). Experiments were ran from June 17 to July 06. For all ambient nutrient conditions the peak of chl $a$ was obtained on day 12, whereas for all doubled nutrients treatments the peak occurred on day 14. However, chl $a$ concentrations were significantly higher for conditions under lowlight whereas highlight and highlight minus UV treatments had similar results. All experimental conditions resulted in dominance of *Phaeocystis pouchetii*, but diatom species such as *Thalassiossira spp.*, *Attheya spp.*, *Synedropsis hyperborea*, *Cylindrotheca closterium* as well as *Navicula spp.* were also observed to be dominant in different samples. These results highlight the sensitivity of under-ice phytoplankton to rapid light exposure, shedding light on the potential response of a surface under-ice phytoplankton bloom during ice break-up.
Photophysiology of Nitrate Limited Phytoplankton Communities in Kongsfjorden

Gemma Kulk1 (g.kulk@rug.nl), Willem Hendrik van de Poll1, Anita Buma1,2
1University of Groningen, Ocean Ecosystems, Groningen, Netherlands, 2University of Groningen, Arctic Centre, Groningen, Netherlands

In Arctic coastal regions, the phytoplankton bloom is initiated by meltwater induced stratification in spring, while the subsequent depletion of nutrients from surface waters is believed to be a driving factor in phytoplankton succession. A series of nutrient addition experiments showed that the phytoplankton community in Kongsfjorden, Spitsbergen, became N limited from mid-June onwards and co-limitation with P occurred later in summer. The onset of N limitation was followed by a pronounced change in taxonomic composition with a shift in dominance from chrysophytes to haptophytes and a decrease in phytoplankton cell size. Additional measurements of PSII photophysiology and electron transport rates by Fast Repetition Rate Fluorometry (FRRf) showed that the community dominated by chrysophytes was characterized by high PSII efficiency and electron transport rates that were efficiently used for growth. While the taxonomic composition of the phytoplankton community changed, alternative electron requirements became more important and energy was likely allocated to the uptake of nutrients rather than growth. It is suggested that the ongoing changes in sea ice cover and melting of marine terminating glaciers could change the duration and intensity of nutrient limitation in the Arctic with consequences for not only phytoplankton taxonomic composition, but also photophysiology and primary production.
The Southern Ocean (SO) is an important sink for anthropogenic carbon dioxide (CO₂). Climate change will cause changes in various environmental parameters, which in turn can affect growth and productivity of SO phytoplankton. Due to global warming, sea surface temperatures will increase and lead to a more stratified and shallower mixed layer resulting potentially in higher light availability and enhanced primary production of iron-limited phytoplankton. On the other hand, ocean acidification may reduce the bioavailability of iron to phytoplankton. To examine the influence of iron availability in combination with current and future higher CO₂ concentrations under low and high irradiance on SO phytoplankton physiology, bottle manipulation experiments with a natural phytoplankton assemblage from the Drake Passage were conducted. Ocean acidification led to lowered abundances of *Pseudo-nitzschia* species at both irradiances. While higher irradiance stimulated daily particulate organic carbon production, this stimulating effect, however, was reduced under high pCO₂, but only under iron-limitation. Moreover, the ratio of biogenic silicate to particulate organic carbon remained unchanged by high pCO₂ for both iron treatments under high light, but declined under low light. Gaining more insight on the complex interplay of multiple environmental factors is valuable to predict future responses of SO phytoplankton to climate change.
Coastal Antarctic waters are amongst the most vulnerable to ocean acidification, as a result of their cold, well-mixed waters making a disproportionally large contribution to global anthropogenic CO2 uptake. Changes in oceanic carbonate chemistry have been shown to differentially effect marine microbial communities, in some cases resulting in strong shifts in primary productivity and community composition, both of which have implications for carbon sequestration and biogeochemical cycling. Here we used 650 L tanks to incubate natural Antarctic marine microbial communities at six levels of fCO2 (343 - 1641 uatm). Increasing fCO2 resulted in a shift in the diatom community, with the larger diatoms (>20um) being negatively affected, while smaller diatoms increased in abundance or showed no change. Similarly, photosynthetic capacity of large diatoms declined, while smaller species were unaffected by the high fCO2. There was a strong decline in silicate incorporation rates with increasing fCO2, and total diatom silification dropped by >60% from the ambient (343 uatm) to the highest (1641 uatm) fCO2 incubation. The loss of larger diatoms and decline in silification could have broad implications for trophic interactions, primary productivity and biogeochemical cycling, altering carbon sequestration capacity of Antarctic waters. Taken together, these data suggest that in a high CO2 world, major changes to the future carbon sink can be expected for this region.
Circulation Patterns of the Atlantic Boundary Current along the Svalbard Shelf

Sebastian Menze\textsuperscript{1} (sebastian.menze@imr.no), Randi Ingvaldsen\textsuperscript{1}
\textsuperscript{1}Institute of Marine Research, Bergen, Norway

Warm Atlantic water enters the Arctic as boundary current through Fram Strait (West Spitzbergen Current, WSC) and is the major oceanic heat source to the Arctic Ocean. Along the North-Western Svalbard shelf, the WSC splits into the shallow Svalbard Branch, the Yermak Branch that follows the slope of the Yermak Plateau and possibly the Yermak Pass Branch that flows across the plateau.

The WSC has previously been studied using moorings, dedicated oceanographic transects and models. In this study, we mapped the WSC using Vessel Mounted Acoustic Doppler Current Profiler data from multiple surveys and vessels during 4 consecutive summers. Despite the “snapshot” nature of this compiled data set, persistent circulations patterns could be discerned.

We observed a stable northward jet between 79 and 80 °N and the 1000 - 500 m isobath, before the WSC divided into several branches, in all summers. Current profiles West of Svalbard and on the Yermak Plateau showed higher variability than North of Svalbard, which is linked to eddies, recirculation, tides and internal waves. Objective mapping showed a meandering boundary current West of Svalbard and a more homogeneous current centered around the 1000 m isobath North of Svalbard. In our data set, the shallow Svalbard Branch reunites with the Yermak Pass Branch between 10 and 15 °E. Transport estimates are given for several sections and compare well with previous observations and models.
Atlantic Water Properties and Circulation North of Svalbard in a Changing Arctic

Zoé Koenig1 (zoe.koenig@locean-ipsl.upmc.fr), Christine Provost1, Nathalie Sennéchael1, Amélie Meyer2, Gilles Garric3, Jean-Claude Gascard1
1LOCEAN - Sorbonne Universités - UPMC/CNRS/IRD/MNHN, Paris, France, 2Norwegian Polar Institute, Fram Centre, Tromsø, Norway, 3Mercator Ocean, Ramonville Saint Agne, France

The Atlantic Water (AW) inflow is crucial for the heat and salt budget of the Arctic. Its properties encountered in the Arctic Basin depend on the processes that largely alter the AW layer North of Svalbard. IAOOS (Ice Atmosphere Ocean Observing System) platforms were deployed during the N-ICE2015 expedition gathering the first winter hydrographic data in the area. They document shallow warm water over the Svalbard continental slope that melts sea ice with ice-ocean heat fluxes reaching up to 400W.m⁻². Heat is brought from the AW layer up to the surface through near-inertial waves generated by winter storms, barotropic tides and geostrophic adjustments. Sea ice extent largely differs between winters 2015 and 2016 and can be explained by convection-induced upward heat fluxes suggested by the analysis of 1/12° operational model outputs from Mercator Ocean.

Model is used to examine AW inflow pathways north of Svalbard. It shows an AW winter pathway not much documented before: the Yermak Pass Branch (YPB) across the Yermak Plateau. YPB properties are examined using one-year (2007-2008) of moored ADCP data in the Yermak Pass. The flow is largely dominated by tides. In winter, baroclinic eddies and pulses of AW carrying AW eastward in the Pass are found. Finally, the model suggests an important mesoscale activity along the AW flow, also suggested by high resolution glider observations performed in summer 2017 across the main AW branches and over the Yermak Plateau.
Satellite-derived Sea Level in the Ice-covered Polar Oceans

Thomas Armitage¹ (tom.w.armitage@jpl.nasa.gov), Ron Kwok¹, Andrew Thompson², Sheldon Bacon³, Alek Petty⁴,⁵
¹Jet Propulsion Laboratory, California Institute of Technology, Pasadena, United States, ²California Institute of Technology, Environmental Science and Engineering, Pasadena, United States, ³National Oceanography Centre, Southampton, United Kingdom, ⁴NASA Goddard Space Flight Center, Cryospheric Sciences Laboratory, Greenbelt, United States, ⁵University of Maryland, Earth System Science Interdisciplinary Center, Greenbelt, United States

Sea surface height (SSH) is poorly observed in the polar oceans due to a lack of tide gauges, poor coverage by conventional altimeters, and the seasonal or perennial ice-cover. Using recently developed techniques to combine conventional altimetry with SSH retrievals from openings in the ice cover, time series of monthly SSH composites have been produced at both poles. In the Arctic, seasonal freshwater fluxes lead to a large SSH seasonal cycle, and SSH changes in the 2000’s reflect Beaufort gyre (BG) freshwater accumulation. Meanwhile, surface circulation intensified and the center of the BG shifted some 300km to the northwest. In the Southern Ocean, the Antarctic Slope Current system is revealed to be a circumpolar feature which is strongest in autumn. Monthly circulation variability in the Ross and Weddell gyres is modulated by the local wind stress curl, which in turn is weakly correlated with the Southern Annular Mode (SAM). There are significant SSH responses to the SAM and the Southern Oscillation; in particular, the 2015-16 El Niño drove sustained negative coastal SSH anomalies, implying shoaling of isopycnals with the potential to deliver circumpolar deep water to the cavities of West Antarctic ice shelves. These data sets provide first looks at seasonal and sub-seasonal SSH variability in the polar oceans and their coupling to atmospheric forcing; extending this data set would provide invaluable observations of how the polar oceans are adjusting under climate change.
Deep-water Upwelling in the Southern Ocean: Spirals, Hotspots, Carbon, and Ice

Northern Deep Waters upwell in the Southern Ocean, carrying low oxygen, high nutrients/carbon from the Indian/Pacific to the sea surface, as well as warm and relatively saline waters from all oceans and especially the Atlantic. The 3-dimensional upwelling within the ACC is tracked using modelled particles and observations. The global-scale southward spiraling of the fronts is guided by underlying topography, shifting them far northeastwards in some regions, interleaving with regions of southward Sverdrup transport over abyssal plains. The nearly isopycnal upwelling is greatly enhanced at eddy hotspots where the ACC crosses topography. A circumpolar ‘upwelling chimney’ of carbon and nutrients results in large carbon outgassing to the atmosphere, as shown from a new array of biogeochemical Argo (‘SOCCOM’) floats and the Southern Ocean State Estimate. These fronts also guide the winter sea ice extent and its variability. Hydrographic observations show stronger penetration of full-depth ACC water into the Amundsen/ Bellingshausen Seas in 2011 compared with 1992, consistent with decreasing sea ice and increasing ice-shelf melt. In contrast, winter sea ice has increased where the southern ACC is topographically locked into northeastward pathways. The standing eddy pattern of ACC poleward heat flux, strengthening winds, and decadal winter sea ice changes are consistent with strengthening circulation along the southern side of the ACC, likely driven by increasing westerly winds.
Climate model simulations suggest that ocean heat transport (OHT) into the Arctic is connected to a strong Atlantic Meridional Overturning Circulation (AMOC) under decadal variability (e.g., Zhang 2015). Meanwhile, when driven by greenhouse gas (GHG) forcing, models predict a robust increase in OHT into the Arctic and a high correlation with the degree of Arctic warming (Hwang et al. 2011; Nummelin et al. 2017). Yet, they also simulate a weakening of AMOC under GHG forcing, suggesting that the dynamics linking AMOC and OHT changes under GHG forcing are distinct from that seen under internal variability.

Here, we identify the dynamics governing OHT changes into the Arctic within GHG-forced and pre-industrial simulations of NCAR's CCSM4. We quantify OHT anomalies in terms of 'active' circulation changes versus 'passive' changes (warming advected by climatological currents). Unforced decadal variability in OHT is dominated by AMOC changes to the south of the subpolar gyre, while increased OHT into the Arctic is driven by active and passive gyre circulations in the Nordic Seas. Under GHG forcing, OHT at 45N decreases as AMOC weakens, while OHT into the Arctic increases due to a combination of climatological overturning and changing gyre circulations in the Nordic Seas. These findings suggest that distinct dynamics control forced and unforced OHT changes, and that links between AMOC and OHT under decadal variability cannot be extrapolated to explain future forced changes.
Metrics for the Evaluation of the Southern Ocean in Climate Models

The Southern Ocean and its role in, and response to, the ongoing anthropogenic trend varies widely among global coupled climate models and earth system models. Observationally-based metrics are critical for discerning processes and mechanisms, and for validating and comparing climate and earth system models. New observations and understanding, especially those gained from semi-autonomous, biogeochemically-sensored floats (from SOCCOM), have allowed for progress in the creation of observationally-based data/model metrics for the Southern Ocean. These metrics provide a means to assess multiple simulations relative to the best available observations and observational products: climate models that perform better according to these metrics also better simulate the uptake of heat and carbon by the Southern Ocean. Observationally-based benchmarks are essential in order to reduce uncertainties in climate projections, and especially uncertainties related to oceanic heat and carbon uptake.
Developing Synthetic Observation System for Polar Atmospheric Research at PRIC

Wentao Huang1 (huangwentao@pric.org.cn), Rui Wang1, Huigen Yang1, Hongqiao Hu1, Zhiguang Han1, Zejun Hu1, Dehong Huang1, Fang He1

1Polar Research Institute of China, Shanghai, China

The polar regions are the entrances for the solar wind energy entering geospace. A conjugated system for space physics observation has been established at the Antarctic Zhongshan Station and Arctic Yellow River Station, which are both located in the unique polar cusp regions and approximately at the conjugated ends of one magnetic field line. To fill the current blank of atmospheric observation, we are developing a synthetic observation system for polar atmosphere, including a Na Doppler lidar currently and other lidars in the future. The Na Doppler lidar under development is to measure the diurnal temperature and winds in the Mesosphere and lower Thermosphere, aiming to investigate the coupling between the activities of space weather and the neutral upper atmosphere. A coherent Doppler wind lidar for measuring tropospheric winds, a Raman temperature lidar and a Rayleigh temperature lidar for measuring tropospheric and mesospheric temperature are in the plan to form a synthetic observation system capable of profiling the vertical structure of atmospheric temperature and/or winds from surface up to lower thermosphere. This system will provide comprehensive data to study the interactions of solar activities with the Earth’s atmosphere, and the dynamical coupling among the atmospheric layers in polar regions.
Atmospheric water vapor is an important indicator of the Earth's climate state and evolution. Although representing a few percentages of the total content, Antarctic water vapor plays an important role in snowfall accumulation and surface mass balance. Thus, accurate long time series of water vapor content are crucial to understand the current climate and to assess the reliability of global climate models. Geodetic measurements are being made at permanent research stations maintained by different institutions. IGS, POLENET and regional networks now cover large sectors of Antarctica and provide long-term data sets that can be used for studying Precipitable Water (PW) and its variability. Long and consistent time series of data are required, possibly recorded by different and independent sensors to overcome systematic errors and obtain accurate results. Thus, Radiosounding (RS) data performed at 7 coastal stations using Vaisala radiosondes were analysed, to fully exploit the capability of GPS to provide reliable PW, even if RS observations are not available. A regional model of the mean Temperature was computed for this purpose. Up to 20-year time series of GPS observations acquired at all available geodetic stations were processed with the purpose of ensuring the utmost accuracy of the results adopting homogeneous, consistent, and up-to-date processing strategies. Results are shown for the available GPS sites, giving an up-to-date picture of the PW behavior over Antarctica.
Latitudinal Ionospheric Scintillation Study in the American Sector

Emilia Correia\textsuperscript{1,2} (ecorreia@craam.mackenzie.br), Lucilla Alfonsi\textsuperscript{3}, Luca Spogli\textsuperscript{3}, Giorgiana De Franceschi\textsuperscript{3}, Vincenzo Romano\textsuperscript{3}, Nicola Linty\textsuperscript{4}, Ingrid Hunstad\textsuperscript{3}, Olivier Terzo\textsuperscript{5}, Fabio Dovis\textsuperscript{4}, Gilmar Alves\textsuperscript{2}, Roberto Camara\textsuperscript{6}

Demonstrator for Global Navigation Satellite System (GNSS) Research and Application for Polar Environment (DemoGRAPE) is an international project leaded by the Istituto Nazionale di Geofisica e Vulcanologia (INGV), in partnership with Politecnico di Torino, Istituto Superiore Mario Boella, and with South African National Space Agency (SANSA) and the Brazilian National Institute of Space Physics (INPE), as collaborators. The aim of project is to improve satellite navigation particularly in Antarctica, where the accuracy is of paramount importance for the surface displacements, and it is strongly affected by atmospheric disturbances. The DemoGRAPE activities started on November 2015 with the system installed at Brazilian Antarctic Station Comandante Ferraz (EACF, 62° 05´07"S, 58°23´29" W) located in the King George Island. To investigate the ionospheric disturbances from high to low latitudes in the American sector we present the GNSS scintillations observed at EACF inside DemoGRAPE activities, which are combined with GNSS observations done at Universidade Mackenzie in São Paulo (23°32´56"S, 46°38´20"W, inside the South American Magnetic Anomaly - SAMA) and at Cauamê Campus of Universidade Federal de Roraima (02°49´12"N, 60°40´23" W) during 2016. The goal is to characterize the occurrence of scintillation at high latitudes in association with the fountain effect at low latitudes and inside the SAMA region.
Small and Medium Scale Gravity Waves Climatology over Ferraz Station

Jose Valentin Bageston¹ (bageston@gmail.com), Gabriel Augusto Giongo¹,², Cristian Max Wrasse³, Cosme Alexandre O. B. Figueiredo³, David C. Fritts⁴, Diego Janches⁵, Yong-Ha Kim⁶, Hosik Kam⁷

Inc., Boulder, United States, ⁵NASA Goddard Space Flight Center, Space Weather Laboratory, Greenbelt, United States, ⁶Korea Polar Research Institute (KOPRI), Division of Polar Climate Change Research, Incheon, Korea, Republic of, ⁷Chungnam National University, Dept. Astronomy, Space Science and Geology, Daejeon, Korea, Republic of

Gravity waves at distinct spectrum of wavelengths and periods play an important role in communicating, through energy and momentum transportation, between the different atmospheric layers. The main aspects associated to the gravity waves are the general circulations processes in the middle and upper atmosphere and the temperature gradients. Regarding the high gravity wave activity and observations at the Brazilian Ferraz Station (62.1°S, 58.4°W), we have been observed small and medium scale gravity waves from an all-sky airglow imager in the last three years, besides a full winter campaign in 2007 and two consecutive winters in 2010-2011. Even we suffered from a lack of observations in 2008-2009 and 2012-2014, during the observed years it was possible to identify many gravity waves of very distinct morphology, i.e., bands, ripples and mesospheric fronts, and a wide range of horizontal wavelength, period and propagation directions. In the present work we will summarize the gravity waves observations at Ferraz Station since 2007 up to 2016, focus firstly in the morphology of the small scale waves, its parameters and propagation directions. Latter on, it will be presented the methodology used to extract the medium-scale gravity wave parameters and the observed and intrinsic wave parameters. At last, will be presented the current status of the observations at Ferraz Station and future plans to maintaining these observations and restore or expand other type of observations.
The ionosphere can affect space-borne Synthetic Aperture Radar (SAR) measurements especially at lower frequencies producing some artefacts in the SAR images. They are mainly addicted to the Total Electron Content (TEC), i.e. the integral of the electron density along the path between the satellite and a given target. TEC fluctuations along the azimuth direction result in the degradation of the quality of the SAR imaging, visible as streaks in SAR images. Furthermore, TEC temporal variation between two SAR passes produces an error in the SAR Interferometry (InSAR) technique known as phase advance. These errors are expected to exacerbate at high latitudes, characterized by ionospheric irregularities and scintillation phenomena due to the direct interaction of the ionospheric plasma with the geospatial environment. In this work, the effects of high latitude ionosphere on selected SAR images are investigated in detail using TEC and scintillation measurements from GNSS receiver networks located at ground. The outcomes of this investigation are shown and critically discussed in relationship with the different roles of troposphere and ionosphere impacts on SAR data.
Comparison between FPI and Meteor Radar Observations for MLT at KSS, Antarctica

Changsup Lee¹ (cslee@kopri.re.kr), Geonhwa Jee¹, Qian Wu², Jeong-Han Kim¹
¹Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of; ²National Center for Atmospheric Research (NCAR), Boulder, United States

Neutral winds and temperature in the mesosphere and lower thermosphere (MLT) have been simultaneously observed by Fabry-Perot interferometer (FPI) and meteor radar (MR) at King Sejong Station (KSS), Antarctica for a full year of 2017. The simultaneous optical and radar observations for the neutral atmosphere in the MLT region provide us with an excellent opportunity of comparing the measurements from the two observation techniques. Furthermore, since Antarctic peninsula has been well known for strong wave activities such as orographic gravity waves, the observations from these two instruments can be used to reveal the characteristics of neutral atmospheric responses to the waves in the MLT region. Using these observations, the neutral winds are compared at two airglow layers of 87 km and 97 km. We found the well-defined semidiurnal tidal structures such as downward phase progression and 90-degree phase difference between zonal and meridional winds. Neutral temperatures estimated from two instruments are also compared to investigate the geomagnetic effects on MLT temperature.
Saildrone Measurements in the Arctic

Edward Cokelet¹, Calvin Mordy¹,², Jessica Cross¹ (jessica.cross@noaa.gov), Alex De Robertis³, Carey Kuhn³, Richard Jenkins⁴, Noah Lawrence-Slavis¹, Christian Meinig¹, Heather Tabisola¹,², Phyllis Stabeno¹
¹NOAA Pacific Marine Environmental Laboratory, Seattle, United States, ²University of Washington, JISAO, Seattle, United States, ³NOAA Alaska Fisheries Science Center, Seattle, United States, ⁴Saildrone, Inc., Alameda, United States

Saildrones are sail- and solar-powered USVs developed by Saildrone Inc., NOAA and UW to make remote, season-long meteorological, oceanographic and fisheries measurements. They sail autonomously between user-controlled waypoints and transmit data ashore via satellite. Saildrones conducted three missions in the Bering Sea in summers 2015-2017 and into the Chukchi Sea and Arctic Ocean in 2017, each sailing over 6000 km per mission. They measure solar irradiance, wind, humidity, barometric pressure, air and water temperature, sea-surface salinity, dissolved oxygen, chlorophyll a, CDOM, and optical backscatter. In 2016-2017 the Bering vehicles made acoustic measurements of the abundance and distribution of walleye pollock, conducted focal follows of satellite-tagged fur seals and recorded the presence of marine mammals. A pCO2 system was added in 2017 to measure CO2 exchange. Measurements were compared with ships and moorings. Wind speeds exceeded 40 knots at times. Low salinity and high CDOM and pCO2 were found 200 km seaward of the Yukon River mouth. Near Bering Strait, the saildrones observed high chlorophyll a and oxygen saturation implying enhanced biological production. One saildrone reached 75°N in the Arctic Ocean basin where it measured a cold surface temperature of -0.23°C and a low salinity of 26.5 (PSS-78) on 13 August 2017. The Saildrone platform has proven to address key research questions and is continually being updated with new sensors and data-sharing capacity.
Under-ice Argo Floats in the Southern Ocean

Esmee van Wijk¹,² (esmee.vanwijk@csiro.au), Luke Wallace¹,³, Stephen Rintoul¹,⁴
¹CSIRO Oceans & Atmosphere, Hobart, Australia, ²Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia, ³RMIT University, Melbourne, Australia, ⁴Antarctic Climate and Ecosystems Cooperative Research Centre, Hobart, Australia

The seasonal sea ice zone of the Southern Ocean is one of the largest remaining 'blind spots' in the global ocean observing system. Key science questions relevant to climate and sea level rise require sustained, broad-scale observations in the high latitudes. Historically, measurements from shipboard hydrography are sparse, particularly during the winter months. Ice-capable Argo floats have provided year-round sampling of the Southern Ocean since 1999, measuring approximately 50,000 profiles below 60°S. We review the status, achievements and future of the Argo array in the Southern Ocean with a focus on under-ice floats (longevity, reliability, dispersion and loss). Novel missions for under-ice Argo, including floats deployed on the Antarctic continental shelf and in polynyas have provided new insights into sea-ice production, air-sea-ice-ocean interactions, circulation, water mass formation and tides. Ice-capable floats parked on the sea-floor between profiles can provide data for several years on the Antarctic continental shelf. A major issue for under-ice profiles is the loss of position data when floats are unable to surface in winter. A new algorithm was developed to improve the estimates of profile location and uncertainty of under-ice data. Deployments of ice-capable floats have proven the feasibility of under-ice observing and provide guidance for the design of a sustained under-ice observing system.
A Challenge towards Cost-effective and Autonomous Observations under the Sea-Ice

Michel Rixen1 (mrixen@wmo.int)
1World Meteorological Organization (WMO), Geneva, Switzerland

The cryosphere is a major indicator of global climate change and plays a fundamental role in the Earth System. Despite advances in numerical modelling, the reliability of weather forecasts and long-term climate predictions in the Arctic and Antarctic is severely limited by the lack of systematic in situ observations of and beneath the sea-ice. In situ ocean observations in polar regions are inherently expensive, risky and sparse, even more so under the sea-ice. Those shortfalls can be addressed by recent progress in Autonomous Underwater Vehicle (AUV) technology.

The World Climate Research Programme (WCRP) and the Prince Albert II of Monaco Foundation (FPA2) are jointly promoting a Polar Challenge that will reward with a Prize of 500,000 Swiss Francs the first team to complete a 2 000 km mission with an AUV under the Arctic or Antarctic sea-ice. Bonus awards will also be delivered for regular measurements of sea-ice thickness or draft, and for successful transmission of under-ice position and environmental data to operational networks in near real-time.

The overall vision of this challenge is to promote a cost-effective, sustainable and autonomous polar ocean monitoring system to drive a new era for research, application and services. The ultimate goal is to achieve with some analogy what ARGO (www.argo.ucsd.edu/) has accomplished for the open ocean with profiling floats.

More details at www.wcrp-climate.org/polarchallenge
Acquiring scientific data in Polar Regions is often problematic due to harsh weather and risky operating conditions. In the last decade the use of robots for substituting human beings in performing difficult, dangerous and burdensome tasks has become more and more frequent. According to this trend, in summer 2015 and 2017, a group of researchers of ISSIA-CNR carried out two scientific campaigns in the Kongsfjorden, an Arctic glacial fjord located in the Svalbard Archipelago. The campaigns involved both marine and aerial autonomous vehicles for collecting environmental parameters. In particular, the two USSVs (Unmanned Semi-Submersible Vehicles) Shark and PROTEUS, and the UAV (Unmanned Aerial Vehicle) OTTO were used to acquire both marine and atmospheric data in the proximity of the dangerous fronts of tidewater glaciers. Sampling in these areas is important to understand the peculiar local phenomena occurring during ice calving but data are missing due to the difficulties in accessing these extremely hazardous sites. The possibility of sudden falls of massive ice blocks and the steep and friable slopes of the sides make it impossible for operators to get close to the front of glaciers and the use of unmanned vehicle proved to be decisive. The success of the campaigns demonstrated that unmanned vehicles technology is mature for collecting data in these areas and can be of great help to scientists involved in the monitoring of processes occurring in the Arctic region.
Snow and Ice Thickness Retrieval from SIMBA Temperature Profiles in Antarctic

Jiechen Zhao¹ (zhaojiechen@outlook.com), Qinghua Yang¹, Bin Cheng², Fengming Hui³, Hui Shen¹, Lin Zhang¹
¹National Marine Environmental Forecasting Center, Beijing, China, ²Finnish Meteorological Institute, Helsinki, Finland, ³Beijing Normal university, Beijing, China

Antarctic snow and sea ice thickness is an important indicator for global climate change and the main parameters for icebreaker sailing in the ice-covered region. A kind of SIMBA buoy with 240 sensors in every 2 cm interval was deployed in the fast ice near Antarctic Zhongshan Station during 2014 and 2015 to record snow and ice temperature profiles and heating responses and study the method to retrieve snow and ice thickness. The analysis showed that the adjacent temperature profiles changed largely in the air, about 2°C; Sea water beneath ice showed stable temperature, -1.7~-1.9°C; Snow and ice had a large temperature gradient vertically. The 60 s heating responses showed that, temperature increment was about 2.0~4.0°C in the air, about 2.5~5.0°C in the snow, about 0.8~1.0°C in the ice and about 0.6~1.2°C in the water. Depending on those results above, two independent methods “automatic algorithm” and “manual detection” were used to analyze snow and ice thickness. Compared to field observed ice thickness, RMSE of those two methods was 6.4 cm and 6.4 cm respectively in 2014, and 6.6 cm and 6.5 cm respectively in 2015. As to snow depth, RMSE was 10.8 cm and 8.5 cm respectively. The retrieved snow and ice thickness had acceptable bias of around 3 sensors for ice and 4~5 sensors for snow, considering the maximum ice thickness of around 150 cm. Therefore this kind of SIMBA buoy and the two methods were suitable and flexible for Antarctic snow and fast ice thickness retrieval.
Observing Stratigraphy and Crevasses with Robot-towed Ground Penetrating Radar

Laura Ray¹, Austin Lines¹ (austin.p.lines.th@dartmouth.edu), Joshua Elliot¹, Madeleine Jordan¹,², Benjamin Walker¹, Mary Albert¹, Steven Arcone¹, James Lever³, Lynn Kaluzienski⁴, Peter Koons⁴
¹Dartmouth College, Thayer School of Engineering, Hanover, United States, ²Helmut Schmidt University, Hamburg, Germany, ³U.S. Army Cold Regions Research and Engineering Laboratory, Hanover, United States, ⁴University of Maine, Orono, United States

We present results of using robot-towed ground penetrating radar for measurements of stratigraphy and crevasse features. We describe the development of lightweight (< 80 kg), electric and solar-electric rovers that navigate autonomously and tow scientific instruments secured to a sled. We report on use of the rovers for
1) imaging surface stratigraphy in a dry snow zone to estimate local variability in compaction;
2) imaging a 25 km² area of a marginal shear zone from surface to marine ice to observe complex shear zone dynamics from the characteristic surface and marine ice crevassing; and
3) autonomous detection and mapping of the length of individual crevasses within the shear zone.

From the first project, we demonstrate how local surveys relate to longer transects for establishing variation in snow and firn compaction. From the latter projects, we demonstrate construction of a local velocity map within the McMurdo Shear Zone (MSZ) derived from annual crevasse motion. The survey provides multiple crossings of long (> 1 km) crevasses that appear in echelon on the western and eastern boundary of the shear zone as well as two or more crossings of shorter crevasses in the chaotic zone. A local velocity field is estimated by mapping these crevasses and crevasse segments in annual datasets and projecting movement of crevasses annually. These projects demonstrate the use of autonomous robots to acquire data that would otherwise be inaccessible from human-operated vehicles.
Regions of juxtaposed active and relict biogeochemical cycling are rare on Earth. Lake Untersee Oasis is one of these environments: it contains two perennially ice-covered lakes (Untersee and Obersee) with benthic, photosynthetic microbial mats, and an adjacent ice-free valley (Aurkjosen) that has evidence of a paleo-lake basin, with relic dried microbial mats buried in permafrost soils. We will present preliminary results of a broad research effort that aims at:

1) characterizing the present-day hydrological conditions of Lake Untersee;
2) characterizing the dynamics of microbial ecosystem in Lake Untersee;
3) reconstructing the past hydrological conditions in the Oasis; and
4) assessing the preservation state of molecular biomarkers in relic microbial mats of the Aurkjosen Valley paleo-basin.

Hydrogeochemical analysis indicates that the lake’s primary source of water is derived from glacial meltwater with a small contribution of groundwater and that water loss is mainly through sublimation of its ice cover. Modeling suggest that the lake’s geochemistry is controlled by sublimation, which affects the amount of freezing and associated D-18O and solute fractionation. d18O analysis of carbonates found in relict microbial mats suggests a water d18O composition evolution to higher values over the Holocene. Upcoming biogeochemical analysis of active and relict organics mats should provide further insights on the preservation potential of organic compounds in this cold environment.
Ice-free areas in the Northern Antarctic Peninsula region are influenced by periglacial, glacial, fluvial, and coastal processes and landforms. Permafrost is present in these areas and influences the fragile ecosystems containing cryosols. The objective of this work is to determine the interaction between periglacial processes and landforms on a variety of soil characteristics within different ice-free areas of the South Shetland Islands. Recent field work identified glacial deposits, patterned ground, pavements, and slope debris among the most prevalent surfaces. Laboratory analyses showed that soil properties are clearly related to lithological and geomorphological factors. In a number of cases, the soils have a sandy loam texture, which indicate a good drainage. Some soils have increased clay content which results in poorly-drained soils. In this case, drainage of the soil and surface processes defining the land cover are closely related to the permafrost environments. Active layer depth with freeze-thaw cycles that take place during the summer influence soil properties such as bulk density, texture and structure as well as the water holding capacity. Factors such as lithology, elevation, slope and distance from the coast further influence the soil properties. Therefore, the active surface processes during the limited Antarctic summer are dominant and soil material becomes displaced causing unstable soil development.
Endolithic and Hypolithic Systems as Protosoils: Evidence from the Two Poles

Nikita Mergelov¹ (nikvox@yandex.ru)
¹Institute of Geography Russian Academy of Sciences, Moscow, Russian Federation

Endolithic and hypolithic bio-abiotic systems can be regarded as protosoils from the several aspects: (1) as the closest modern analogues of soil progenitors that existed on Earth before vascular plants with root systems established, (2) as precursors of more advanced soil formations in contemporary landscapes and (3) as steady state soil-like bodies in regions with climatic extremes (e.g. East Antarctica). We will discuss in the presentation the structure, composition and weathering mechanisms in endolithic and hypolithic bio-abiotic systems providing the evidence for soil-like processes that occur in these formations at the both Poles: East Antarctica oases (Larsemann and Thala Hills, Schirmacher) and High Arctic archipelagos (Novaya Zemlya and Franz Josef Land). The areas with extreme climatic conditions at the both poles give an opportunity to study cyanobacteria and lichen driven endo- and hypolithic systems as protosoils with the minimum influence from more advanced organisms common to other environments. The newly formed products of biota-to-mineral interactions both in hypo- and endo- cryptic niches are redistributed by erosion processes and contribute significantly to raising complexity of the polar landscapes that are limited in energy and nutrients sources. Besides that endolithic colonization increases weathering rates, induces exfoliation and, thus, reshapes mineral surfaces contributing regularly to the biogeomorphological processes at the both Poles.
Metal Enrichment in Desert Varnish from Ice-free Areas of Coastal Antarctica

Daniel Nyvlt¹ (daniel.nyvlt@seznam.cz), Ondrej Zverina², Renata Copjakova³, Filip Hrbacek¹
¹Masaryk University, Faculty of Science, Department of Geography, Brno, Czech Republic, ²Masaryk University, Faculty of Medicine, Department of Public Health, Brno, Czech Republic, ³Masaryk University, Faculty of Science, Department of Geological Sciences, Brno, Czech Republic

Desert varnish is a coating that forms on the exposed surface of stones located in both hot and cold arid areas. The semi-arid ice-free area of Ulu Peninsula, James Ross Island, represents the largest deglaciated land in Antarctic Peninsula (AP) region that contains numerous granite and basalt cobbles and boulders with well-developed desert varnish. It is generally accepted that desert varnish is composed of clay particles rich in iron and manganese oxides and that iron enrichment is typical for cold environments while desert varnish enriched in manganese is frequently associated with hot environments. Enrichment by 399 ± 239 % and 16 ± 8 % for manganese and iron, respectively, was found at basalt clasts by in situ X-ray fluorescence. The same values for AP granite clasts are 511 ± 644 % and 126 ± 170 % for manganese and iron, respectively. Both petrotypes show high enrichment in manganese. Fe-rich basalts tend to enrich by iron much less than Fe-poor granites. More variable enrichment found for granites corresponds to their larger grain-size and higher mineralogical diversity. At the microscopic level, metal oxides enrichment is connected with quartz and feldspar dissolution and formation of fluorapophyllite and zeolites. Our field and laboratory electron microprobe data from desert varnish on basalt and granite clasts from Ulu Peninsula show that the original rock petrology and mineralogy is more important for specific metal oxide enrichment than the environment.
Wind-driven Rock Abrasion in Antarctica’s Ice-free Valleys: Rates and Controls

Bernard Hallet¹ (hallet@uw.edu), Michael C. Malin², Ronald S. Sletten³
¹University of Washington, Earth and Space Sciences, Seattle, United States, ²Malin Space Science Systems, San Diego, United States, ³University of Washington, Seattle, United States

Wind is a principal geomorphic agent in dry regions of Earth and Mars, where it transports sediments and erodes rock surfaces, creating diverse geomorphic features, and helping generate dust and regolith. Despite its importance, few studies have defined rates of rock abrasion under natural conditions. We report rock abrasion rates well characterized through a comprehensive long-term (>30 year) field experiment in the hyper-arid ice-free McMurdo Valleys, Antarctica. More than 5000 rock targets of several lithologies (dolerite, basalt, and non-welded tuff) were installed at 5 heights above the ground (7 to 70 cm) facing the 4 cardinal directions at 10 sites. Periodic collecting of rock targets exposed to abrasion define the progressive mass loss, a simple measure of the amount of abrasion, after 1, 5, 10, 30 and 31 years of exposure. Abrasion rates generally show striking consistency for a given lithology at any site, but they vary considerably from site to site owing to differences in availability of transportable sediment, wind regime, and surface roughness. For example, for dolerite, basalt, and tuff targets facing the dominant winds, annual abrasion averaged 21, 49, and 3400 microns respectively in central Wright Valley (site 7); in contrast, it averaged 2, 4, and 200 microns at site 8, only 23 km directly up valley of site 7. At each site, rates primarily depend on target orientation relative to the dominant winds and, secondarily on height above the ground.
In extensively glaciarized permafrost areas as Continental Antarctica, rock glaciers are quite common and considered postglacial cryotic landforms. This paper reveals that, two landforms previously mapped on geomorphological bases as rock glaciers, located in Northern Victoria Land should have the same glacial origin. In fact, by integrating different geophysical investigations and borehole stratigraphy, we show that both landforms have similar internal structures and cores of buried glacier ice. Therefore, this kind of rock glacier is possibly related to the long-term creep of buried ice rather than of permafrost creep alone. This interpretation can be extended to the larger part of the features mapped as rock glacier in Antarctica. In addition, a high-reflective horizon sub-parallel to the topographic surface was detected in Ground Probing Radar (GPR) data over a large part of the study area. Combining all the available information, we conclude that it cannot be straightforwardly interpreted as the base of the active layer but rather represents the top of a cryo-lithological unit characterized by ice lenses within sediments that could be interpreted as the transition zone between the active layer and the long-term permafrost table. More generally, the combined use of GPR and ERT is extremely helpful to understand the origin of landforms that can be found also on Mars and, possibly to contribute to understand the paleoclimatic evolution of the cryosphere.
Constructing the Pasts of Polar Futures: History and Heritage in Polar Conflicts

Dag Avango1 (avango@kth.se)
1KTH-Royal Institute of Technology, Div of History of Science, Technology and Environment, Stockholm, Sweden

This paper analyses the role of history and heritage in the international competition for resources and political influence in the Polar Regions. The paper builds on a book project contributing to a broad field of research exploring the production of future visions about the polar regions. A striking feature of these visions is the degree to which they are based on notions about the past. Actors involved in the competition for natural resources and political influence there have used and produced history and heritage as a part of their strategies to influence the future. They have done so on different arenas: through corporate and policy documents, popular history publications, museums, and through designation, narration and management of heritage sites. This paper discusses such practices in the Arctic and Antarctic over the course of the 20th century up until the present. The results show that such politics of memory have played significant roles in the polar regions. By enrolling actors from the past and the material remains of their actions into actor networks, competing actors have populated places with allied actors and actants. These networks have played different roles, defending national prestige, attracting tourists, creating a sense connectedness to distant polar places, as well as legitimizing claims for influence over territories and natural resources.
Antarctica was the last continent to be known. Human encounters with the region acquired different characteristics over time. Within the framework of dominant narratives, the early 'exploitation' of the territory was given less attention than late nineteenth-early twentieth-century 'exploration'. Dominant narratives on the period refer to the captains of sealing vessels, the discovery of geographical features, the volume of resources obtained. However, they do not consider the life of the ordinary sealers who lived and worked on the islands. In this chapter we will try to show the power of archaeology to shed light on these 'invisible people' and their forgotten stories. We hold that archaeology offers a possibility for reimagining the past of Antarctica, calling for a revision of traditional narratives.

In this presentation we will discuss some of the new lines of inquiry we are working with, and some of the results already obtained by the international project “Landscapes in White; Archaeology and Anthropology in Antarctica”. We will focus on the archaeology of experience, and the ways in which “being-in-the-place” could be useful to discuss the life of the 19th-century sealers we are studying. Furthermore, we will present the results of the excavations we are conducting, the use of new technologies in the research, public archaeology and the creation of an interactive record for the archaeological sites.
Competing Discourses and Practices at the Heritage-making Process in Antarctica

Maria Ximena Senatore¹ (mxsenatore@gmail.com)
²CONICET, UNPA-UBA, Buenos Aires, Argentina

Heritage making in Antarctica is a complex process that occurs at multiple contexts (e.g. policy making, archaeological research and tourism), and levels (e.g. international, national, individual). In this paper, heritage is considered a cultural process concerned with negotiating, creating and re-creating cultural memories and values. This process involves a range of discourses and actions used to construct meanings that have relevance and utility in the present. The aim of this paper is to present the characterization of three different competing discourses that underlie different contexts of the heritage making process:
a) policy making in the context of the Antarctic Treaty System,
b) archaeological research and,
c) tourism visitation.
I found that competing discourses understand Heritage as “a thing”, as “a means to an end” and as “an experience”. The actions and practices were analyzed through bibliographical review of the academic production published form 1960 to the present identifying the main objectives and actions taken place in Antarctica in the frame of research projects or conservation projects. I also analyzed the ATCM documents referring to historic sites form 1960 to 2016.
Antarctic Heritage: Cooperation and Conundrums

Bryan Lintott¹ (bjl44@cam.ac.uk)
¹Scott Polar Research Institute, University of Cambridge, Cambridge, United Kingdom

In recent years, there has been increased public interest in Antarctic heritage, ranging from major centennial events to conservation projects. There has also been increasing cooperation between several Antarctic nations in sharing experience and expertise relevant to historic site and monument (HSM) management and conservation.

However, concerns have been raised regarding several aspects of Antarctic heritage. These include an appeal for increased involvement with the values associated (puesta en valor / mise en valeur) with Antarctic heritage, and broader recognition of less prominent people from Antarctica’s past. Standards of HSM management and conservation, and the question of whether or not to retain artefacts in Antarctica - a remote location with a hostile environment - have also arisen.

The decision, in 2015, by the Committee for Environmental protection (CEP) to have a temporary ‘hold’ on future proposals for new HSMs, and the subsequent establishment of an Intersessional Contact Group to consider several heritage matters demonstrates that there are unresolved subjects related to Antarctic heritage.

Since 1961, heritage has been incorporated within Antarctic diplomacy. Whilst a system of HSM designation and protection was developed it was not entirely satisfactory. This presentation will review the history of Antarctic heritage, and identify and discuss the major diplomatic and cultural matters that inform the current conundrums.
Antarctica’s absence of native human population poses challenges and opportunities for those communities living in the periphery of the Southern Ocean in creating connections with the South. Unlike the Arctic communities, people at the today-known Antarctic gateway cities had little association, if so, with Antarctica. Once the geopolitical and economic significance of their role in facilitating access to Antarctica, and its associated knowledge and services, is recognized by their respective nations, multiple strategies are set in place to establish a legitimate polar connection. Cultural imaginings of Polar heritage are employed daily in public spaces as reminders of polar explorers’ past visits to the city, and of the participation of local heroes in Antarctic expeditions. This paper examines the use of Antarctic-related public art within each city, such as statues of polar explorers, the historical and political context in which these statues were erected, and the current significance to the local community in constructing polar belonging and the city’s relationship with Antarctica throughout time.
New Aerogeophysical Survey of Titan Dome and Ice-core Drilling Potential

Lucas Beem¹ (lhbeem@utexas.edu), Duncan Young², Don Blankenship¹, Jamin Greenbaum¹, Gail Muldoon¹, Jason Roberts², Catherine Ritz³, Guo Jingxue⁴, Sun Bo⁴

¹University of Texas -- Institute for Geophysics, Austin, United States, ²Australian Antarctic Division, Kingston, Australia, ³Laboratoire de Glaciologie Géophysique de l'Environment, Saint Martin d'Hères, France, ⁴Polar Research Institute of China, Shanghai, China

Ice domes and divides, including East Antarctic Titan Dome and Dome C, are interior boundaries of major glacier drainages and are thought of as stable regions of ice sheets. As a result, these regions are targets for ice-core drilling including the search for high-resolution climatological proxies that date back 1 to 1.5 Myr. However, subglacial processes and ice flow-reorganization over glacial-cycle timescales can belie the stability of these regions. A new survey of Titan Dome conducted through a partnership between Polar Research Institute of China and University of Texas-Institute for Geophysics offer constraints on the subglacial environment and the distribution of water and heat. Though a combination of data analysis, radar and potential fields, and hydrological modeling the basal heat budget, geological character, and drilling site potential are evaluated. Analysis of Titan Dome observations reveal the presence and distribution of liquid water and complex internal ice structure including locations of local drawdown, suggesting past ice flow or enhanced basal melt. Subglacial water flow, including within the subsurface, influences the basal heat flux by up to multiple factors of assumed geothermal flux. This analysis is aided by the context of a similar but higher density survey of Dome C. Together they offer insights into ice sheet processes that occur at ice-sheet divides and future drilling site potential including in service to NSF’s Rapid Access Ice Drill.
Searching for Oldest ice in Antarctica, an Ice Sheet Modelling pre-site Survey

Johannes Sutter\textsuperscript{1,2} (johannes.sutter@awi.de), Thomas Kleiner\textsuperscript{1}, Klaus Grosfeld\textsuperscript{1}, Nanna B. Karlsson\textsuperscript{1}, Brice Van Liefferinge\textsuperscript{3}, Frank Pattyn\textsuperscript{3}, Hubertus Fischer\textsuperscript{4}, Olaf Eisen\textsuperscript{1,5}

\textsuperscript{1}Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, \textsuperscript{2}University of Bern, Physics Institute & Oeschger Centre for Climate Change Research, Bern, Switzerland, \textsuperscript{3}Université Libre de Bruxelles, Brussels, Belgium, \textsuperscript{4}University of Bern, Physics Institute & Oeschger Centre for Climate Change Research, Climate and Environmental Physics, Bern, Switzerland, \textsuperscript{5}University of Bremen, Bremen, Germany

Covering the Middle-Pleistocene Transition (MPT) transition with a well resolved ice core record is the main motive of the European Beyond EPICA - Oldest Ice (BE-OI) efforts. Pre-MPT glacial cyclicity was dominated by obliquity (ca. 40 ka) which then shifted to 100 ka eccentricity-driven glacial-interglacial cycles typical for the last ca. 800 ka. The drivers of this transition are still obscure, hence a well resolved Antarctic ice core record spanning this transition would provide much needed proxy information. We present transient continental scale 3D ice sheet simulations of the Antarctic Ice Sheet (using the Parallel Ice Sheet Model PISM) which span the last 2 million years to capture, both, pre-MPT as well as eccentricity driven ice dynamics. Employing passive tracers, we dynamically reconstruct the stratigraphy of existing deep ice cores and indicate potential sites of oldest ice around Dome Fuji and Dome C. Around the latter ice core sites, we incorporate new radar derived bedrock topographies to improve the lower boundary conditions. The ice sheet model is forced by a compilation of different geothermal heat fluxes, sea level and climate scenarios to account for a range of potential paleoclimate boundary conditions and their effects on ice dynamics. This study contributes to a variety of modelling and observational efforts to establish the most promising drill site for an ice core up to 1.5 million years old.
In situ Cosmogenic $^{14}$C and $^{36}$Cl Inform Deglacial Ice Extents in Western DML

MAGIC-DML is a Swedish-US-Norwegian-German-UK collaboration focused on improving ice sheet models by filling critical data gaps that exist in our knowledge of the timing and pattern of ice surface changes along the western Dronning Maud Land (DML) margin, combined with advances in numerical techniques. To provide empirical data on the timing of ice surface lowering, field studies in austral summer 2017 targeted slopes in the Heimefrontfjella and Vestfjella nunatak ranges for in situ cosmogenic nuclide (CN) sampling at a range of elevations above the modern ice surface. Comparing concentrations of nuclides with widely differing half-lives in bedrock and erratic samples from such sites can provide information on complex burial and exposure histories, and thus, past configurations of non-erosive ice. Quartz-bearing samples were analyzed for in situ $^{10}$Be ($t_{1/2}$ 1.4 My), $^{14}$C ($t_{1/2}$ 5.7 ky), $^{21}$Ne (stable), and $^{26}$Al ($t_{1/2}$ 705 ky), and mafic lithologies were analyzed for in situ $^{36}$Cl ($t_{1/2}$ 301 ky). In situ $^{14}$C is unique among these nuclides in that its short half-life makes it particularly sensitive to complex histories since the Last Glacial Maximum (Marine Oxygen Isotope Stage 2). We present preliminary in situ $^{14}$C results from selected bedrock and erratic samples across the field area, compared with long-lived nuclide results (presented separately), as well as preliminary in situ $^{36}$Cl results from associated glacially striated basaltic bedrock.
Pleistocene Paleoceanographic Changes of the Southern Ocean off the Ross Sea

Sunghan Kim¹ (delongksh@kopri.re.kr), Jae Il Lee¹, Kyu-Cheul Yoo¹, Young-Suk Bak², Min Kyung Lee¹, Hi Il Yoon¹
¹Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of, ²Chonbuk National University, Jeonju, Korea, Republic of

A 8.4 m long gravity core RS15-GC107 was collected from a seamount in the Southern Ocean off the Ross Sea (68°04.0741'S, 178°37.9066'W, 3050 m deep). Geochemical proxies (biogenic opal, CaCO₃, TOC) and oxygen isotope of planktonic foraminifers (Neogloboquadrina pachyderma (sin.)) were measured in order to reconstruct paleoceanographic changes of the Ross Sea Sector of the Southern Ocean. Because CaCO₃ was relatively well preserved in upper 6 m of the core, the age of the upper part was constrained through planktonic foraminifer oxygen isotope correlation to LR-04 stack. CaCO₃ became to be preserved from 6.2 m of core RS15-GC107, whereas biogenic opal decreased from this interval. The changes at 6.2 m of core RS15-GC107 most likely corresponded to the beginning of the Mid-Pleistocene Transition (MPT) climate change. This means that the Ross Sea Sector of the Southern Ocean shifted from relatively more siliceous ocean to carbonate ocean during the MPT. Oxygen isotope values became lower during the interglacial periods with larger glacial-interglacial contrast at 1.5 m of the core, ~430 ka, which corresponds to the Mid-Brunhes Event (mWP). Interestingly, glacial planktonic Oxygen isotope values also became relatively lighter from ~430 ka than before. This may suggest that post-mWP glacial periods became more stratified along with increased ice volume.
Nonlinearities in Southern Ocean Response to CO₂ and Obliquity Forcing

Elizabeth D Keller¹ (l.keller@gns.cri.nz), Nicholas Golledge¹², Richard Levy¹, Katrin J Meissner³
¹GNS Science, Lower Hutt, New Zealand, ²Victoria University of Wellington, Antarctic Research Centre, Wellington, New Zealand, ³University of New South Wales, Climate Change Research Centre and ARC Centre of Excellence for Climate System Science, Sydney, Australia

Paleoclimate records suggest an increased sensitivity of the Antarctic ice sheet to orbital forcings when atmospheric CO₂ concentrations reach above ~500 ppm. Here we present model experiments designed to explore the relative sensitivity of atmospheric CO₂ and obliquity forcing in Antarctica and the Southern Ocean using the University of Victoria Earth System Climate Model (UVic ESCM). We focus on the Pliocene, as this interval contains several orbital cycles and provides an example of Southern Ocean dynamics in a warmer-than-present, high CO₂ world in which the West Antarctic Ice Sheet (WAIS) is absent. We find a nonlinearity in the system response to obliquity when CO₂ is between 500-650 ppm, particularly in ocean temperature at intermediate depths. We analyse the possible drivers of this result and the implications for future warming.
Paleobathymetry of the Cenozoic Southern Ocean and its Various Consequences

Katharina Hochmuth1 (katharina.hochmuth@awi.de), Karsten Gohl1, German Leitchenkov2, Isabel Sauermilch3, Joanne Whittaker3, Laura DeSantis4, Elisabetta Olivio4, Gabriele Uenzelmann-Neben1, Bryan Davy5

1Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, 2VNII Okeangeologia, St. Petersburg, Russian Federation, 3Institute of Marine and Antarctic Studies, University of Tasmania, Hobart, Australia, 4Institute Nationale di Oceanographica e di Geofisica Sperimentale (OGS), Trieste, Italy, 5GNS Science, Lower Hutt, New Zealand

Although the Southern Ocean plays a fundamental role in the global climate and ocean current system, paleo-ocean circulation models of the Southern Ocean suffer from missing boundary conditions. A more accurate representation of the geometry of the seafloor and its dynamics over long time-scales are key for enabling more precise reconstructions of the development of the paleo-currents, the paleo-environment and the paleo-ice sheets of Antarctica.

The reassessment of all available seismic reflection and borehole data from Antarctica as well as its conjugate margins of Australia, New Zealand, South Africa and South America allows us to create paleobathymetric grids for various time slices during the Cenozoic. We generated grids from the Eocene/Oligocene Boundary, the Mid-Miocene Climatic Optimum and the Pliocene/Pleistocene. These grids reveal changes in sediment distribution and volume as well a local sedimentation rates.

The observation of sediment distribution and local sediment volumes opens the door towards more sophisticated paleo-topography studies of the Antarctic continent and more detailed studies of the paleo-circulation. Local paleo-water depths at the oceanic gateways or the position of paleo-shelf edges highly influence the regional circulation patterns supporting more elaborated climate models.
Variability in Glacier Dynamics of a Greenland Glacier Using Sentinel-1 SAR Data

Christoph Rohner¹ (christoph.rohner@geo.uzh.ch), Rémy Mercenier¹, Andreas Vieli¹, Martin Lüthi¹, David Small¹
¹University of Zurich, Department of Geography, Zürich, Switzerland

Following the general warming trend in Greenland, an increase in calving rates, retreat and ice flow can be observed at ocean-terminating outlet glaciers. These changes contribute substantially to the current mass loss of the Greenland Ice Sheet. In order to constrain models of ice dynamics, detailed knowledge of geometry, ice-flow, and environmental forcing factors are needed.

Using spaceborne synthetic aperture radar (SAR) systems in conjunction with in-situ measurements, we investigate the intra- and inter-annual variability of the flow dynamics of a medium-sized ocean-terminating outlet glacier located in Western Greenland. The satellite datasets consist of a time series comprising more than 150 acquisitions from ESA’s Sentinel-1 SAR platform starting in 2014 as well as 20 Radarsat-2 images from 2015/2016. By applying feature tracking approaches, the data from these C-band SAR sensors allows derivation of quasi-continuous velocity estimates at high spatial and temporal resolutions. In addition, the C-band backscatter enables detection of surface melt and ice mélange extent as well as the position of the calving front with almost no additional knowledge required. The availability of such data time-series stemming from one single platform will allow investigation of the influence of environmental forcing (melt and ice mélange) on the variability in flow and terminus dynamics, and thereby provide constraints for models of calving dynamics.
Coastlines in the Arctic are made vulnerable by longer ice-free seasons, but studying the timing of freeze-up is limited by a lack of observations. Existing passive microwave sea ice concentration products are undefined near shore, and limited coverage of higher-resolution products can mean missing most of the freeze-up season. This presentation explores a new approach to remote sensing of coastal sea ice cover, loosely based on the NASA Team algorithm. Designed specifically for pixels with partial land and partial ocean area, it uses local land pixels as seasonally-varying tie points to control for changing land surface conditions over the course of the winter. The approach uses polarization and gradient ratios from brightness temperature retrievals to determine ice presence in the fraction of a pixel that is ocean. A reference dataset of visible, infrared, and SAR imagery complements local observations (compiled through SlZOnet) to validate the passive microwave approach.
Monitoring of Ice Dynamics and Mass Balance in Central Dronning Maud Land

Christoph Knöfel¹ (christoph.knoefel@tu-dresden.de), Mirko Scheinert¹, Ludwig Schröder¹, Benjamin Ebermann¹, Veit Helm², Martin Horwath¹
¹Technische Universität Dresden, Institut für Planetare Geodäsie, Dresden, Germany, ²Alfred-Wegener-Institute, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany

Since 1991, various geodetic and glaciological research activities have been carried out in the region southeast of Schirmacherose, Dronning Maud Land, East Antarctica. This region is characterized by the slowly floating Potsdam Glacier that crosses a wider area of bare blue-ice surface. Repeated ground-based surveys (mainly GNSS) realized during the last 25 years serve as a basis to studying the long-term behaviour of surface heights, ice velocity, accumulation and ablation in that region. In the last few years our ground-based measurements have been performed simultaneously with airborne radar and lidar observations. Additionally, we incorporated satellite laser and radar altimetry data from ERS-1/2, Envisat, ICESat and CryoSat-2. Satellite images (e.g. taken by Landsat satellites) provide optical snapshots over several decades.

We will discuss the long-term evolution of the ice regime based on surface-height variations and flow velocities. In terms of mass balance, the combination of ground-based, airborne and satellite-based data allows to give a comprehensive picture of the entire region. Furthermore, the comparison leads to accuracy estimates of the derived trends. Results based on temporarily and spatially limited GNSS observations serve as constraints for airborne and spaceborne measurements which cover larger areas. It will be shown that the permanent monitoring of relevant regions is essential for the derivation of reliable long-term trends.
Melt ponds are common on Arctic sea ice. They are linked to surface albedo and energy transfer to the ocean from the atmosphere and are important in Arctic climate studies. This paper presents a first attempt to retrieve melt pond fractions from hybrid-polarized compact polarization (CP) SAR imagery, which will be available from RADARSAT Constellation Mission to be launched in 2018. CP SAR has wider swath and shorter revisit time than quad-polarization systems, like RADARSAT-2 (RS-2). The co-polarization (co-pol) ratio has been verified to provide estimates of melt pond fractions. But it is a challenge to link CP parameters and the co-pol ratio. The theoretical basis is presented for making this linkage with the CP parameter $C_{22}/C_{11}$ (the ratio of the elements of the coherence matrix of CP SAR) for melt pond detection with the tilted-Bragg scattering model for the ocean surface. An empirical formulation, the 'compact polarization and quad-pol' ('CPQP') model, is proposed based on 2062 RS-2 quad-pol SAR images, collocated with in situ measurements. We compare the retrieved melt pond fraction with CP parameters simulated from quad-pol SAR data and results retrieved from the co-pol ratio from quad-pol SAR images from the Arctic-Ice (Arctic-Ice Covered Ecosystem in a Rapidly Changing Environment) project. Results are comparable for observed melt pond data in spatial and temporal distributions. Thus, the CP mode SAR is able to estimate melt pond fractions on first year ice.
Variations in the Extent and Elevation of the Larsen Ice Shelf, Antarctica

Changqing Ke¹ (kecq@nju.edu.cn), Jun Chen¹
¹Nanjing University, School of Geography & Oceanography, Nanjing, China

Ice shelf extent is extracted from declassified aerial photographs and modern satellite images, and a very long time series of the areal extent of the Larsen A Ice Shelf (LAIS) and the Larsen B Ice Shelf (LBIS) is compiled. In addition, we characterize the surface elevation changes of the LAIS and the LBIS over the last two decades by combining the Ocean Topography Experiment/Poseidon (T/P) and the Envisat Radar Altimeter-2 (RA-2) using the collinear analysis method. The northern Larsen Ice Shelf (LIS) displayed no significant changes until the late 1980s, whereas the LAIS has retreated rapidly since 1986, and the LBIS has followed a similar pattern since the early 1990s. The gradual retreat of the northern LIS is interrupted by several catastrophic calving events. The LAIS and the LBIS have already diminished by approximately 14,000 km² in total since 1968. At the same time, the surface elevations of the LAIS and the LBIS exhibit progressive lowering from 1992 to 2010, whereas the lowering rate of the LAIS is significantly higher than that of the LBIS. The northern LIS has warmed substantially in all seasons, but summer displays the least warming. The warmer air temperatures and increasing surface meltwater production and refreezing lead to continuous surface lowering by firn densification. However, considering the continuous retreat of the northern LIS, its surface elevation is more sensitive to the collapse and retreat of the ice shelf than atmospheric warming.
Advance of Western Margin of the Vavilov Ice Cap Assessed by Remote Sensing Data

Irina Bushueva¹, Andrey Glazovsky¹ (icemass@yandex.ru), Gennady Nosenko¹
¹Institute of Geography Russian Academy of Sciences, Glaciology, Moscow, Russian Federation

The Vavilov ice cap (79.30° N, 95.47° E) is situated on October Revolution Island of the Severnaya Zemlya archipelago. In this project the images obtained from Landsat-1, 5, 7, 8, Terra (ASTER), Sentinel-1 and Corona were applied. We found out that from 1963 to 2017 the ice cap margin advanced seaward by 11.7 km (central line), and its area increased by 133 km². The accelerated advance started in 2010, in summer 2016 the marginal front terminated in sea began to disintegrate, in 2017 the advance continued but with lower velocity.

The data on ice cap velocities was taken from two sources. The first one is GoLIVE project, also we analysed the synthetic aperture radar data from Sentinel-1 satellite. Comparison of the velocities acquired from two sources for the same period shows that they are in a very good correlation. Maximum velocity of glacier was in 2016 and reached 25.4 m/day. From 2016 the velocity started to decrease.

To evaluate the volume changes of western part of the Vavilov ice cap we analysed ASTER DEMs of 2000 and 2015, radar data obtained during fieldwork in 2014 and topographic maps of scale 1:200 000. Above the contour line of 100 m (2015) the main trunk of the newly formed outlet glacier thinned by at least 1.918 km³, and at the same time its snout increased by 4.101 km³.

This study is supported by the Russian Foundation for Basic Research, grant 16-35-00333, and by the Russian Science Foundation, grant 14-37-00038.
Physical and Biogeochemical Properties of Winter Sea Ice during Pipers, Ross Sea

Jean-Louis Tison¹ (jtison@ulb.ac.be), Ted Maksym², Jan Lieser³, Gauthier Carnat¹, Celia Sapart¹, Steve Ackley⁴, Johannes de Jong¹, Fanny Vanderlinden⁵, Sharon Stammerjohn⁶, Bruno Delille⁶

The PIPERS (Polynyas, Ice Production and its seasonal Evolution in the Ross Sea) cruise on N. B. Palmer into the early winter Ross Sea took place between April 11 and June 14 2017. The main objective was to investigate the Atmosphere-Ice-Ocean interactions in the Terra Nova Bay and Ross Ice Shelf coastal polynyas. The cruise however extended these polynyas studies to a series of ice stations transects “in” and “out” of the Ross Sea. It involved a large set of multidisciplinary activities aiming at the detailed documentation of processes across the ocean-ice-atmosphere continuum. This paper presents the basic physical (Temperature, bulk salinity, brine volume, Rayleigh number) and biogeochemical properties (water stable isotopes, Chl-a) of the sea ice cover at 27 ice stations. The cruise encountered unusual sea-ice conditions in the 2016/2017 season, where exceptionally low sea-ice summer extent was recorded Antarctica-wide as early as November 2016, which stayed below previous records of the satellite era for the rest of the austral summer. It is also a year where active primary production was evidenced within the Ross Sea and Terra Nova Bay Polynya, a few weeks before the cruise took place. We will show how these conditions have potentially affected (or not) the physical and biogeochemical properties of the sea ice cover in the Central Ross Sea and discuss the contrasts with the sea ice properties of the Terra Nova Bay polynya and the MIZ.
Coastal polynyas are areas of anomalous open water and thin ice in regions that are otherwise covered by sea ice. They frequently occur around the Antarctic continent in response to strong offshore katabatic wind stresses. The loss of heat from the open ocean to the cold atmosphere can enormously enhance rates of ice production. In polynya areas, the coupling between the atmosphere, sea ice and ocean is complex, and the role of ice formation on the budget of the main climate forcing carbon gases remains unknown. During the PIPERS expedition on the N.B. Palmer from April to June 2017, we performed continuous measurements of methane and carbon dioxide concentrations in the atmosphere and in the surface water from New Zealand to the polynyas of the Ross Sea. Discrete sampling was carried out in parallel to calibrate the continuous systems and to later measure the stable isotope ratios of both gases in the water and in the air. The stable isotope data enable unravelling the pathways involved in gas formation and removal. While the concentrations of both gases were relatively low in the surface waters of polynyas, the preliminary atmospheric data show higher methane and carbon dioxide levels in the atmosphere at locations where sea ice formation was most intense. These data together with the isotopic ratios of both gases and with meteorological data will be discussed to better understand the role of sea ice formation on the exchange of climate forcing gases.
Sea ice is a biome actively participating in the regional cycling of CO₂ as both a source and a sink at different times of the year depending on its trophic status (autotrophic vs heterotrophic). In the frame of the YROSIAE project (Year-Round survey of Ocean-Sea-Ice-Atmosphere Exchanges), carried out at Cape Evans in McMurdo Sound (Antarctica) from Nov. 2011 to Dec. 2012, ice cores, seawater, and brines were collected at regular time intervals. We used dissolved inorganic carbon (DIC) and chlorophyll-a (chl-a) as proxies of net community production and autotrophic biomass, respectively. From spring, very high chl-a concentrations (>2400µg.L⁻¹) were observed at the bottom of the ice. This suggests high primary production. Strikingly, at the same time, nutrients increased significantly indicating strong remineralization at the bottom. In the ice interior, evolution of DIC was marked by a succession of autotrophic and heterotrophic phases. The overall increase of DIC suggests that the ice interior was rather heterotroph. Such sea ice system should expel CO₂. Yet, strong under-saturation in CO₂ and DIC depletion appeared at the ice surface, suggesting that sea ice should take up CO₂ from the atmosphere. On the whole, land fast sea ice in McMurdo Sound appears as a puzzling ecosystem. High primary production and remineralization develop simultaneously at the bottom while the top of the ice is rather heterotrophic but still able to pump CO₂ from the atmosphere.
Modeling Iron Distribution in the Early Stages of Sea-ice Growth

Julie Janssens¹ (julie.janssens@utas.edu.au), Sebastien Moreau¹, Martin Vancoppenolle², Klaus Meiners³, Delphine Lannuzel¹

¹Institute for Marine and Antarctic Studies, Hobart, Australia, ²Laboratoire d’Oceanographie et du climat, Institut Pierre-Simon Laplace, Paris, France, ³Australian Antarctic Division, Hobart, Australia

Primary productivity in the Southern Ocean (SO) is affected by the release of iron (Fe) from melting sea ice. Despite this, representation of sea ice as a source of Fe for the surface waters of the SO is poorly represented in models. Sea-ice extent and volume are predicted to reduce in the future. The extend to which these climate-induced changes will affect biological activity in the seasonal ice zone, and therefore primary productivity in the SO, both having a significant role on the climate system, is currently unknown.

We implemented a one-dimensional modelling framework (LIM-1D) to identify the main processes responsible for Fe distribution in a single ice floe during the very early stages of sea-ice growth. The model simulations are compared with field observations carried out during in situ ice-growth experiments during Austral winter in the Weddell Sea, Antarctica. The model successfully represented the vertical distribution of iron in newly formed sea ice, when the processes of entrapment and adsorption were included to represent the initial physical enrichment of particulate iron and dissolved iron. Our study is a first step towards the development of large scale modelling tools to simulate sea-ice associated primary production and further simulate its feedback impact on the climate, ultimately helping to forecast the response of Antarctic ecosystems to environmental changes.
Using under-ice Radiance Spectra to Determine Antarctic Fast Ice Algal Biomass

Pat Wongpan¹ (pat.wongpan@postgrad.otago.ac.nz), Klaus Meiners²,³, Pat Langhorne¹, Petra Heil²,³, Inga Smith¹, Greg Leonard⁴, Rob Massom²,³, Lesley Clementson⁵, Tim Haskell⁶

Fast ice is an important component of Antarctic coastal ecosystems, providing a habitat for thriving ice algal communities. This work examines the relationships between the normalized difference indices (NDI) calculated from under-ice radiance measurements and both sea ice algal biomass and snow depth for Antarctic fast ice. While this technique has been calibrated to assess biomass in Arctic fast ice and pack ice, and Antarctic pack ice, relationships are currently lacking for Antarctic fast ice. We analyze measurements along transect lines at two contrasting fast ice sites: near (affected by platelet ice) and distant from an ice shelf, i.e. in McMurdo Sound and off Davis Station, respectively. Snow and ice thickness, and ice salinity and temperature measurements underpin our paired in situ optical and biological measurements. NDI wavelength pairs near the first chlorophyll-a (chl a) absorption peak (=440 nm) explain up to 70% of the total variability in algal biomass. Snow depth is estimated from an NDI with a wavelength pair of 648 nm and 567 nm explaining 88% of its total variability. Accounting for pigment packaging effects by including the ratio of chl a specific absorption coefficients improved the NDI-based algal biomass estimation only slightly. Our new observation-based algorithms can be applied to estimate Antarctic fast-ice algal biomass and snow depth non-invasively from moored sensors (time-series) or to map their spatial distributions using underwater vehicles.
On the Fate of Primary Production in the Sea Ice Zone of the Southern Ocean

Sebastien Moreau1,2 (sebastien.moreau@hotmail.com), Philip W. Boyd1, Peter Strutton1, Delphine Lannuzel1
1University of Tasmania, Institute for Marine and Antarctic Studies, Hobart, Australia, 2Norwegian Polar Institute, Tromso, Norway

Primary production (PP) in the Southern Ocean is of paramount importance for two main reasons. First, it contributes to the largest biological pump on the planet, mitigating climate change. Second, it is the basis food support for the Antarctic krill, the animal on the planet with the largest biomass, which feeds the largest number of top predators. In the Southern Ocean, the sea-ice zone and the sea ice itself only account for 10% of the basin-scale PP. However, sea ice is the critical habitat for overwintering krill and a reduction in its cover can have dramatic consequences on the food-web. Moreover, the release of algae by melting sea ice is often uncoupled from grazing activity and consequently sinks into the Ocean’s interior. Hence, the sea ice zone plays additional ecological and biogeochemical roles above its contribution to the PP of the Southern Ocean. In this context, we present here a new algorithm to derive and demarcate the two main fates of PP - zooplankton grazing and the export of phytodetritus and faecal pellets - from a combination of biogeochemical sensors mounted on bio-Argo floats. We focus on floats which were profiling within the sea ice zone of the Southern Ocean over the last 5 years. We find that ~90% of the annual PP is grazed by zooplankton, while phytodetritus, the remaining 10%, accounts for up to 75% of the annual organic carbon export. This new proxy provides a new tool to study remotely the fate of PP in a geographically-remote environment.
Runoff Generation Processes in Extratropical Andean Catchments

James McPhee¹ (jmcphee@uchile.cl), Yohann Videla¹
¹Universidad de Chile, Santiago, Chile

Understanding the physical processes that dominate the volume and residence time of water stored in the extratropical Andes is of great importance to the success in the management of the resource for around 10 million people. A lack of direct, long term process observations motivates the use of hydrological modeling for hypothesis testing and process understanding, with the ultimate goal of achieving robust hydrological predictions under global change scenarios. Here, we employ a physically based suite of hydrological routines to estimate the energy and mass balance components of snow hydrology in extratropical mountain catchments, and their contribution to runoff. The model is forced with data from the Era-Interim re-analysis for the 2000-2016 period, which have been corrected through spacial and temporal downscaling and yield a very good agreement with observed snowpack dynamics. Our results suggest that in this complex topography, 22% of the snow is subject to reallocation either by wind or gravitational effects, such that meteorological elevation gradients are not in themselves enough for explaining snow water equivalent distribution. An estimated 80% of summer flow (DJF) comes from glacial melting, while it is shown that snow and ice melt contribute to runoff at all times of the year, dispelling the notion of distinct accumulation and melt seasons.
Glacier Meltwater Mitigates the Impact of Severe Droughts in the Semiarid Andes

Alvaro Ayala1,2 (ayala@vaw.baug.ethz.ch), David Farias3, James McPhee4,5, Francesca Pellicciotti6, Daniel Farinotti1,2

1ETH Zurich/VAW, Department of Civil, Environmental and Geomatic Engineering, Zürich, Switzerland, 2WSL Swiss Federal Institute for Forest Snow and Landscape Research, Birmensdorf, Switzerland, 3University of Erlangen-Nürnberg/Institute of Geography and Geosciences, Erlangen, Germany, 4Universidad de Chile, Department of Civil Engineering, Santiago, Chile, 5Universidad de Chile/AMTC, Santiago, Chile, 6Northumbria University, Department of Geography, Newcastle, United Kingdom

Glaciers in semiarid regions have been highlighted as key reservoirs of fresh water resources with the potential to sustain minimum flow levels in high-elevation catchments. However, few studies have quantified the glacier contribution to runoff during severe droughts. Here, we estimate the ice loss and associated runoff contribution of glaciers in the Maipo River catchment (semiarid Andes of Chile) in 2010-2015, the longest and most extensive drought on local records. The Maipo River is the largest source of freshwater for the capital city Santiago, and contains more than 800 glaciers, covering 377 km². We use the physically-oriented TOPKAPI-ETH hydrological model at a daily timestep and at a spatial resolution of 100 m to simulate snow processes, glacier mass balance and runoff generation. While the average summer streamflow at the catchment outlet decreased from 165.8 m³ s⁻¹ in 2000-2009, to 97.8 m³ s⁻¹ (-41%), during the drought, our preliminary results indicate that summer runoff from ice melt increased from 27.2 to 34.0 m³ s⁻¹ (+24.9%), providing additional 65 Mm³ y⁻¹, and more than doubling its summer relative contribution, from 15 to 34%. We build scenarios of extensive glacier retreat in which we estimate the impacts that similar droughts will have on the availability of water resources in a warming climate. Our study quantifies the impact of glacier retreat on water availability in a region where the frequency of droughts is expected to increase with climate change.
Quantifying Rock Glacier Contribution to Streamflow in Semiarid Catchments

Shelley MacDonell1 (shelley.macdonell@ceaza.cl), Francesca Pellicciotti2, James McPhee3, Nicole Schaffer1, Ivan Fuentes3, Ben Robson4, Marion Réveillet1, Francisco Fernando5, Álvaro Ayala6
1Centro de Estudios Avanzados en Zonas Aridas (CEAZA), La Serena, Chile, 2Northumbria University, Newcastle, Chile, 3Universidad de Chile, Santiago, Chile, 4University of Bergen, Bergen, Norway, 5Universidad Andrés Bello, Viña del Mar, Chile, 6ETH Zürich, Zurich, Switzerland

In high altitude areas vulnerable to climatic change, rock glaciers act increasingly as important sources of water, especially during summer and dry periods. These cryoforms are considered to be long term water reservoirs that support efficient water storage and slow delivery. The role of rock glaciers in the wider hydrological system of the semiarid Andes is little known, and is the driving impetus for this study. As water resources become increasingly scarce, and their demand increases, there is a need for improved understanding of existing sources, and changes within the context of a warming climate. This study will take a multi-method approach utilising a combination of glaciological, geomorphological, geophysical, geochemical and modelling techniques to better elucidate the structure and function of the hydrological system of rock glaciers and to subsequently evaluate rock glacier contribution to streamflow in the Elqui catchment where there are over 300 rock glaciers. In this presentation, we will highlight the methodological considerations for undertaking such a study, will provide a first inventory of rock glaciers and their changes in the last six decades in semi-arid Andean catchments, and compare their distribution, characteristics and potential hydrological importance to that of glaciers in the same region.
Accurate quantification of snow accumulation and the contributions of snow and ice melt to river streamflow is of critical importance for water management in the semi-arid Andes of central Chile (32-34°S). This is particularly noteworthy because of a heightened socio-economic demand following recent drought events, which have reached unprecedented duration. There is, however, much uncertainty regarding the spatial distribution of snow and snow depth ($dS$) as a source of meltwater in the upper basins of major rivers, which is often modelled assuming simple statistical relationships and with data extrapolated from low elevation meteorological stations. Here we explore the appropriateness of leveraging modern satellite techniques for derivation of $dS$ in combination with high resolution ground-based LiDAR data in order to address some of these uncertainties. We evaluate the representation of $dS$ in a glacierised basin of the upper Maipo River (Rio del Yeso, 112 km$^2$) using recently developed techniques with optical tri-stereo imagery from the French Pléiades satellites (resolution $< 2$ m). We discuss the sub-pixel variability of $dS$ in relation to topographical features of the landscape and compare with alternative statistical models in the literature. Finally, we begin to present the importance of this information for seasonal hydrological forecasting when prescribed as initial conditions in a glacio-hydrological model for the winter-summer season of 2017/2018.
Central Chile’s economy relies on melt water from glaciers and seasonal snow to sustain a robust growth, as well as to provide drinking water to major cities, particularly during dry periods. These recurrent climatic events play an important role on glacier storage, runoff production and long-term changes in glacier mass balance and streamflow. Here we present a modelling study that aims at reconstructing the climatic forcing, glacier response and runoff generation from a high elevation catchment of central Chile over the past 4 decades. Recent modelling studies have considerably advanced our understanding of water storage and of the spatial distribution of energy, mass and water fluxes in glacierised Andean catchments. However, they all have focused on simulations of a few years or melt seasons for which extensive field datasets were available to constrain model parameters. Very little is known about long-term fluctuations in glacier mass balance and the resulting changes in runoff from glacierised catchments, and the partition of snow and ice contribution over the long term. Debris-covered glaciers are an important element of the Andean cryosphere that has been to date largely neglected in hydrological studies. These types of glaciers, common in the central Andes, are increasingly recognized as responding in a distinctive manner to climate compared to clean ice glaciers and have the potential to affect the hydrological regimes of catchments substantially.
Supraglacial ice cliffs enhance locally melt and mass losses of the otherwise insulated ice on debris covered glaciers. However, their contribution to the total glacier mass balance has never been quantified, with inference obtained from upscaling models or observations at selected cliffs. Their overall importance remains little understood.

From six high-resolution satellite images we derive an inventory of ice cliffs in the Langtang catchment (Nepal) for 2006-2015 and we use it to:

i) assess the frequency and distribution of cliffs and ponds;
ii) characterize cliff geometries, pond areas and the life cycle of cliff-pond systems.

The volume losses associated with the backwasting of cliffs for the debris-covered glaciers of the Langtang catchment are calculated with a physically-based backwasting model considering the cliff-atmosphere energy-balance, reburial by debris and the effects of adjacent ponds. To estimate the contribution of ice cliff melt to total glacier mass balance we compare simulated cliff melt to the distributed glacier mass balance values from a glacio-hydrological model (TOPKAPI-ETH).

Ice cliffs vary greatly in space and time. The associated volume losses are a non-negligible term (with values >60% on the lower sections of the debris-covered tongues) in the total glacier mass balance of debris-covered glaciers, providing a partial explanation of the higher-than-expected mass losses of debris-covered glaciers of High Mountain Asia.
Role of Scale in the Analysis of Arctic and Southern Ocean Benthic Functions

Heike Link¹ (heike.link@uni-rostock.de), Philippe Archambault², Joshua Kiesel³, Dieter Piepenburg⁴,⁵,⁶, Derya M. Seifert⁴, Gritta Veit-Köhler⁷

¹University of Rostock, Department Maritime Systems, Rostock, Germany, ²Université Laval, Département de Biologie, Quebec, Canada, ³Kiel University, Institute for Geography, Kiel, Germany, ⁴Kiel University, Institute for Ecosystem Research, Kiel, Germany, ⁵Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, ⁶Helmholtz Institute for Functional Marine Biodiversity at Oldenburg University, Oldenburg, Germany, ⁷Senckenberg am Meer, German Centre for Marine Biodiversity Research, Wilhelmshaven, Germany

Comparative ecosystem studies are acknowledged to be crucial for soundly estimating the relative importance of physical-chemical (temperature, salinity) and biological (Chl a, faunal abundance) factors for ecosystem functions (e.g. remineralisation). However, such studies are still scarce in polar benthic habitats, as they are elaborate to conduct, and constraints imposed by differences in methodological approach, regional particularities, and spatio-temporal scales are known to bias the analyses and subsequent upscaling efforts. Here, we present the findings of comparative within-region versus across-region analyses of studies in Arctic and Antarctic shelf waters (Canadian Arctic and Laptev Sea, as well as Weddell Sea and off the Antarctic Peninsula). We demonstrate how the analysed scale can influence results and conclusions on the effects of environmental and biological drivers on benthic ecosystem functions (benthic remineralisation, oxygen consumption). The highly standardized field approach (ex situ incubations) applied in each region reduces methodological bias and allows for a sound comparison on different spatial scales. Our results point to the difficulties of comparative studies but also provide suggestions how to handle those issues when aiming for and interpreting upscaling approaches in polar marine benthic systems.
A Seascape View of Decadal Change along the Western Antarctic Peninsula

Jeff Bowman\(^1\) (jsbowman@ucsd.edu), Maria Kavanaugh\(^2\), Scott Doney\(^3\), Hugh Ducklow\(^4\)
\(^1\)Scripps Institution of Oceanography, UC San Diego, La Jolla, United States, \(^2\)Oregon State University, College of Earth, Ocean and Atmospheric Sciences, Corvallis, United States, \(^3\)University of Virginia, Charlottesville, United States, \(^4\)Lamont-Doherty Earth Observatory of Columbia University, Palisades, United States

Located near the edge of the winter sea ice maxima, the marine ecosystem of the western Antarctic Peninsula (WAP) is a bellwether of global climate change. The Palmer Long Term Ecological Research (LTER) project has been documenting changes to the WAP marine ecosystem since 1993 with an annual summer cruise. To enable a comparison between multiple years in the Palmer LTER dataset we developed a seascape unit (SU) classification system based on temperature, salinity, nutrients, and chlorophyll \(a\). By objectively mapping these parameters for each cruise we were able to classify the Palmer LTER grid into 8 recurrent SUs. We used clustering and PCA to evaluate the distribution of SUs between years, finding that years formed two statistically significant clusters. While mean chlorophyll \(a\) concentration did not differ between clusters, the location and SU association of chlorophyll \(a\) biomass differed. We used correlations and elastic-net regression to identify environmental factors and modes of climate variability that might account for cluster membership and SU abundance. We detected a strong association between early spring sea ice conditions and cluster membership, suggesting that early spring nutrient drawdown can impact the distribution of summer chlorophyll \(a\) biomass. Future improvements to the seascape concept for the WAP will enable further insights, and wider application to the coastal Antarctic may lead to a unified view of marine ecosystem distribution and change.
Arctic marine biota are affected profoundly and at large scales by accelerating environmental change, such as sea-ice decline. Moreover, increasing human activities, e.g. exploitation of natural resources, add further cumulative pressures. Substantial shifts in ecosystem functions and services, e.g. biodiversity, are expected. To understand, predict, and mitigate the profound ecological consequences of such shifts, it is critical to identify and analyse the relationships between environmental drivers and ecosystem functions at regional and pan-Arctic scales. We address this challenge by developing a pan-Arctic knowledge system on benthic biota (PANABIO). Underpinned by international efforts to combine data and expertise, PANABIO integrates quality-controlled and geo-referenced data on benthic communities in a public data-warehouse. This will support (a) providing ecological baseline-data to gauge ecosystem changes, (b) analysing coupling mechanisms between environmental drivers and ecosystem functions/services on regional and pan-Arctic scales, (c) developing future ecosystem scenarios in response to external forcing, and (d) creating online stakeholder-oriented visualization and analysis tools.

The talk will demonstrate the huge up-scaling of benthic data we realised, our achievements to support data-sharing, as well as first results of multi-variate species distribution models to discern distinct benthic sea-ice communities.
Physiological Models in Antarctica: Dynamic Inferences in a Changing Environment

Charlene Guillaumot¹ (charleneguillaumot21@gmail.com), Antonio Aguera¹, Bruno Danis¹
¹Université Libre de Bruxelles, Brussels, Belgium

The Western Antarctic Peninsula is facing rapid global changes which are currently the focus of an intense research effort to understand the potential of marine benthic populations response. Our knowledge about the impact of environmental changes on Antarctic species physiology has mostly been gathered from short term experimental designs and is limited by a broad range of practical constraints.

An alternative to these experimental designs is to use mechanistic models that relate species functional traits to environmental characteristics. Dynamic Energy Budget (DEB) theory describes organisms uptake and allocates energy throughout their entire life cycle. Their parametrisation requires observations of species life cycle and physiology, which are often available from the literature.

In this presentation, we showcase DEB models built for a series of representative benthic Antarctic species. Metabolic performances (growth rate, age at metamorphosis, reproductive performance, survival) will be assessed for these species on the extent of the Western Antarctic Peninsula. Potential shifts in physiological traits will be predicted and compared for a range of environmental scenarios (RCP scenarii, IPCC, 5th report) in order to characterise species sensitivity in the context of a fast-changing environment.
How Universal is the Keystoneness of Krill in Southern Ocean Food Webs?

Stacey A. McCormack¹ (stacey.mccormack@utas.edu.au), Jessica Melbourne-Thomas²,³, Rowan Trebilco³, Julia L. Blanchard¹, Ben Raymond¹,²,³, Andrew Constable²,³
¹University of Tasmania, Institute for Marine and Antarctic Studies, Hobart, Australia, ²Australian Antarctic Division, Department of the Environment and Energy, Hobart, Australia, ³University of Tasmania, Antarctic Climate and Ecosystems Cooperative Research Centre, Hobart, Australia

A principal goal of ecosystem ecology is to develop and test theories regarding the nature of species interactions and their contribution to the organisation of biological communities. In Southern Ocean ecosystems, Antarctic krill (Euphausia superba) are widely recognised to play a keystone role in transferring energy from primary producers, supporting large populations of marine mammals and seabirds. However, it is not clear whether the dominant role of krill in Southern Ocean food webs is universal. An alternative configuration is more diffuse trophic networks, where a variety of mid-trophic level organisms, other than krill, play major roles in energy transfer.

To evaluate how universal the keystone role of krill is in Southern Ocean food webs, we used the Southern Ocean Dietary Database to undertake the first large-scale circumpolar analysis of food web structure across the four major oceanic sectors of the Southern Ocean. Here, we describe how we quantified the contributions of various species and groups to energy flow within each sector, and provide a summary of our key findings. Previous analyses of Antarctic ecosystems have focused entirely on a single web topology or have provided qualitative descriptions of small sub-systems. We discuss how our generalised approach facilitates cross-system comparisons, emphasises critical processes for maintaining food web structure within each sector, and can inform the future management of Antarctic ecosystems.
Towards Monitoring of Primary Production in Polar Regions

Gemma Kulk1 (g.kulk@rug.nl), Jacco Kromkamp2, Gerrit van der Goot1, Hugh Venables3, Mike Meredith3, Anita Buma1,4

1University of Groningen, Ocean Ecosystems, Groningen, Netherlands, 2Royal Netherlands Institute for Sea Research, Estuarine and Delta Systems, Yerseke, Netherlands, 3British Antarctic Survey, Cambridge, United Kingdom, 4University of Gronigen, Arctic Centre, Groningen, Netherlands

Active chlorophyll a fluorescence techniques have the potential to provide estimates of phytoplankton primary production at unprecedented temporal and spatial scales. Fast Repetition Rate fluorometry (FRRf) is such a promising technique, however knowledge of the electron requirement of carbon fixation ($\Phi_{e,C}$) is required to accurately estimate primary production from FRRf measurements. While the $\Phi_{e,C}$ has been studied in fast areas of the open oceans, only a few studies have focused on polar regions. In the Arctic, the $\Phi_{e,C}$ seems to vary with in situ light conditions and is closely related to non-photochemical processes and other physiological processes such as cyclic electron flow. The present study assessed the $\Phi_{e,C}$ experimentally in freshly isolated Antarctic diatom species. In addition, the $\Phi_{e,C}$ was measured in natural phytoplankton communities from Ryder Bay, West Antarctic Peninsula, during two summer seasons. While $\Phi_{e,C}$ was influenced by species composition and environmental conditions, results showed a linear relationship between electron transport and carbon fixation. These results were used to estimate primary production from automated FRRf measurements in both the laboratory and the field. Further upscaling of the chlorophyll a fluorescence technique can strongly advance our understanding of factors that regulate primary production of marine phytoplankton in one of the most rapidly warming regions of the world.
Arctic warming is exposing permafrost coastlines, which account for 34% of the Earth's coasts, to rapid thaw and erosion. Coastal erosion rates as high as 25 m yr$^{-1}$ together with the large amount of organic matter frozen in permafrost are resulting in an annual release of 14.0 Tg ($10^{12}$ gram) particulate organic carbon into the nearshore zone. We highlight the crucial role the nearshore zone plays in Arctic biogeochemical cycling, as here the fate of the released material is decided.

With Arctic warming, erosion fluxes have the potential to increase by an order of magnitude until 2100. Such increases would result in drastic impacts on global carbon fluxes and their climate feedbacks, on nearshore food webs and on local communities, whose survival still relies on marine biological resources. Quantifying the potential impacts of increasing erosion on coastal ecosystems is crucial for food security of northern residents living in Arctic coastal communities. We need to know how the traditional hunting and fishing grounds might be impacted by high loads of sediment and nutrients released from eroding coasts, and to what extent coastal retreat will lead to a loss of habitat. Quantifying fluxes of organic carbon and nutrients is required, both in nearshore deposits and in the water column by sediment coring and systematic oceanographic monitoring. Ultimately, this will allow us to assess the transport and degradation pathways of sediment and organic matter derived from erosion.
Impacts of Sea-level Change on Antarctica

Jasmine Lee¹ (jasmine.lee1@uqconnect.edu.au), Steven Chown², Richard Fuller³, James Watson⁴, Aleks Terauds⁵
¹University of Queensland, Centre for Biodiversity and Conservation Science, St. Lucia, Australia, ²Monash University, School of Biological Sciences, Melbourne, Australia, ³University of Queensland, School of Biological Sciences, Brisbane, Australia, ⁴University of Queensland, School of Earth and Environmental Sciences, Brisbane, Australia, ⁵Australian Antarctic Division, Antarctic Management and Conservation, Hobart, Australia

Whilst much Antarctic research has been focused on determining how Antarctic ice sheets will contribute to global sea-level rise under warming, the potential effects on Antarctica of sea-level change have not been as comprehensively considered. Here we assess the potential effects of forecast sea-level rise and fall to Antarctic biodiversity and human infrastructure by 2100, using multiple sea-level scenarios (0.5 m, 1 m, 2 m). Under a 2 m rise scenario, up to 60% of Antarctic Specially Protected Areas, 58% of Important Bird Areas, 68% of penguin breeding colonies, 40% of research infrastructure, and 71% of tourist landing sites could be at risk of partial or complete inundation. A fall in sea-level would see infrastructure and biodiversity further from the coast, resulting in changed environmental conditions and new logistic challenges for National Programs. Simultaneous impacts on human activity and terrestrial biodiversity will compel several forms of adaptation across both groups, with potential for growing conservation problems. Better spatially explicit understanding of sea-level change is therefore also pressing from a conservation perspective.
Frequent interactions with indigenous communities can lead to novel approaches in studying climate change. Such approaches generate new forms of knowledge, but also generate a fuller understanding of climate change as it occurs in infrequently studied regions. This presentation focuses on storm intensity in one such region in Alaska, the Bering Strait. While it is likely that storm intensity has increased and will continue to increase in this region with additional warming, there is little evidence to support these claims. This project aims to generate evidence of storm intensity in the region by combining natural science and traditional Siberian Yupik naming traditions. Driftwood deposits laid to rest at the extent of the storm surge are used as indicators of a given storm's intensity. The date of when the driftwood was deposited, however, cannot be determined precisely by dendrochronology techniques. Traditional ecological knowledge of storm events stored in the names of indigenous peoples in Savoonga, Alaska may reveal the dates of large storms that left the driftwood on their beaches. This Siberian Yupik village names babies after significant events, like large storms, to retain knowledge of those events; their birth dates are used to identify, with great precision, the date of past storms. Storm surge maps can be generated from these sources and the direction of storm intensity change may be identified.
Coastal Landscape Transformation in Sørkapp Land (Spitsbergen), 1899 - 2016

Wieslaw Ziaja¹ (wieslaw.ziaja@uj.edu.pl)
¹Jagiellonian University, Institute of Geography and Spatial Management, Krakow, Poland

Sørkapp Land is the southern Spitsbergen peninsula - a wedge between the Barents and Greenland Seas. Its coasts transformed under climate warming since 1899. The eastern, most glaciated and coldest, mountainous coast (70 km long) underwent a huge change: - recession of tidewater glaciers (rapid since the 1980s) formed the new Hambergbukta fjord and Isbukta bay, and exposed the coastline to sea abrasion and accumulation, - hence, the plain with Davislaguna was abraded by the sea and several new plains appeared in areas abandoned by glaciers, - recession of glaciers located above the sea-level led to formation of a new landscape (new deposits, landforms and water-bodies), - animal colonization allowed plant succession what began soil formation. The western - least glaciated and warmest - lowland coast (55 km long) underwent a progressive change since 1899. It was generally ice-freed at the end of Pleistocene and covered with tundra, overgrazed by reindeer regenerated there since the 1990s. Recession of the only tidewater glacier led to origin of the Stormbukta bay. The coastline was modified due to shortening of a sea-ice season what intensified sea-action: filling bays with deposits and abrasion of headlands. The northern fjord coast (55 km long) lengthened a lot since 1899 due to recession of tidewater glaciers, which formed new lateral fjords and bays (Samarinvågen is the longest). The southern lowland coast is 27 km long and most stable due to a shallow sea offshore.
Building a Collaborative Framework to Support Adaptation in Coastal Alaska

Stephen Gray¹ (sgray@usgs.gov), Amy Holman², Nicole Kinsman², Jeremy Littell¹, Molly McCammon³, Karen Murphy³, Jacquelyn Overbeck³, Karen Pletnikoff⁶, Aaron Poe⁷

¹US Geological Survey, Alaska Climate Science Center, Anchorage, United States, ²NOAA Alaska Region, Anchorage, United States, ³Alaska Ocean Observing System, Anchorage, United States, ⁴US Fish and Wildlife Service, Western Alaska LCC, Anchorage, United States, ⁵Alaska Department of Natural Resources, Anchorage, United States, ⁶Aleutian Pribilof Islands Association, Anchorage, United States, ⁷US Fish and Wildlife Service, Aleutian and Bering Sea Islands LCC, Anchorage, United States

In environments undergoing rapid change, increased adaptive capacity and resilience are only achieved with strong, ongoing collaboration. Recognizing this challenge, decision makers working in coastal communities across Alaska convened a series of workshops to share knowledge on current and future changes, their impacts, and potential responses. These workshops began in late 2012 with a focus on coastal hazards, and have continued through 2017 with a string of discussions centered on regional impacts. The 300+ participants included Alaska Natives, local governments, and State and Federal agencies, with input from all of these groups feeding into an assessment of the data and information needed to help communities better respond to coastal change. Based on these ongoing efforts, we will provide a summary of key data gaps related to the environment in these coastal zones (e.g., bathymetry, sea ice conditions, vessel traffic), and progress to date in addressing these gaps. Moreover, we hope to present an overview of how these workshops have been used to strengthen collaboration across stakeholder groups; consolidate and leverage research (both western and traditional); and ensure that results reach the stakeholders who need them. Overall, we seek to present a suite of “lessons learned” for those wishing to create a dynamic, collaborative process for identifying needs, conducting research, and communicating in support of those living and working in Polar coastal zones.
Our work aims to address deficiency in understanding of mechanisms controlling the development of rocky coasts in polar regions. Over last few years we studied the processes controlling the evolution and behaviour of rock coasts in representative areas of South Shetland Islands (Antarctic) and Svalbard (Arctic).

Rock surface weathering and downwearing surveys along several morphologically different coast types demonstrated broad variety of interrelations between rock surface resistance and distance from present-day shoreline as well as thickness of snow covers. In general, cliff surfaces were the most resistant in their lower and middle zones which are thermally insulated by thick winter snowdrifts. Whereas the more exposed cliff tops were heavily fractured and weathered. The differences in rock resistance and downwearing rates observed along the shore platforms were highly dependent on thickness of sediment cover and shoreline configuration. These characteristics favoured stronger rock surfaces in areas exposed to the longest wave fetch, but also washing by meltwaters from decaying ice-foot. The results of ERT survey suggest that most of the rocky capes and platforms are free of continuous permafrost and frozen ground conditions develop further inland. The results presented in this paper emphasize the richness of microrelief features and processes operating in polar rock coastal environments.

This paper is a contribution to NCN project UMO2013/11/B/ST10/00283.
Kelps, large brown seaweeds of the order Laminariales, are important ecosystem engineers in Arctic coastal ecosystems. However, knowledge of seaweed ecosystem functioning under Arctic winter conditions is scarce, but essential to understand adaptive life strategies and adaptability in an era of climate change. In high latitude coastal systems, kelps, as perennial and primarily photoautotrophic marine plants, have to face several months of darkness, precluding photosynthetic activity. Still, winterly growth of kelp tissue has been observed, fuelled by the consumption of stored carbohydrates.

In the Arctic Kongsfjord (Svalbard), a pronounced increase in seawater temperature has been detected since 2006, and is expected to continue. Thus, it is essential to understand temperature related modulation of winterly ecophysiology in Arctic seaweeds. Two species of Arctic kelps (the cold-temperate *Saccharina latissima* and the endemic *Laminaria solidungula*) have been studied for the expression and regulation of house-keeping physiological processes in autumn and just at the end of the polar night. In *S. latissima* more than 80% of the storage carbohydrate laminaran is consumed during winter under current *in situ* fjord temperature, and our data suggest that carbohydrate turn-over will further increase with temperature. Experimentally increased temperature conditions during dark exposure point to a complex network of physiological adjustments of kelps in a changing Arctic environment.
Spatial Variation in the Structure of Benthic Communities in Siberian Shelf Seas

Miriam Hansen1 (mhansen@ecology.uni-kiel.de), Casper Kraan2,3, Dieter Piepenburg4,5

1Christian Albrecht University of Kiel, Palaeoceanography, Kiel, Germany, 2Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Functional Ecology, Bremerhaven, Germany, 3Helmholtz Institute for Functional Marine Biodiversity (HIFMB) at University Oldenburg, Oldenburg, Germany, 4Christian Albrecht University of Kiel, Kiel, Germany, 5Alfred Wegener Institute, Bremerhaven, Germany

Climate change and its consequences pressure the Arctic Siberian shelf region and impact marine benthic organisms severely. Since polar ecosystems are used to long-time stable conditions, even small changes could have wide-ranging consequences for benthic communities, food webs, and ecosystem functions. Yet, little is known about the response of Arctic benthic organisms to changing environmental conditions. We address this knowledge gap by combining data from different Arctic regions and employing recent ecological modelling techniques and study community structure, diversity and ecosystem functions in Arctic benthos across larger scales.

Expeditions in the Arctic seas from the years 1991, 1993, 2013 and 2014 provide the required ecological data for the modelling approaches. Sixty-nine stations across the Arctic Sea were sampled by trawling and grab methods within the TRANSDRIFT-framework. By employing multivariate spatial analysis tools, such as Moran's eigenvector mapping, an answer to the following question shall be provided: whether to include relationships between spatial structure and abiotic variables allow scientists to better detect patterns of species and communities in the Arctic Siberian Sea. The expected result will show which environmental variables are important at which scale, and which macrobenthic species are most associated with these distinct scales.
Genetic Monitoring for Climate Change in Antarctic Marine Invertebrates

Nerida Wilson¹ (nerida.wilson@museum.wa.gov.au)
²Western Australian Museum, Molecular Systematics Unit, Welshpool, Australia

Climate change is expected to disproportionately affect the diversity of polar regions. In comparison, in other areas with latitudinal scope, organisms may be able to respond by changing their distributions to suit their physiological capacities. However this is not possible for polar species that simply have nowhere colder they can migrate to, even if they were able to. Although some level of adaptation and response to changing conditions is predicted, undoubtedly the loss of species diversity is ultimately expected. We show here the importance of having baseline phylogeographic information to be able to detect when the species diversity of Antarctic communities begin being impacted. Our study system utilises cryptic species diversity in the Antarctic crinoid Promachocrinus, and differential species distributions to create a warning system of marine invertebrate community change.
The main question in the debate on climate change is whether some species will be able to adapt fast enough to keep up with the rapid pace of changing climate. Whatever the type of adaptive responses, underlying mechanisms are due either to evolution or plasticity. Empirical evidence suggests that physiological plasticity is often more important than genetic contribution in complex, long-living species. Of particular concern are “tipping points” where ecosystem thresholds can lead to irreversible shifts. The biological effects of increasing temperature on marine ecosystems are already evident. Temperature governs the rate of chemical reactions and pathways regulating the development and decline of life. Sensitivity to temperature influences the success of organisms in all habitats, and is caused by the susceptibility of biochemical processes, including protein function, to temperature change. Recent studies indicate that only minor structural modifications are needed to change the intrinsic stability of cold-adapted proteins, and that local rather than global flexibility may play an important role. In this contribution, we first summarise how cold temperature affects the physiology, then focus on the molecular mechanisms of cold adaptation revealed by recent biophysical, biochemical and genetic studies of a specific group: oxygen-binding proteins.
The northern high latitudes are experiencing some of the most rapid and severe climate change recorded globally. Changes apparent in the Arctic climate system are now well established and evidenced in observations of substantial warming and dramatic reductions in summer sea ice extent and thickness. However, the response of key components of Arctic ecosystems, such as benthic faunal assemblages, to environmental change is poorly understood. Here we investigate the ecological consequences of climate change in the Arctic by characterising and quantifying change in the functional response traits of representative benthic species along a gradient of variable sea ice conditions. To inform our interpretations, we focus on biogeochemically and population-relevant biological activities, including bioturbation and bioirrigation, and growth and reproduction, respectively. Our findings detail how and when the response of benthic invertebrate species and/or communities lead to functionally important changes in behavior that, in turn, alter important ecosystem processes and function.

Climate and the Magnitude of Blue Carbon Storage by Circumpolar Shelf Benthos

David K A Barnes¹ (dkab@bas.ac.uk), Narissa Bax², Rachel Downey³, Christoph Held⁴, Camille Moreau⁵, Bernabe Moreno⁶, Maria Paulsen⁷, Chester J Sands¹
¹British Antarctic Survey, Cambridge, United Kingdom, ²University of Tasmania, Hobart, Australia, ³Australian National University, Canberra, Australia, ⁴Alfred Wegner Institute, Bremerhaven, Germany, ⁵Université Libre de Bruxelles, Bruxelles, Belgium, ⁶Universidad Científica del Sur, Lima, Peru, ⁷University of Bergen, Bergen, Norway

High latitude continental shelves provide carbon capture and storage of millions of tonnes annually. The magnitude and variability in this biological accumulation, immobilization and ultimate sequestration of Carbon has been little quantified. Darwin Initiative, Antarctic Circumnavigation Expedition (ACE) and ICEBERGs projects have supported the Antarctic Seabed Carbon Capture Change project to sample shelf benthos in order to attempt estimation of this carbon budget by region and across years. This was undertaken by using Shelf Underwater camera System (SUCS) and video/photo-equipped trawls to estimate benthos densities and specimens were collected to evaluate carbon per age per species. SubAntarctic continental shelf benthos seem to play only a small role in carbon cycling, but are globally significant in terms of carbon storage and very likely sequestration. There is considerable temporal variation in benthic carbon storage, particularly around West Antarctica, correlated with climate forced sea-ice losses (and ice shelf disintegration). There is also evidence of warming increasing benthic carbon storage budgets, through faster growth. SubAntarctic continental shelves have considerable phytoplankton blooms, little sea ice and warmer sea temperatures than Antarctica; together with polar shelves they represent one of Earth's most significant and growing negative feedbacks on climate change.
Measuring precipitation in the Antarctic is very difficult and at present no reliable way of ground truthing the data exists. It is a very important parameter to accurately measure so that the measurements can be used for model verification. At the British Antarctic Survey's Rothera station on the Antarctic Peninsula at (67.5S, 68.1W) we are comparing a selection of precipitation sensors to assess which is the most accurate.

Three optical sensors are being compared, they are a Thies Laser Precipitation Monitor (LPM), a Biral VPF-730 combined precipitation and visibility sensor and a Campbell Scientific PWS100. They all use different measuring techniques to estimate precipitation type and intensity by analysing how the water droplets and snow particles interfere with the optical beams.

There is also a UPG1000 - Universal Precipitation Gauge that is manufactured by Environmental Measurements Ltd (EML). When snow falls into this gauge it is melted and then measured using a tipping bucket.

Initial results show a large difference between all of the sensors on a monthly scale but in low wind speed conditions there is close agreement between all. More analysis of the data are being carried out to try and ascertain which of them is most accurate for use in the Antarctic.

This presentation will look in more detail at the operation of the sensors and how the data compares in different wind regimes.
There are various estimates of the trends of certain meteorological parameters in different water areas and coastal zones of the Russian and rest Arctic regions. Taking into account the increasing number of dangerous phenomena and outlooks for the Arctic coast, the task of providing the region detailed hydrometeorological and climatic information with a horizontal resolution of at least several kilometers becomes particularly topical. To get there, we will use well-known regional climate model COSMO-CLM v5.0.

The regional reanalysis for Russian Arctic, an integrated archive of hydrometeorological parameters with a spatial resolution of less than 5 km, will be obtained for the first time after long-term simulation experiments. Detailed hydrometeorological fields in the Arctic over a long period (1980 - 2016) will be derived by the two-step downscaling technology with ~13 km and ~4 km domains and will cover most of Russian Arctic (western Arctic seas more detailed).

The regional reanalysis output is possible to use as inputs to modelling the ocean’s characteristics (wind waves and dynamics), coastal ecosystems (turbulent heat fluxes, greenhouse gases), more detailed research of individual phenomena on nested domains (extreme situations, hazardous weather events), analysis of trends in the frequency of occurrence of extreme events and features of their spatial distribution, the hydrometeorological regime of coastal areas studies, climatology and tracking of polar mesocyclones, etc.
The Arctic is warming twice as fast as the global average. This feature, known as the Arctic amplification, results in and is a result of rapidly changing climate system components, where the effects of clouds remain one of our largest unknowns.

The joint field campaign Arctic CLoud Observations Using airborne measurements during polar Day (ACLOUD) May 22 - June 28, 2017 aimed at improving our understanding of physical processes above, below and in Arctic clouds. It offers crucial data for the representation of clouds and atmospheric processes in weather and climate models representing the new normal in the Arctic.

ACLOUD made use of two aircrafts based in Longyearbyen, Svalbard. Flying mostly together at different levels, the aircrafts Polar 5 and 6 applied in situ measurement techniques and remote sensing instruments. ACLUD was coordinated with surface-based observations from the station in Ny-Ålesund and an ice camp north of Svalbard operated within the joint campaign PASCAL around RV Polarstern. This allowed us to measure properties of cloud and aerosol particles, trace gas concentration, and turbulent and radiative fluxes in the atmospheric column over and around Svalbard.

In this presentation, the first results of ACLUD are given, with a focus on the synoptic situation during the campaign. We highlight the importance such field campaigns have also beyond the scientific community.
Assessing the evolution of Antarctic climate and SMB by the end 21st century is of first importance for evaluating the potential contribution to SLR. In this frame, we evaluate the contribution of atmosphere-only GCM, ARPEGE, with a stretched grid allowing a resolution of 45 kms on Antarctica. First, the ability to reproduce Antarctic climate of a free AMIP simulation (1981-2010) is assessed using observational data set, reanalysis and model inter-comparisons. Firsts results show that ARPEGE succeed in reconstructing surface climate. The use of an intermediate-complexity snow model allows taking into account processes such as snow sublimation and run-off. However, errors on atmospheric general circulation, particularly the underestimation of Amundsen Sea Low affects the spatial distribution of precipitations over West Antarctica. Nevertheless, mean 1981-2010 SMB of Antarctic Ice sheet of 2317.7 Gt.yr⁻¹ concours with recent publications (e.g. Agosta et al., 2013, Lenaerts et al., 2015). Then, we use ARPEGE to evaluate changes of Antarctic climate and SMB in a RCP8.5 scenario. Thirty years simulations at the end of the 21st century (2071-2100) are realized using bias correction of oceanic forcings coming from CMIP5 AOGCM scenarios following recommendations from Beaumet et al., (submitted). Remaining uncertainties coming from the climate change signal for oceanic surface conditions in different CMIP5 model are assessed independently from the bias on historical climate.
Due to the poor observational constraint in the Southern Ocean, atmospheric analysis and reanalysis datasets are associated with larger uncertainties in this region than in the Northern Hemisphere. On this poster a series of 98 vertical soundings collected during the ship-based Antarctic Circumnavigation Expedition (ACE) in the austral summer 2016/2017 is compared to operational analysis data of the European Centre for Medium-Range Weather Forecasts. The ACE soundings were not assimilated and thus provide an independent validation data set. The vertical structure of temperature, humidity, and wind is analysed. In many soundings, a good match of the observations with the operational analysis is found for the upper troposphere ($p < 500$ hPa). In contrast, in the lower troposphere, 50-100 hPa thick humid layers generally associated with clouds are either not represented in the analysis data or shifted in space and time. Three cases of a marked isothermal mid tropospheric dry air layer above a precipitating cloud are discussed in more detail based on a Lagrangian analysis of the airmass history in this layer.
A new 22 GHz water vapor spectrometer, VESPA-22, was installed in July 2016 at the Thule High Arctic Atmospheric Observatory located at Thule Air Base (76.5° N, 68.8° W), Greenland (http://www.thuleatmos-it.it/). It was designed and built at the INGV and measures the 22.235 GHz water vapor emission line with a bandwidth of 500 MHz and a resolution of 31 kHz. The collected spectra are inverted using an optimal estimation algorithm in order to retrieve water vapor vertical profiles from about 25 to 75 km with an overall uncertainty between 5 and 12%. Depending on season and weather conditions, 2 to 4 vertical profiles a day are obtained. VESPA-22 has been operating in an autonomous mode since its installation, with very few short periods of data gaps. This study will present water vapor stratospheric profiles over Thule obtained during a complete yearly cycle, from July 2016 to July 2017, showing both the rapid variations measured in winter when the polar vortex moved away from Thule and the slow seasonal variations due to the air subsidence inside and at the edge of the polar vortex. VESPA-22 water vapor vertical profiles have been compared with version 4.2 of concurrent Aura/Microwave Limb Sounder (MLS) profiles. In the sensitivity range of VESPA-22 retrievals, the intercomparison between the two datasets reveals a correlation coefficient of about 0.8 or higher and an average difference reaching its maximum of -6% or -0.2 ppmv at the top of the sensitivity range.
Column Water Vapor Impact on the Surface Infrared Radiation at Thule, Greenland

Giovanni Muscari\textsuperscript{1} (giovanni.muscari@ingv.it), Daniela Meloni\textsuperscript{2}, Giandomenico Pace\textsuperscript{2}, Gabriele Mevi\textsuperscript{1,3}, Alcide Giorgio di Sarra\textsuperscript{2}, Tatiana Di Iorio\textsuperscript{2}, Marco Cacciani\textsuperscript{4}

\textsuperscript{1}Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy, \textsuperscript{2}ENEA, Laboratory for Observations and Analyses of Earth and Climate, Rome, Italy, \textsuperscript{3}Roma Tre University, Mathematics and Physics Department, Rome, Italy, \textsuperscript{4}University of Rome 'La Sapienza', Physics Department, Rome, Italy

The absorption of longwave radiation by water vapor and clouds influences temperature at the surface creating complex feedback cycles. Direct measurements of surface irradiance in the Arctic region are sparse and accurate parameterizations are therefore required in order to constrain climate models and study such cycles. This study presents an analysis of the impact of precipitable water vapor (PWV) and surface temperature on downwelling longwave clear-sky irradiance at the surface measured at the Thule High Arctic Atmospheric Observatory located at Thule Air Base (76.5° N, 68.8° W), Greenland (http://www.thuleatmos-it.it/). PWV measurements are obtained with the 22 GHz spectrometer VESPA-22 and the RPG HATPRO radiometer, whereas the longwave irradiance is measured by means of a CGR4 pyrgeometer. VESPA-22 and HATPRO PWV measurements are intercompared with those obtained by Aqua/AIRS, and by means of a Cimel sunphotometer (AERONET network) and a GPS receiver also installed at Thule. A new semi-empirical parameterization model is formulated using high-time resolution observations collected from July 2016 onwards. The relative weight of column water vapor and temperature on clear-sky longwave irradiance at the surface is investigated by means of the MODTRAN radiative transfer model during a full annual cycle. The semi-empirical model implemented in this study proves to be a valuable tool for parameterizing clear-sky longwave irradiance at high latitudes.
Comparison Between Cloudsat and In-situ Radar Snowfall Rates in East Antarctica

Florentin Lemonnier\textsuperscript{1} (florentin.lemonnier@lmd.jussieu.fr), Jean-Baptiste Madeleine\textsuperscript{1}, Chantal Claud\textsuperscript{4}, Norman Wood\textsuperscript{2}, Tristan L’Ecuyer\textsuperscript{2}, Gerhard Krinner\textsuperscript{3}, Alexis Berne\textsuperscript{4}, Claudio Duran-Alarcon\textsuperscript{3}, Cyril Palerme\textsuperscript{3}, Christophe Genthon\textsuperscript{3}

\textsuperscript{1}Laboratoire de Météorologie Dynamique/IPSL, École Normale Supérieure, Paris, France, \textsuperscript{2}University of Wisconsin-Madison, Madison, United States, \textsuperscript{3}Institut des Géosciences de l’Environnement, Grenoble, France, \textsuperscript{4}École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

The Antarctic continent is a vast desert, the coldest and the most unknown area on Earth and contains its largest fresh water reservoir. Current global warming could threaten this ice sheet, leading to sea level rise. The main goal of the French-Swiss APRES3 project (Antarctic Precipitation, Remote Sensing from Surface and Space) is to document and understand current precipitation over the south polar cap, knowing that current climate models do not agree on snowfall amounts over the ice sheet [Palerme, Clim. Dynamics 2017]. Remote sensing observations of the coastal regions and the continent using CloudSat radar give a snowfall rate of 153 mm/year whereas the IPSL Climate Model gives a higher rate of 172 mm/year, knowing that CloudSat uncertainties are hard to constrain and range from about 50% up to 175% [Wood, Thesis 2011]. We did a comparison between CloudSat radar observations and a Micro-Rain Radar located at the French Dumont d’Urville station that brings a better understanding of CloudSat uncertainties and leads to a reassessment of these values. We compared these two different data sets over February 2017, when CloudSat overpassed the Dumont d’Urville radar four times, at one vertical level and the agreement is suitable. Using different CloudSat vertical levels and additional surface precipitation observation by a PLUVIO2 weighing gauge, we explore and analyze the vertical profile of precipitation over Dumont d’Urville and revisit the results over the whole continent.
Precipitation and snowfall in particular are of great importance for the Arctic climate system due to their implications on physical mechanisms like sea ice growth and melt, permafrost, as well as on ecosystems and society.

Unfavorably, there are only few circum-Arctic stations and hardly any in the Central Arctic itself measuring precipitation. Therefore, many related studies use model simulations or reanalyses. However, it is somehow unclear how big the uncertainties from a specific product are.

Our study examines the spatiotemporal distribution and statistical characteristics of precipitation from various reanalyses (ERA-Interim, MERRA-2, JRA-55, ASR, CFSR) in the Arctic for 1979-2016. We show that the spatial distribution of precipitation and the timing at which the precipitation occurs are very similar across the reanalyses, as those are mainly influenced by the large-scale circulation. However, there does exist a large spread in the amount of precipitation caused by synoptic events as well as in the total amount.

Since the used parametrization schemes vary widely in the way they determine the precipitation phase, large differences in the snowfall to precipitation ratio can be observed.

We analyze how the trend in the amount of precipitation and the precipitation phase can be interpreted.

This work was supported by the SFB/TR 172 "Arctic Amplification: Climate Relevant Atmospheric and Surface Processes, and Feedback Mechanisms (AC)³" in sub-project E04 funded by the DFG.
Characteristics of Gravity Waves over Antarctica Using Radiosonde Observations

N Koushik¹ (koushiknk@gmail.com), Geetha Ramkumar¹, Karanam Kishore Kumar¹, Kandula V Subrahmanyam¹
¹Space Physics Laboratory, Vikram Sarabhai Space Centre, Indian Space Research Organisation, Thiruvananthapuram, India

By now the momentous role of atmospheric gravity waves in shaping the thermal and dynamical structure of the middle atmosphere is irrefutable. More observations of gravity waves in the polar stratosphere, especially over the remote and hostile Antarctic, are required for the betterment of their representation in models. In this regard, a study was conducted to characterize gravity waves in the Antarctic lower stratosphere using campaign mode balloon borne radiosonde observations from the Indian research base at Antarctica, Bharati (69oS, 76.8oE) during the austral summers of 2014-15, 2015-16 and 2016-17. The average potential energy densities in the lower stratosphere were found to be less than 1J/kg. The gravity wave kinetic energy densities were found to be much higher than the corresponding potential energy densities (KE/PE>1), suggestive of the dominance of inertia-gravity waves in the wave field. Further, Stokes parameter analysis was used to extract the propagation characteristics. The intrinsic period of the gravity waves were found to be closer to the inertial period at the location. The deduced horizontal wavelengths were large, of the order of 1000km. The observed waves were predominantly upward propagating which is typical of summertime Antarctic stratosphere. The significance of the present study lies in bringing out the characteristics of gravity waves over Antarctica during three summer seasons with different prevailing atmospheric conditions.
Influence of Ozone Hole on Precipitation in the Pacific Coast of South America

Alessandro Damiani1 (alecarlo.damiani@gmail.com), Raul Cordero2, Pedro Llanillo2, Sarah Feron3, Juan Pablo Boisier4
1Chiba University, CEReS, Chiba, Japan, 2Universidad de Santiago de Chile, Santiago, Chile, 3Leuphana University, Lüneburg, Germany, 4Universidad de Chile, Santiago de Chile, Chile

Both simulations and observations consistently proved that the ozone hole left a clear signature of its effects on the surface climate of the Southern Hemisphere. Within this framework, results based on an ozone attribution study, performed by some of the models participant to the Coupled Model Intercomparison Project Phase 5 (CMIP5) initiative, suggest that the evolution of the ozone hole contributed to the previously identified reduction of precipitation occurred along the Pacific coast of southern South America during the last decades. Such ozone-induced variations, which maximize in summer, are coupled to corresponding changes in cloud fraction and surface temperature. The individual response of each model is shown to be dependent on the magnitude of the ozone forcing. This influence is explained by the ozone hole impact on the general atmospheric circulation and confirms previous results pointing to a large-scale control on this region. In particular, the response to ozone hole in the zonal winds is shown to determine the strength of uplift on the windward side of the Andes with consequent larger humidity there and, possibly, dry conditions in the eastern plains. Since the ozone hole is simulated to recover by the next decades, its forcing is shown to counteract the GHG forcing under the RCP4.5 scenario. As a consequence, no evident changes in cloudiness and precipitation affect the investigated region during this period.
Overview of Stable Water Isotope Meteorology in the Southern Ocean during ACE

Iris Thurnherr¹ (iris.thurnherr@env.ethz.ch), Graf Pascal¹, Franziska Aemisegger¹, Stephan Pfahl¹, Maxi Böttcher³, Yongbiao Weng², Harald Sodemann², Josué Gehring³, Alexis Berne³, Irina Gorodetskaya⁴, Heini Wernli¹

¹ETH Zurich, Institute for Atmospheric and Climate Science, Zurich, Switzerland, ²University of Bergen, Geophysical Institute & Bjerknes Centre for Climate Research, Bergen, Norway, ³EPFL, ENAC-LTE, Lausanne, Switzerland, ⁴University of Aveiro, Centre for Environmental and Marine Studies, Aveiro, Portugal

The dynamics of the large-scale atmospheric flow strongly influences the Southern Ocean fresh water budget. For example, the passage of cyclones is responsible for a large part of strong precipitation events, whereas cold-air outbreaks are often associated with intense ocean evaporation. Stable water isotopes (SWI) are useful tracers to analyse atmospheric moisture sources and transport pathways. During the Antarctic Circumnavigation Expedition (ACE), a unique observational dataset was collected on board the vessel Akademik Tryoshnikov from 16 Dec 2016 to 17 March 2017. These observations include measurements of SWI in atmospheric water vapour, precipitation and surface waters, radar observations of precipitation, high-resolution humidity measurements, and atmospheric profiles from radiosondes. Together with different meteorological diagnostics, these observations are used to investigate key aspects of the Southern Ocean water cycle. The meteorological conditions during austral summer 16/17 are presented using operational analysis data of the European Centre for Medium-Range Weather Forecasts. Various tools to identify weather systems are used to characterise the meteorology during the ACE expedition. The encountered weather systems are then linked to the SWI composition of atmospheric water vapour. This includes a detailed characterisation of the spatial and temporal SWI variability in atmospheric vapour along the ship track, and the involved meteorological phenomena.
The asymmetry in the Antarctic total ozone zonal distribution has changed during the last four decades, showing an eastward shift in the zonal ozone minimum of quasi-stationary planetary wave. The satellite data 1979-2016 analyzed by the authors related to changes in the zonal asymmetry of the Antarctic ozone and to their coupling with atmospheric parameters in the Southern Hemisphere (SH) are presented. Long-term changes of total ozone content in the SH in spring are accompanied by changes in its asymmetric distribution. Interannual variations of the longitudinal ozone minimum position demonstrate statistically significant relation to the structure of the quasi-stationary planetary waves in the distribution of atmospheric parameters. The long-term longitudinal shift of the ozone minimum is similar to shift in the zonal structure of planetary waves in the tropospheric parameter distribution and is also accompanied by meridional displacement of the climatic anomalies toward the equator. The obtained relationships characterize interdependence between the large-scale tropospheric and stratospheric disturbances in the SH during the ozone hole season. Eastward movement of the zonal ozone minimum over Antarctica has slowed and reversed to westward during the last decade that can relate to the first sign of recovery in Antarctic ozone. The zonal ozone asymmetry behavior accompanying ozone depletion/recovery could be associated with regional climate changes in the SH in spring.
The Finnish Meteorological Institute (FMI) has collaborated with the Servicio Meteorológico Nacional, Argentina, to establish new UV measurements in Antarctica. A GUV-2511 multifilter radiometer was installed at Marambio (64ºS) in January 2017. The radiometer measures spectral irradiance at five UV wavelengths and one wavelength in the visible (555 nm). An addition channel measures PAR. The new observations continue UV measurements performed between 2000 and 2012 with a NILU-UV radiometer of the Antarctic NILU-UV network, which is a collaboration between FMI, SMN, Spain, and DNA-IAA, Argentina. The gap between the two UV time series can be filled with measurements of a broadband UV radiometer, which is part of the albedo measurement setup in Marambio.

The FMI measures UV radiation at seven stations in Finland. In Sodankylä (67ºN), measurements started in 1990, and the spectral UV time series is among the longest in the Arctic. Observations are made with a Brewer spectroradiometer, which also measures total ozone. As both Sodankylä and Marambio are located in areas of spring-time stratospheric ozone depletion at similar latitudes but in different hemispheres, it is interesting to compare the measured UV time series. The irradiance scale of the measurements was homogenized and is traceable to Aalto-MIKES, Finland. At Sodankylä, the maximum UV index was found to be 6 (summers 2011 and 2013). At Marambio, the maximum UV index measured between 2000 and 2010 was 12 (Nov 2007).
Ozone monitoring is still very important even more than 30 years after the Montreal Protocol agreement, because the first signs of ozone layer healing have only been observed very recently. Since February 2010, the Czech Hydrometeorological Institute monitors the total column ozone and vertical ozone profiles at the Marambio Base (64° S, 56° W), eastern Antarctic Peninsula, by the MK-III Brewer spectrophotometer B199. Using the eight years (2010-2017) of observed data, we have been focusing mostly on these topics:

1. Assessment of the total column ozone variability
2. Intercomparisons of the B199 total ozone column with various satellite data products
3. Validation of the B199 Umkehr vertical ozone profiles using the Finnish Meteorological Institute ozone soundings

Our results indicate that due to dynamical processes in the stratosphere, the ozone layer recovery is more variable in time than the ozone depletion onset. For example in 2013, a fast recovery was observed, while in 2011 the ozone hole lasted till mid-November. Moreover, we confirmed that B199 data fits very well satellite total column ozone. The most reliable dataset seems to be OMI (TOMS) with over 95 % variability in common with B199. On the other hand the Umkehr profiles are too smooth and overestimating the ozone amount in days characterized by the strong ozone depletion linked with strength of the polar vortex.
Since December 2010, a Brewer ozone spectrophotometer for measuring the total ozone column and UV spectra (283 to 363 nm) has been operated during austral summers at the Belgian research station Princess Elisabeth (PES), in the Sør Rondane Mountains in East Antarctica (72° S, 23° E, 1390 m asl). We will present an overview of the measurement results since 2010/11 up to 2017/18. In 2015, the Antarctic ozone hole was one of the largest and most stable one on record and total ozone amounts showed local record minima between 170 to 180 Dobson Units for the end of November 2015. These conditions persisted until 15 December 2015. Consequently, the UV index reached local record values up to 12.

In addition, weather balloons with radio sondes (vertical profile of temperature, relative humidity, pressure, wind speed and direction up to 30 km) have been launched during austral summers 2014/15, 2015/16 (planned for 2017/18). During season 2014/15 the mean tropopause height was 9607 ± 836 m asl with a corresponding temperature of -56.6 ± 4.9 °C (9178 ± 735 m and -56.9 ± 4.1 °C in 2015/16, respectively). During summer season 2014/15 a distinct temperature inversion at around 2500 m asl was observed during almost all launches in January and February. However, this pattern was not observed in season 2015/16. The mean relative humidity ranged between 30 and 50 % throughout the troposphere in 2014/15 and 2015/16. However, February 2016 showed distinctly higher relative humidity profiles.
The Interplay between Cold Air Outbreaks, Convergence Zones and Polar Lows

Annick Terpstra¹² (annick.terpstra@uib.no), Lukas Papritz², Clemens Spensberger², Ian Renfrew¹
¹University of East Anglia, Norwich, United Kingdom, ²Geophysical Institute, University of Bergen and Bjerknes Centre for Climate Research, Bergen, Norway

Geographically confined, equator-ward excursions of cold air masses into ice-free regions are frequently accompanied by the development of severe mesoscale weather phenomena, such as intense low-level jets and polar lows. Cold air outbreaks and polar lows have both been studied independently and are known to be closely related, though it remains unclear how often polar lows accompany cold air outbreaks. Furthermore, polar lows tend to develop at the leading edge and outer boundaries of cold air outbreaks, yet little is known about the temporal and structural evolution of this cold air outbreak periphery and the triggering mechanisms for mesoscale cyclone development along these frontal structures.

In this study we utilize ERA5-reanalysis data to examine the interplay between cold air outbreaks, convergence zone formation and mesoscale cyclone development focusing on the Nordic Seas region. We apply objective detection methods for each of these features, and identify regions and atmospheric conditions which are (non)-favorable for the development of polar lows during cold air outbreaks. We examine the spatial and structural evolution of contrasting cases, i.e. with/without mesoscale development, and explore the role of thermal and moisture gradients at the fringes of cold air outbreaks for mesoscale cyclone initiation.
On the Mean Age of Stratospheric Air and the Polar Vortex Preconditioning

Petr Šácha¹ (sacha@uvigo.es), Aleš Kuchař², Petr Pišoft², Laura de la Torre¹, Juan Añel¹
¹Universidade de Vigo, Facultade de Ciencias de Ourense, Ourense, Spain, ²Charles University in Prague,
Department of Atmospheric Physics, Prague, Czech Republic

The mean age of stratospheric air (AoA) is a useful transport diagnostic. We study the hypothesis that AoA can be used as a proxy for the polar vortex preconditioning, because it reflects the cumulative effect of transport processes. Using a composite analysis of sudden stratospheric warming events from the CMAM specific dynamics simulation we formulate an AoA anomaly index and study its ability to predict polar vortex events up to one month prior to the event. The dynamical origin of these anomalies is then analysed with respect to the anomalous planetary and gravity wave activity.
Atmospheric rivers (AR) are long and narrow regions in the atmosphere that accounts a major horizontal transport of moisture outside the tropics. AR are responsible for coastal heavy rainfalls in midlatitudes. Similarly, AR contributes significantly to heavy snowfall events in coastal Antarctica. In the Antarctic peninsula, AR events are important due to their impact on the surface mass balance of the ice sheets, that may be positive by snow accumulation or negative by snow melting caused by liquid rain events in summer. Other significant impacts involve their potential to transport microbial propagules from South America that may succeed into the deglaciated areas of the Shetland Islands.

To study AR reaching Livingston Island, a climatology of 368172 trajectories (12 year between 2005 and 2016, 4 times a day and 21 levels) has been computed using the Hybrid Single-Particle Lagrangian Trajectory model (HYSPLIT). Following the methodology described by Gorodetskaya et al (2014) to detect AR at high latitudes, we selected the cases where AR impinged on JCI station at Livingston Island between 2005 and 2016. In this communication we present the lagrangian analysis of these events focusing on their climatology, their moisture sources and the synoptic settings that produces them.
In January 2016, the Ross Ice Shelf (RIS) experienced one of its most prominent surface melt events since the advent of satellite observations in the late 1970s. This event followed a pattern already seen during previous events: the melting begins along the Siple Coast, on the eastern side of the RIS, expands to the rest of the ice shelf, before retreating to where it started. Previous work has highlighted the role of the strong 2015-16 El Niño event in promoting warm air advection toward western West Antarctica. While important in initiating the melt event, this phenomenon only partially explains the spatial and temporal distribution of the melting and ignores other important physical mechanisms. Here, we present the results of a detailed three-dimensional investigation of the meteorology of the January 2016 event based on model output from the Antarctic Mesoscale Prediction System (AMPS) and the ERA5 Reanalysis. Using backward trajectory analysis, we highlight in particular the foehn effect taking place downwind of the coastal mountain ranges of Marie Byrd Land, which acts to amplify the warm advection, especially during the early stage of the melt event. To our knowledge, the existence of this foehn effect has thus far never been demonstrated nor its effect quantified. Our analysis underscores the importance of high resolution for atmospheric simulations of West Antarctic surface climate, an important aspect to consider when projecting the future of the RIS.
Snowfall Rate Retrieval and its Relation with the Antarctic Surface Mass Balance

Niels Souverijns¹ (niels.souverijns@kuleuven.be), Alexandra Gossart², Stef Lhermitte², Irina V. Gorodetskaya³, Stefan Kneifel⁴, Maximilian Maahn⁵,⁶, Francis L. Bliven⁷, Alexander Mangold⁸, Quentin Laffineur⁸, Andy Delcloo⁸, Nicole P. M. van Lipzig¹

The Antarctic Ice Sheet (AIS) is the largest ice body on earth. In order to understand its contribution to sea level rise, local surface mass balance (SMB) measurements are crucial. Precipitation is generally considered the dominant source term in the SMB budget of the AIS. Both SMB and snowfall are not well constrained in both models and observations, and the relation between both quantities remains unknown.

At the Princess Elisabeth station (East Antarctica), a ground-based vertically pointing 24 GHz Micro Rain Radar provides radar reflectivity measurements. When information about snow particle microphysics is available, one can get an idea of snowfall rates. This is provided by an optical disdrometer (Precipitation Imaging Package). As such, radar reflectivity snowfall rate relations (Z=a*SRb) are derived for the East Antarctic escarpment region including an overview of their uncertainties.

The local SMB at the station is measured using an Automatic Weather Station and the link between snowfall rates and accumulation at the surface was investigated. It was found that snowfall events are much more common than accumulation events. During 38% of the snowfall cases observed, the freshly-fallen snow is ablated by the wind during the course of the event. In this study, the conditions for ablation and accumulation are investigated discovering a non-linear relation between snowfall and accumulation at the surface.
What Controls Deuterium Excess in Coastal Antarctica?

Sentia Goursaud¹ (sentia.goursaud@lsc.e.ipsl.fr), Camille Bréant², Amaelle Landais², Valérie Masson Delmotte², Michel Legrand³, Martin Werner⁴

¹Institut des Géosciences de l’Environnement, Université Grenoble Alpes, Saint Martin d’Hères, France, ²Laboratoire des Sciences du Climat et de l’Environnement, Gif-sur-Yvette, France, ³Institut des Géosciences de l’Environnement, Saint Martin d’Hères, France, ⁴Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, France

The second-order water stable parameter deuterium excess (d-excess) can be used to understand the spatial and temporal changes in the isotopic-temperature relationship. However, so far no simple result is obtained from statistical analyses of continental surface measurements or from measurements in precipitation and ice cores.

In order to make progress in understanding d-excess measured in Antarctica, we compiled an updated database of water stable isotope data from vapour, snow surface and ice cores. We then completed this database with new data from Adélie Land, obtained from in situ water vapor monitoring at Dumont d’Urville during 40 days of the austral summer 2016/2017 and new high resolution measurements from one shallow ice core drilled at 25 km from the station during the austral summer 2014/2015. Our data are combined with the meteorological observations from Dumont d’Urville and the dry and wet back-trajectories simulated by Hysplit and Flexpart respectively.

Our limited dataset shows the complexity of d-excess signals, and call for new datasets obtained in water vapour, snowfall, surface snow and shallow ice. We show that coastal Antarctic d-excess variability is not controlled by local climate variables and appears related to atmospheric circulation and moisture transport at the local to regional scale. Further studies are needed to deconstruct the exact drivers of coastal Antarctic d-excess and exploit this signal.
Cyclone Activity in the Arctic from an Ensemble of Regional Climate Models

Mirseid Akperov¹, Annette Rinke², Igor Mokhov¹ (mokhov@ifaran.ru), Heidrun Matthes², Vladimir Semenov¹
¹A.M. Obukhov Institute of Atmospheric Physics, Russian Academy of Sciences, Moscow, Russian Federation,
²AWI, Potsdam, Germany

The ability of state-of-the-art regional climate models to simulate cyclone activity in the Arctic region is assessed based on an ensemble of 13 simulations from 11 models from the Arctic-CORDEX initiative. Some models employ large-scale spectral nudging technique. Cyclone activity characteristics simulated by the ensemble are compared with four reanalyses in winter and summer during the 1981-2010 period. Biases in cyclone frequency, intensity and size over the Arctic are quantified. Variations in cyclone frequency across the models are partly related to the differences in cyclone frequency over land. The variations across the models are largest for small and shallow cyclones for both seasons. A connection between biases in the zonal wind at 200 hPa and cyclone characteristics is found for both seasons. Most models underestimate zonal wind speed in both seasons, which likely leads to underestimation of cyclone mean depth and deep cyclone frequency in the Arctic.

In general, the RCMs are able to represent the spatial distribution of cyclone characteristics in the Arctic region but models that employ large-scale spectral nudging are in much better agreement with ERA-Interim reanalysis than the rest of the ensemble. Trends also exhibit the benefits of nudging. Most non-nudged models cannot reproduce cyclone trends while the opposite is true for models with spectral nudging. However, the choice of nudged variables also affects the cyclone characteristics and trends.
Polar mesoscale cyclones (PMCs) are automatically detected and tracked over the Nordic seas using the Melbourne University algorithm applied to the ERA-Interim reanalysis. The novelty of this study is the length of the dataset (1979-2014) and the usage of PMC tracks to infer relationships to large-scale flow patterns. The angle between the ambient mean and thermal wind is used to distinguish two different PMCs genesis environments. The forward shear environment (thermal and mean wind in same direction) features typical baroclinic conditions with a temperature gradient at the surface and a strong jet stream at the tropopause. The reverse shear environment (thermal and mean wind in opposite direction) features an occluded cyclone with a barotropic structure throughout the entire troposphere and a low-level jet.

In contrast to previous studies, PMC occurrence does neither feature a significant trend nor a significant link with the North Atlantic Oscillation and the Scandinavian Blocking (SB), though the SB negative pattern seems to promote reverse shear PMC genesis. The sea ice extent in the Nordic seas is not associated with overall changes in PMC occurrence but influences the genesis location. Selected cold air outbreak indices and the temperature difference between the sea surface and 500 hPa (SST-T500) show no robust link with PMC occurrence but the characteristics of forward shear PMCs and their synoptic environments are sensitive to the choice of the SST-T500 threshold.
Identification of a Physically Based Arctic Cold and Transition Seasons

Taneil Uttal\(^1\) (taneil.uttal@noaa.gov), Alexander Makshtas\(^2\), Christopher Cox\(^3\), Nikolay Ivanov\(^2\)

\(^1\)NOAA Earth System Research Laboratory, Physical Science Division, Boulder, United States, \(^2\)Arctic and Antarctic Research Institute of Roshydromet (AARI), St Petersburg, Russian Federation, \(^3\)Cooperative Institute for Research in Environmental Sciences, NOAA/ESRL/PSD, Boulder, United States

Arctic 'seasons' are physically unique compared to lower latitudes and have strong latitudinal dependence within the Arctic due sun-earth geometry. Therefore, physically-based seasons are here defined to be a long cold season (~6 months), two short transition seasons, and a warm season. Arctic extremes and trends must be defined using different criteria for each of these seasons. In the warm season the obvious extremes are in changing sea-ice extent/area. Trends and extremes for transition seasons are more defined by a trend towards earlier (latter) melt (freeze-up) dates. The Arctic cold season is therefore the most interesting for looking at temperature trends, variability and trends. For in-situ temperature records from Tiksi, Russia, cold season temperature trends are shown to decrease as the length of the record over which trend is calculated increases due to a significant warm period in the 1940s. The incidence of extreme temperature events (exceeding the 95th and 99th percentiles) also show a bimodal distribution with peaks in the 1940s and the present. Results from Tiksi are compared to
(1) various reanalysis products and
(2) other Arctic sites such as Barrow, Alaska.

It is proposed that it is the temperatures during the Arctic cold season are the most relevant for determining linkages with global climate and weather. In addition, the seasonal partitioning described here is expected to be useful for analysis of data from YOPP.
Polar Lows are intense mesoscale maritime storms, which form over open sea during wintertime north of the main baroclinic zone. They occur during cold air outbreaks and are generally associated with heavy snowfalls, reduced visibility, and changing surface winds which can be in excess of 30 m/s. The degree of predictability varies from case to case but they have always represented a challenge in terms of forecasting: their rapid development, their small scale extent (200-600 km) and short lifetime (average 15-20 hrs), the absence or rarity of synoptic observations and real time satellite derived winds, the poor radar coverage and, in many cases, unreliable model fields, has led in the past to a rather low skill, with even some polar lows undetected until they affect coastal regions.

The Barents Sea has long been known to be a prime site for the development of such storms, but climatological aspects of Polar Lows affecting this region are poorly known. In addition, recent retreating sea ice may expose this area to increased occurrences of extreme weather systems. The characteristics of Barents Sea Polar Lows over more than 15 years and the synoptic environment in which they develop will be discussed.
Enhancement of Gravity Wave over Syowa Observed by Rayleigh/Raman Lidar

Masaru Kogure1 (kogure.masaru@nipr.ac.jp), Takuji Nakamura2, Yoshihiro Tomikawa2, Mitsumu K. Ejiri2, Masaki Tsutsumi2, Takanori Nishiyama2
1SOKENDAI (The Graduate University for Advanced Studies), Department of Polar Science, Tokyo, Japan, 2National Institute for Polar Research, Tokyo, Japan

Typical gravity wave activities and its seasonal variations have been studied at various places around the world. However, what causes a shorter temporal and local variations of the activities are poorly understood. To understand this cause, we estimated the potential energy of gravity wave over Syowa Station (69°S, 40°E) from a Rayleigh/Raman (RR) lidar observation between 2011 and 2015. We found a clear enhancement of the potential energy during 8th-21st August 2014. The energy in this period was about two and five times as large as the winter mean in the other years at 50 and 60 km. There are two possible causes. The first one is that some source would exist around 45 km, but there seemed no specific source within the MERRA. The second one is that the gravity waves would converge from the lower atmosphere at lower and higher latitudes due to the meridional gradient of the westerly wind [Dunkerton, 1984]. The polar night jet around 40°E during the enhancement period slanted to ~70°S from ~50°S. In such condition, the gravity waves with west-ward wavenumber incline to converge to Syowa. We estimated paths of gravity waves in order to examine whether the gravity waves could converge to Syowa. We found that the large-scale gravity waves could converge to 50-55 km altitudes over Syowa in that period. This result suggests that the enhancement could be caused by the convergence of the gravity waves. We will show these results and discuss the cause of the enhancement.

Stratospheric Ozone and Nitrogen Oxides in Antarctic Regions

Daniele Bortoli¹,² (db@uevora.pt), Fabrizio Ravegnani², Maria Joao Costa¹,³, Giorgio Giovanelli²
¹University of Evora, Institute for Earth Sciences, Evora, Portugal, ²Institute for Atmospheric Sciences and Climate, Bologna, Italy, ³University of Evora, Department of Physics, Evora, Portugal

Since the discovery of the ozone hole phenomena in Antarctica during the spring season, the studies on the atmospheric tracers related to the ozone chemistry are of extreme interest for the scientific community. At the Mario Zucchelli station, since 1995, GASCOD (Gas Analyzer Spectrometer correlating Optical Differences) equipment performs measurements of zenith sky scattered radiation, for the assessment of stratospheric NO2 and O3. In 2013 the SAMOA (Automatic Station monitoring Antarctic Ozonesphere) system is placed side by side to the old spectrometer to assure the continuation of the time series for the above mentioned compounds and to enlarge the monitoring capabilities. SAMOA is composed of the UV-Vis GASCOD NG1 (New Generation), the VELOD (Vertical Looking Device) to measure the zenith sky scattered radiation and the MIGE (Multiple Input Geometry Equipment) to perform measurements in different directions. Here, the SAMOA station is described and the improvements with respect to the old system are highlighted. Moreover, the DOAS and MAX-DOAS algorithms are briefly introduced and the results obtained during the full period of measurements of the GASCOD instrument are presented and discussed together with a trend analysis for NO2 and O3 total columns. The first comparison of the observations obtained with the two systems, are analyzed.
Terra Nova Bay is often affected by storms moving along the coast and katabatic flow from the continental interior towards the coast. Data from Jang Bogo Station, other available automated weather station (AWS) from Terra Nova Bay and ERA interim reanalysis are used as the primary dataset to develop the climatology of near surface winds. In-situ surface meteorological parameters from the AWS used in the study are wind speed, direction, temperature and pressure. The surface wind field over the Jang Bogo Station is influenced by its complex topography. A bimodal direction in the wind regime is noted throughout the season with wind speed greater than 10 m s\(^{-1}\) coming from the direction 225° to 315°. Criteria were set to classify wind events based on the wind speed and duration. A strong wind event is defined as the event which has wind speed more than two standard deviations. Several thresholds in terms of duration are tested to capture a representative number of wind events for further analysis. The mesoscale and synoptic background of the events are also investigated using reanalysis data. Boundary layer characteristics during the SWEs were also analyzed using SODAR and Radiosonde data. Case studies of SWEs over Terra Nova Bay was carried out to understand the interaction between and katabatic wind and storm of the coast.
Riming in Alpine and Antarctic Precipitation

Josué Gehring¹ (josue.gehring@epfl.ch), Jacopo Grazioli², Christophe Praz¹, Nikola Besic¹, Christophe Genthon³
¹EPFL, ENAC-LTE, Lausanne, Switzerland, ²MeteoSwiss, Locarno, Switzerland, ³IGE, Grenoble, France

Precipitation is crucial in the Alps for water resources and hydro-power. In Antarctica, it is a key term in the surface mass balance but it remains poorly understood because of extreme conditions making observations very challenging. Precipitation in the Alps is better documented, thanks to past field campaigns, and operational measurements including weather radars. However, the interactions between cloud microphysics and orography need to be further investigated. In particular riming, the collection of supercooled water by ice crystals, can significantly contribute to snow accumulation. It is therefore necessary to investigate riming in Alpine and Antarctic precipitation to further its understanding in both environments.

We present results from two field campaigns in Antarctica and in the Swiss Alps. The occurrence and intensity of riming are investigated using hydrometeor classifications from polarimetric radar data and snowflake photographs. The results show that besides aggregates, graupel is the second most important hydrometeor type. The vertical structure of precipitation during riming events is different in the Alps and in Antarctica. In the Alps, the proportion of rimed particles is larger and intense riming is confined to a layer of about 1000 m. In Antarctica, the proportion of rimed particles is less variable in the vertical, without intense riming layers. This study contributes to document an important process for Alpine and Antarctic precipitation.
Urban Heat Island Arctic Research Campaign (UHIARC): Results and Perspectives

Pavel Konstantinov1 (kostadini@mail.ru), Mikhail Varentsov1, Alexander Baklanov2
1Lomonosov Moscow State University, Faculty of Geography, Department of Meteorology and Climatology, Moscow, Russian Federation, 2World Meteorological Organization (WMO), Research Branch, Geneva, Switzerland

Now, in 2017 more than one half of Earth population lives in urbanizes areas. So, the problem of land-use and microclimate changes in city area becomes more important in the context of inhabitants' long-term quality of life. And good knowledge about nature of urban climate and formation of urban heat islands (UHI) became one of important tasks.

Despite the number of big cities are located in high latitudes, especially in Russian Arctic (Murmansk with ≈300 000 inhabitants, Norilsk with ≈180 000 inh., Novy Urengoy with ≈110 000 inh. and a number of cities with more than 50 000 inh.), the climatology of their UHIs has not been practically studied. For Arctic region such investigation was performed only for towns in Alaska (Barrow and Fairbanks). Keeping in mind that during polar night and polar day sunlight conditions are quite different, the idea to explore UHI climatology in Arctic becomes more and more attractive.

After the first experience in 2013-2014, our team developed Urban Heat Island Arctic Research Campaign (UHIARC) in five cities of Russian Arctic. Four of them are located within flat and homogeneous terrains which makes them especially prospective places for Arctic UHI study.

Analysis of the collected data showed the existence of significant UHI with the difference between city center and surrounding landscape up to 10-12ºC that can have strong impact on house heating strategies and inhabitants' thermal comfort.
The Antarctic circumpolar vortex (ACV) forms each winter and spring as a zone of strong stratospheric westerly winds surrounding Antarctica. The ACV presents a barrier to transport of air masses between middle and high-latitudes which contributes to stratospheric temperatures above the polar region dropping sufficiently low in spring to allow for the processes leading to ozone loss. The dynamics of the stratosphere and how they may be changing over time can also affect circulation in the troposphere and have an impact on weather and climate. The processes controlling the permeability of the ACV, and how they are likely to respond to a changing climate and a recovering ozone hole, have not been well studied, and as a result are not well simulated in Global Climate Models (GCMs). This research makes use of reanalysis data and GCM data - using the UK Met Office Unified Model (UM) - together with trajectories from Loon balloon flights over Southern Hemisphere middle and high latitudes to determine how well the permeability of the ACV is represented in a GCM. Results are expected to indicate how improved representation of ACV transport process can be captured in GCMs.
Comparison of Temperature Extremes between the East and Antarctica Peninsula

Aihong Xie¹ (xieaiah@lzb.ac.cn), Shimeng Wang¹, Yicheng Wang¹
¹Northwest Institute of Eco-environment and Resources, Chinese Academy of Sciences, Lanzhou City, China

On the base of daily minimum, maximum, and mean surface air temperatures ($T_{\text{min}}$, $T_{\text{max}}$, $T_{\text{mean}}$) at Great Wall Station (GW, 1985-2015) and Zhongshan Station (ZS, 1989-2015) in Antarctica, changes in temperature extremes are analyzed in the last three decades. Annual mean temperature reveals the strongly warming trend in $T_{\text{min}}$, slightly warming in $T_{\text{mean}}$, while cooling in $T_{\text{max}}$, and shows different seasonal variabilities with the least variability in summer. Annual mean of daily temperature range (DTR) has decreased by -0.39 and -0.29 °C/decade at Great Wall Station and Zhongshan Station, respectively. More importantly, we have found that the seasaw exists East Antarctica and Antarctica Peninsula in the interannual time scale. Eleven indices of extreme temperature are also examined. The occurrence of extreme warm days has decreased by -0.53 and -0.048 d/decade at GW Station and ZS Station, respectively, while the occurrence of extreme warm nights has shown nonsignificant trend with much variability. The number of melting days has increased by 4.3 d/decade at Great Wall Station. Although our analysis can explain part of the variability by changes in winds or to the coastal icescape, an additional but unknown factor is how atmosphere has responded to changes in ocean heat. Unraveling cause and effect, critical for predicting changes to the ocean-atmosphere-sea ice-ice sheet system, will require more in situ observations and improved atmosphere modeling.
The ozonesonde measurement program at Marambio was established in late 1980s, soon after the discovery of the Antarctic ozone hole. The Marambio Antarctic Station is located in an island at the North of the Antarctic Peninsula, surrounded by Weddell Sea (at 64º 14 ´S, 56º 38´W 198 m.a.s.l). The location is suitable for observing Antarctic stratospheric ozone depletion. In addition to the springtime measurements we have also performed regular soundings during other seasons. The soundings have been made by electrochemical concentration cell ozonesondes, using a potassium iodide solution. The sounding system in Marambio is DigiCORA III from Vaisala and the radiosondes are Vaisala RS92-SGP. The sondes measure ozone profiles from surface up to the altitude of 30-35 km. The effective altitude resolution is 100-150 meters, uncertainty of the stratospheric ozone measurements is about 5 %. Here we present results of the long term measurements. The time series have been recalculated using the knowledge from dual ozonesonde experiments. The ozonesonde observations are also compared to the available total ozone measurements by a ground based Dobson instrument at Marambio and by satellite borne instruments. Finally, the reprocessed data set is used to study trends and variability in measured ozone profiles. A statistical model is applied on the profile data, the model includes terms for effective equivalent stratospheric chlorine and meteorological variability.
A Numerical Simulation of Strong Wind Event at King Sejong Station, Antarctica

Hataek Kwon¹ (dixon409@gmail.com)
²Korea Polar Research Institute (KOPRI), Inchon, Korea, Republic of

In this study, a strong wind event that recorded a 10-min average wind speed of about 22 m/s at King Sejong (KSJ) station was simulated using the Polar WRF (Weather Research and Forecasting) model, which is an optimized version of WRF. Also, sensitivity experiments of the initialization time on a strong wind simulation is conducted. Through this, first we have evaluated the strong wind simulation performance of the Polar WRF by carrying out cross validation by comparing with local surface observations and reanalysis data. Second, we verified that the main cause of the strong wind event observed in KSJ Station by analyzing in detail observations and numerical simulation results. In addition, we investigate the climatological characteristics of the surface meteorological fields by analyzing the in situ meteorological observations for 22 years in KSJ station. It is revealed by in situ observations, numerical weather prediction, and reanalysis fields that the synoptic and mesoscale environment of the strong wind event was due to the passage of an intense low pressure system with the center pressure of 950hPa. Verifying model results from 3 km grid resolution simulation against observation showed that high skill in simulating wind speed and surface pressure, respectively. The surface variables of 10m wind, 2m temperature and surface pressure observed in KSJ station shows clear annual cycles in the analysis of long-term observation from 1994 to 2015.
Urban Heat Islands in the Arctic: The First Quasi-climatological Results

Mikhail Varentsov¹,³ (mvar91@gmail.com), Pavel Konstantinov¹
¹Lomonosov Moscow State University, Moscow, Russian Federation, ³A.M. Obukhov Institute of Atmospheric Physics, Russian Academy of Sciences, Moscow, Russian Federation

Urban heat island (UHI) effect is well studied for moderate and low latitudes and is considered in general as a negative phenomenon due to its influence on human thermal comfort and energy consumption rates. For the Arctic, on the contrary, its positive effects could be related with mitigation of severe frosts and fuel economy for house heating. However, until nowadays the knowledge about polar UHIs was extremely poor and limited by few studies for Alaskan towns, while the biggest Arctic cities located in Russian sector of Northern Eurasia were the terra incognita for urban climatology.

In this study we present the first quasi-climatological estimates of UHI intensity (urban-rural temperature difference) for Arctic winter conditions. They are based on UHIARC (Urban Heat Island Arctic Research Campaign) seasonal-scale experimental meteorological observations in five medium-sized Russian Arctic cities (Apatity, Vorkuta, Nadym, Novy Urengoy, Salekhard). Measurements in these cities have shown quite similar values of UHI intensity and patterns of its temporal variation. For all of them the average winter UHI intensity could be estimated as 1-1.5 °C, while extremes up to 6-7 °C are observed in frosty anticyclonic weather. However, the Arctic UHIs could be strongly amplified by local orography. For Apatity this results in extremely high (up to 12 °C) values of temperature differences between the city, located at the top of the hill, and WMO weather station at the lowland.
Gravity Wave Propagation through a Tidally Varying Wind above Davis, Antarctica

Peter Love¹, Michael Taylor², P.-Dominique Pautet², Damian Murphy³ (damian.murphy@aad.gov.au)
¹Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia, ²Utah State University, Logan, United States, ³Australian Antarctic Division, Kingston, Australia

Gravity waves in the night-time mesosphere/lower thermosphere can be observed using infrared imagers sensitive to emissions from the hydroxyl layer. Wave propagation directions from these imagers are often used to infer possible lower atmosphere source regions either approximately by direct projection or using ray tracing methods. However, it is generally assumed that the waves are propagating in an invariant wind environment. The height region around the hydroxyl layer (near 87 km) coincides with significant increases in tidal wind amplitudes and is thus subject to strong diurnal or semidiurnal wind fluctuations. These have the potential to change the propagation characteristics of gravity waves just prior to their observation. In this study, gravity-wave horizontal wavelengths, frequencies, orientations and phase propagation speeds are extracted from images of the hydroxyl layer above Davis station, and used to seed ray tracing analyses of 3-D wave propagation. MLS satellite observations provide daily average temperature profiles and instantaneous wind fields were obtained using the Davis MF Radar. The influence of the wind and its variations can thus be assessed by back tracing the observed gravity waves through a mean or tidally varying field. The results of this study will be presented. Their implications for these and other ANGWIN measurements will be discussed.
Atmospheric gravity waves play a fundamental role in transporting energy and momentum between atmospheric regions and drive circulations that affect key processes like the formation of the ozone hole and the cold summer polar mesosphere. Despite their importance, gravity-wave activity over Antarctica suffers from a lack of comprehensive observations. The ANtarctic Gravity Wave Instrument Network (ANGWIN) is a highly successful grassroots programme that was started in 2011. It seeks to use a network of observations to measure gravity waves continent wide and through all levels of the atmosphere, in order to fully understand their impact and to constrain modelling work. Although initially focused on the Antarctic, the group is now aiming to develop collaborations in both Polar Regions.

ANGWIN is an international network, supported by activities based in Australia, Brazil, Japan, Korea, the United Kingdom and the United States of America.

The objectives of the ANGWIN network include: Quantify the longitudinal variation in gravity-wave activity and determine causes; Characterise wave propagation and influence; Relate observed gravity waves to sources throughout the atmosphere; Study the interaction of gravity waves with global scale waves; Compare polar wave observations to model parameterizations; Determine the effects of gravity waves on polar stratospheric cloud formation.

This poster will describe the ANGWIN network, its objectives and some recent results.
Simultaneous Observations for Neutral Winds and Ion Drifts at JBS, Antarctica

Geonhwa Jee¹ (ghjee@kopri.re.kr), Changsup Lee¹, Nikolay Zabotin², Terry Bullett²

¹Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of, ²University of Colorado, Boulder, United States

It is well known that the thermospheric winds are mainly driven by the ionospheric plasma convection in the polar region. However, it was observed that there are significant differences between thermospheric winds and ion drifts in the polar cap region. The ionosphere and the thermosphere have been simultaneously observed by Vertical Incidence Pulsed Ionospheric Radar (VIPIR) and Fabry-Perot Interferometer (FPI), respectively, at Jang Bogo Station, Antarctica, which is located in the polar cap region. Using these unique observations, we investigate how much the thermospheric winds are affected by ion drifts in the southern polar cap region. In this study, we will present the response time, relative velocity and direction of thermospheric winds with respect to ion drifts as well as the physical characteristics in the polar cap region during the observation periods.
Climatological Behaviours of the Total Electron Content over Antarctica

Nicolas Bergeot1 (nicolas.bergeot@oma.be), Jean-Marie Chevalier1
1Royal Observatory of Belgium, Brussels, Belgium

The understanding of the impact of solar activity on polar regions upper atmosphere is not as strong as compare to low and mid-latitudes due to lack of experimental observations, especially over Antarctica. To characterize the differences in the ionosphere-plasmasphere total electron content (TEC) climatological patterns over Antarctica, we reprocessed the GNSS (GPS + GLONASS) data available since 1999 up to now for stations situated at latitudes below 55°. For that, we used the data from POLENET/IGS networks and stations installed around the Princess Elisabeth polar Base (Utsteinen, North-East Antarctica). The estimated TEC data set is then employed to constrain an empirical model to predict the TEC from F10.7P solar index in entrance using a least-square adjustment. To minimize the differences between the modelled and observed vTEC we considered: (1) an eight-order polynomial function with monthly coefficients between the TEC and F10.7P; (2) a discretization with respect to different zones over Antarctica region to highlight different climatological patterns; (3) different time definitions such as Solar Local Time, Magnetic Local Time, and UTC.

From the output of this model we discuss the different climatological behaviors identified in the ionosphere-plasmasphere TEC at these high latitudes. Finally, we show some examples of typical TEC disturbances observed during extreme solar events.

ULF Geomagnetic Activity and Atmosphere Dynamics in the Southern Polar Cap

Patrizia Francia¹ (patrizia.francia@aquila.infn.it), Mauro Regi¹, Marcello De Lauretis¹, Gianluca Redaelli¹

¹University of L’Aquila, Department of Physical and Chemical Sciences, L’Aquila, Italy

We investigated the possible coupling between geomagnetic activity and the low atmosphere dynamics in the polar cap. To this purpose, we compared the ULF geomagnetic activity, computed from geomagnetic field measurements at Terra Nova Bay (Antarctica, corrected geomagnetic latitude \( \lambda \sim 80^\circ S \)), with several atmospheric parameters (temperature, zonal wind, specific humidity and cloud cover) obtained from re-analysis dataset. We used data collected in the years 2003-2007. We found a statistically significant correspondence of temperature and zonal wind fluctuations in the stratosphere and troposphere (greatly reduced at the tropopause height) with geomagnetic ULF power fluctuations at the \( \sim 27 \) day periodicity, related to the Sun’s rotation period. We observed a similar, clear relationship between the atmospheric parameters and the polar cap potential difference.

We also found that the atmospheric parameters significantly change following the increase of geomagnetic activity within 1-2 days. These changes are evident in particular when the interplanetary magnetic field is oriented southward with the azimuthal component duskward. We suggest that both the precipitation of electrons induced by ULF activity, and the intensification of the polar cap potential difference, modulating the microphysical processes in the clouds, can affect the atmosphere conditions.
The scientific research community dealing with polar regions is increasing its interest in ICT solutions allowing to overcome the strong environmental limitations of these areas in terms of power, data exchange and computing infrastructures.

The “Upper atmosphere observations and Space Weather” project, developed under the SCAR GRAPE (GNSS Research and Application for Polar Environment) expert group, aims to extend the GNSS measurements to new sites for the assessment of the delay and corruption induced by the ionosphere on satellite signals in polar regions.

On-field data are acquired by means of an energetically autonomous prototype with pre-processing capabilities (called GreenLab), which has been successfully installed in Antarctica, close to the Italian base “Mario Zucchelli”, which is able to send data to the base station by means of an innovative smart antenna. Data can then be further processed exploiting the cloud computing federated infrastructure already deployed in DemoGRAPE project and leveraging the Linux Containers technology (i.e. Docker) to run applications where data are stored, thus avoiding to move large amounts of data.

These two main blocks, the GreenLab and the federated cloud infrastructure, constitute a complete ICT framework for data acquisition and management, which could be a reference architecture for several scientific topics dealing with polar regions.
Global Navigation Satellite Systems (GNSS), including the Global Positioning System (GPS) support a wide range of civilian and military applications, and have become indispensable in precise positioning and time keeping. As our society moves towards a state characterized by an increasing dependence on space technologies, and since our environment affects our daily life like never before, understanding the Solar-Terrestrial interaction, and its impact on the geo-space environment, has become critical to the well being of our modern technology-dependent society.

Scintillation, random rapid fluctuations of the trans-ionosphere radio signal, is caused by the refractive and diffractive properties of the medium, and the structures within it. Understanding the generation and dynamics of these irregularities will in turn help model/forecast this physical phenomenon, and mitigate it if possible. Over the last few years we have been focussing on the scintillation indices to develop a better understanding of the underlying physics of the scintillation producing irregularities, and attempt to develop predictive models. However, we believe that relying on such indices may very well be the wrong approach. We will show with evidence, using very high sampling rates (50 & 100 Hz), that the conventional approach relying on the conventional indices led us down the wrong path. We will propose a new approach to study the micro-physics of scintillation producing ionospheric structures.
Impact of Solid Earth Tide Model Error on Tropospheric Zenith Delay Estimates

Shengkai Zhang¹ (zskai@whu.edu.cn), Jintao Lei¹, Fei Li¹, Chao Ma¹, Weifeng Hao¹, Dongchen E¹, Qingchuan Zhang¹
¹Wuhan University, Wuhan, China

The elastic response of the crust due to the external Tide Generating Potential (TGP) is called the solid Earth tide, which can result in periodic 3-dimension displacements of a point on Earth’s surface. To demonstrate how ‘error’ in the modelling of the solid Earth tide affects the estimates of tropospheric zenith total delay (ZTD) and how it propagates into long-period signal in the daily GPS time series, we analyze GPS observations collected between 2009 and 2013 for 13 sites in the coastal regions around Antarctica using GAMIT/GLOBK 10.6 software. Satellite orbital parameters, 2-hour tropospheric zenith delays, atmospheric gradients and Earth orientation parameters are estimated along with site coordinates. Two solutions are generated with or without the inclusion of K₁ correction in the frequency domain of IERS2003 model, while all other processing strategies are held constant. We show the differenced time series of both the ZTD estimates and site coordinates, along with their corresponding admittances (ratio of amplitude of output signal to amplitude of input signal). In such a way, we conclude that ZTD differenced time series, with amplitude at the 2 mm level, have inverse correlation with the input K₁ error, and the corresponding admittances range from 6% to 14%; Propagated spurious annual signals are evident in the vertical component of coordinate differenced time series, with amplitudes at the mm level and admittances of around 2% to 11%.
Fast Dynamic of Polar Ionosphere from GNSS SDR High Sampling Rate Measurements

Claudio Cesaroni\(^1\) (claudio.cesaroni@ingv.it), Lucilla Alfonsi\(^1\), Luca Spogli\(^2\), Nicola Linty\(^3\), Fabio Dovis\(^3\), Antonio Ciccone\(^4\), Mirko Piersanti\(^4\), Pierre Cilliers\(^5\)

\(^1\)INGV, Environment, Rome, Italy, \(^2\)INGV, Rome, Italy, \(^3\)Politecnico di Torino, Torino, Italy, \(^4\)Università di L’Aquila, L’Aquila, Italy, \(^5\)SANSA, Cape Town, South Africa

Software Defined Radio (SDR) receivers are able to process Intermediate Frequency (IF) signals acquired by a front-end in order to generate Global Navigation Satellite Systems (GNSS) In-phase and Quadrature amplitude values at very high sampling rate (up to 1000 Hz). The analysis of GNSS signals at frequencies higher than the usual 50 Hz, provided by the traditional ionospheric scintillation receiver monitor, gives the possibility to describe the dynamics of the scintillation driven irregularities spanning a wider time scales range. In this work, a new spectral decomposition analysis technique named Adaptive Local Iterative Filter (ALIF) is applied to the data provided by a GNSS SDR developed by Politecnico di Torino in order to highlight the contributions to the scintillations characterized by frequencies higher than 50 Hz. The objective is to relate such contributions to the very fast dynamics processes typical of the ionosphere at polar regions that are not caught using the very well-known scintillation indices \(S_4\) and \(s_f\) that is calculated on 50 Hz samples. Results on scintillation case events using data from both SDR and Septentrio PolaRxS receivers installed in the South African Antarctica station SANAE IV (71° 40' S, 2° 50' W) in the framework of the DemoGRAPE project are here presented.
Contributions to the knowledge of the Earth's magnetism from polar regions is extremely important to understand the magnetospheric dynamics because local field lines reach extreme magnetospheric regions where the interactions with the solar wind occurs. The Earth's magnetic field shows temporal variations which go from seconds to hundreds of thousands of years. We study low frequency fluctuations (approximately in the Pc5 range, ~1-7 mHz).

INGV has a consolidated experience in Antarctic research activities and in management of permanent geomagnetic observatories as Mario Zucchelli (MZS, at Terra Nova Bay) and Concordia (DMC, at DomeC) stations, as well as temporary installations as Talos Dome (TLD), installed during 2007-2008 Antarctic campaign and working for a few months. The availability of simultaneous measurements from MZS, TLD and SBA (Scott Base), allows to make an interesting comparison in that the three stations are located approximately at the same geomagnetic latitude (~80°S), with approximately 2 hours total displacement in magnetic local time. This location is particularly useful to study the signal propagation in the azimuthal direction. We review the results obtained so far from the analysis of diurnal variation, coherence, power and propagation direction of Pc5 pulsations observed along the 80°S geomagnetic parallel, underlying the importance of such observational point, in anticipation of the future installation of a new geomagnetic station at TLD.
Studies of Antarctic Atmospheric Dynamics by a Large Aperture Atmospheric Radar

Kaoru Sato¹, Masaki Tsutsumi², Toru Sato¹, Takuji Nakamura² (nakamura.takuji@nipr.ac.jp), Akinori Saito³, Yoshihiro Tomikawa², Koji Nishimura², Masashi Kohma¹, Taishi Hashimoto³
¹University of Tokyo, Tokyo, Japan, ²National Institute of Polar Research, Tachikawa, Japan, ³Kyoto University, Kyoro, Japan

A large-aperture atmospheric radar, PANSY (Program of the ANtarctic SYowa Mesosphere, Stratosphere, and Troposphere/Incoherent Scatter [MST/IS] Radar) radar, was constructed at Syowa station (69S, 39E) during the 2010-11 austral summer (Sato et al., 2014). Valuable atmospheric data in Antarctic troposphere, stratosphere and mesosphere has been being accumulated based on continuous operation using a quarter system since early 2012 and the full system since late September 2015. Such continuous observation data set using a full MST/IS radar system is the first of its kind in the world. It will enable us to capture various temporal- and spatial-scale phenomena in the Antarctic atmosphere with high temporal and vertical resolutions throughout the year and to contribute to improving global climate models for better understanding of future climate change.

The Japanese Antarctic Research Expedition (JARE) is currently in a six-year long research project, Phase IX (2016-2021). The main scientific theme, “Investigation of changes in the Earth system from Antarctica”, has been launched in Phase IX. The PANSY radar is the core facility of one of the three projects in the main theme, “The global atmosphere system explored by precise observations of the Antarctic atmosphere”, which combines various radio and optical instruments for comprehensive understanding of the whole atmosphere. In this paper, recent studies using the PANSY radar are reviewed.
Quantitative evaluation of energy transfer in and around the auroral oval under the influence Solar plasma ejection and the electromagnetic status of the interplanetary medium were carried out on the ground based data collected at the stations in Dronning Maud Land, Enderby Land and Princess Elizabeth Land of Antarctica. Geomagnetic storms with negative and positive vertical component of interplanetary magnetic field were chosen for evaluation. This evaluation of the release and transfer of energy due to drifting or injection of energetic particles during various geomagnetic conditions may give us ability to identify critical inputs of the dynamics of the entry of energetic charged particles into the polar upper atmosphere. Moreover geomagnetic quiet time enhancement of total electron content shows the indirect energy transfer in polar ionosphere from magnetotail along the field lines. The drifted energetic particles and subsequent precipitation of energetic particles in the sub-auroral, auroral and polar region gives the estimated time delay, span and duration of ionospheric irregularities. Thus dynamics of energy transfer and drift of energetic charged particles in polar upper atmosphere that involved in linking the entire system, under the influence of interplanetary magnetic field were analysed which begins at the Sun and ends on the Earth.
Observations of the ionospheric convection during a storm main phase on 9th September 2011 were examined. Measurements were obtained by three SuperDARN radars (ZHO, SYE and MCM) located in the southern hemisphere, the conjunction of these 3 radars plays an important role in revealing the dynamic process in magnetosphere-ionosphere coupling system. During the storm period, MCM radar scanning polar cap ionosphere monitored sequential strong antisunward large-scale plasma irregularities, which clearly presents the polar cap patches moving across the pole to the nightside and eventually into the the nightside auroral oval in quasi-periodical variation. While the ZHO radar recorded intense ionospheric backscatter echo power and moderate Doppler negative velocity in the poleward boundary of the nightside auroral oval, and simultaneous observation by the optical auroral imager did not get aurora data. In the duskside sector, Doppler velocity monitored by the SYE showed irregular plasma structures towards or away from the radar site. Furthermore, ionospheric digisonde at Zhongshan station observed strong spread F during the storm main phase. For this kind of event, coordinated observations suggest that the ionospheric convection dominates the periodical plasma transportation during typical disturbed geomagnetic environment.
Collaboration at the NOAA Atmospheric Baseline Observatories

Brian Vasel\(^1\) (brian.vasel@noaa.gov)
\(^1\)NOAA Earth System Research Laboratory, Global Monitoring Division, Boulder, United States

The NOAA Global Monitoring Division (GMD), based in Boulder, CO, has operated four long-term atmospheric baseline observatories for over 40-years. These sites are located at Barrow, AK; Mauna Loa, Hawaii; Tula, American Samoa; and South Pole, Antarctica. In addition, GMD previously operated observatories at Trinidad Head, CA and at Summit, Greenland; however, both sites were downgraded from full baseline observatories in 2017 following a GMD reprioritization of global observing networks. These long-term sites with NOAA facilities, technical staff, baseline atmospheric measurements, and meteorology, are also available to support cooperative research proposals from the global community. The one exception being South Pole Station, as the site is operated by the National Science Foundation and they approve science projects at the station. This poster will detail measurements at the four sites, focusing on Barrow and South Pole, and encourage collaboration. In addition, it will discuss the vision for the sites to become more “green” with added renewable technologies and backup power and safety measures to ensure continuity of operations. Often emergency plans from remote sites can be challenging and NOAA has various plans in place for each location. Finally, other NOAA/GMD measurements from across the Artic and Antarctic will also be highlighted, including sampling sites in: Canada, Greenland, Norway, Russia, Finland, and the Antarctic Peninsula.
Polar Lows and Climate Change

Helene Bresson¹ (h.m.e.bresson@pgr.reading.ac.uk), Kevin Hodges¹, Len Shaffrey¹, Giuseppe Zappa¹
¹University of Reading, Department of Meteorology, Reading, United Kingdom

Polar lows (PLs) are intense mesoscale cyclones (diameter of 200-600km) that form at high latitudes during winter. Their wind speeds (above 15m/s) can substantially impact on and offshore activities. PLs may have an impact on deep-water formation, and thus affect the Atlantic Meridional Overturning Circulation (AMOC), which suggests that PLs are important for the climate system. However, there are still large uncertainties in their frequency, spatial distribution and response to climate change. Previous studies showed that PLs may experience a decrease in the future over the North Atlantic Ocean, due to a future increase in static stability caused by a faster increase in sea surface temperatures compared to the increase in mid-tropospheric temperatures. This decrease would imply a reduction of PLs impact on deep ocean convection with the concomitant weakening of the AMOC. To investigate PLs possible future changes, the UPSCALE dataset is used: a series of ensemble simulations of the HadGEM3 global atmosphere-only model at resolutions of 130, 60 and 25km for present climate conditions and a potential future climate scenario, the IPCC RCP 8.5 scenario. The aim is to explore how PLs might respond to climate change and how this response may be affected by the model resolution. The 25km results will be compared to the PL climatology previously analyzed from the coupled climate model HadGEM3-CG2. Results will be presented on PLs representation for the current and future climates.
The Arctic is changing rapidly carrying the potential to influence weather and climate in mid-latitudes. It is therefore crucial to predict these changes and their impacts. Recognizing this priority, a European consortium of scientists set out to advance our capability to predict the weather and climate in the Arctic and beyond in the framework of the EU-funded project APPLICATE. The project aims to improve the representation of key processes in coupled atmosphere-sea ice-ocean models, in order to deliver enhanced numerical weather forecast, seasonal to interannual climate predictions and centennial climate projections. The linkages between the Arctic and mid-latitudes is explored through a coordinated multi-model approach using coupled atmosphere-ocean models. APPLICATE will also provide guidance for the design of the future Arctic observing system to improve our capacity to reanalyse the climate system and enhance models' predicting skills. The APPLICATE Consortium is also engaging in clustering activities to exploit synergies with other programs. On the European level we participate in the EU Arctic Cluster, but we also have strong links with North American partners (e.g., US CLIVAR), and several other international projects (e.g., the Polar Prediction Project, MOSAiC). In this presentation, we will give an overview of APPLICATE activities as part of our effort to understand changes in the Arctic and their far-reaching impacts for both environment and communities.
Lagrangian Meteorological Simulations to Study Polar Aerobiology

Sergi Gonzalez¹ (sgonzalez@aemet.es), Francisco Vasallo², Ana Justel³, Julio Rodriguez³, Pablo Sanz⁴, Alberto Luna⁵, Eugenio Rico⁶, David Velazquez⁶, Pablo Almela⁶, Samuel Cires⁶, Marcela Svarc⁷, Lucas Fernández⁷, David Pearce⁸, Antonio Quesada⁶

¹Agencia Estatal de Meteorología, Grupo Antártico, Barcelona, Spain, ²Agencia Estatal de Meteorología, Grupo Antártico, Rota, Spain, ³Universidad Autónoma de Madrid, Departamento de Matemáticas, Madrid, Spain, ⁴Universidad Autónoma de Madrid, Centro de Computación Científica, Madrid, Spain, ⁵Universidad Autónoma de Madrid, Departamento de Ecología, Madrid, Spain, ⁶Universidad Autónoma de Madrid, Departamento de Biología, Madrid, Spain, ⁷Universidad de San Andres, Departamento de Matemáticas, Buenos Aires, Argentina, ⁸Northumbria University, Department of Applied Sciences, Newcastle-upon-Tyne, United Kingdom

Aerial dispersal in polar regions is a booming issue because it provides new insights on biogeography and may allow forecasting alterations in biodiversity in a global change scenario. Moreover, it is a major challenge due to the difficulties of gathering representative samples of airborne propagules and tracking their paths to estimate where they come from. As a result, this issue is nowadays poorly understood. To improve our knowledge on this topic a multidisciplinary project is being conducted to fill this gap at three different scales: local, regional and global, in both polar regions.

There are a variety of strategies to track the airborne propagules into the atmosphere, each one with specific advantages and disadvantages. In this communication we focus on the simulation of the trajectory of a single particle into the atmosphere on the assumption that propagules transit altogether. Thousands of simulations have been conducted using HYSPLIT model with different configurations and input data for each specific requirement.

We present some of these experiments: backward trajectories at sampling sites in Byers peninsula, trajectories of the air parcels reaching the ship during the Antarctic Circumpolar Expedition and the WindSled during the Ice River Greenland Expedition, and a lagrangian climatology of trajectories over the Southern Ocean. Trajectories simulated are widely dispersed with some preferential directions that will be analyzed using clustering techniques.
The total extent of Arctic sea ice over the last half century has dramatically declined, at a rate of nearly 5% a decade, with yearly Arctic sea ice minimums in each of the last five years being at least two million square kilometres below the mid 20th century average. Focusing on the total sea extent over the Arctic polar cap, several recent studies have shown that only approximately half of the recent loss is anthropogenically forced, suggesting that internal (i.e. unforced) variability may be responsible for the remaining half. Analysing 40 historical runs of the CESM Large Ensemble over the period 1950-2015, we here ask whether the relative contributions of anthropogenic forcing and natural variability to September sea ice loss over that period have a robust regional structure. We find a large spread in regional patterns of September sea ice loss across the Large Ensemble: however, these patterns are well captured by the leading EOFs of internal variability, highlighting two key regions, which have experienced the largest September trends in recent decades: the East Siberian Sea and the Barents Sea. We will discuss our findings detailing for which regions the forced response is dominant and for which regions internal variability is more important. Implications for future trends and for potential impacts on the mid-latitudes will be discussed.
Estimating Changes in the Collins Glacier, King George Island, Antarctica

Carina Petsch¹ (carinapetsch@gmail.com), Kátia Kellem da Rosa¹, Rafaela Mattos Costa¹, Matthias Holger Braun², Jefferson Cardia Simões¹
¹Universidade Federal do Rio Grande do Sul / INCT da Criosfera, Porto Alegre, Brazil, ²Friedrich Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany

This work proposes future scenarios for the extent of the Collins Glacier (King George Island, Antarctica) and for hydrogeomorphological changes in its periglacial environment. We used a method based on ellipsoidal height changes to estimate modifications in this ice mass up to 2067. We assume insignificant ice flow, refreezing and basal melting, and the same climatic conditions of the period 1998-2009. The ice mass will continue to retreat in all sectors, if the current regional warming trend is maintained, and the periglacial ice-free zone will increase by 4.5 km². The current area of the glacier is 15 km² and according to this scenario can reach 10.5 km². The local hydrological system will be strongly modify, mainly in the Maxwell Bay area, and a proglacial lake formed in the last 30 years may disappear by then, influencing the patterns of sedimentary deposition and local erosion. The new ice-free area may develop a new meltwater stream system at the ice margin, forming lakes and wetlands, increasing chemical weathering, creating soils favouring the fixation and expansion of vegetation. In short, the expected changes may cause a rapid change from proglacial to periglacial environment.
Social, economic and environmental benefits of forecasts of weather and climate are obvious. Among others, risks in hydroenergy production are usually connected to extremes, which can be estimated from projected exceedance probability curves (EPCs) of annual runoff. The exceedance probability indicates the likelihood that a particular annual runoff value will be exceeded. In our study the EPCs of annual runoff were applied to evaluate the potential hydropower production in Finland. The climate related changes in hydroelectric production of the existent plants were estimated based on the the EPCs of annual runoff at catchment and regional scales.
Recording, Predicting and Responding to Rapid Environmental Change in Siberia

Henry Burgess¹ (henry.burgess@bas.ac.uk), Terry Callaghan²,³, Aleksandr Sokolov⁴, Alexey Titovsky⁵, Sergey Kirpotin⁶

¹NERC/ British Antarctic Survey, NERC Arctic Office, Cambridge, United Kingdom, ²University of Sheffield, Sheffield, United Kingdom, ³Tomsk State University, Tomsk, Russian Federation, ⁴Institute of Plant and Animal Ecology, Ural Branch, Russian Academy of Sciences, Arctic Research Station, Labytnangi, Russian Federation, ⁵Government of Yamal Nenets Autonomous District, Director, Department of Science and Innovations, Salekhard, Russian Federation, ⁶Tomsk State University, Head of the BioClimland Centre of Excellence, Tomsk, Russian Federation

The pace and depth of environmental change across the largest terrestrial region of the Arctic - Siberia - is dramatic. The impact of vegetation alteration across the taiga and tundra zones; changes in biological productivity and hydrology; and the resulting impact on fauna, especially those relied upon by Indigenous and local people, is combining to create environmental and human impacts with local, regional and global effect. More than ever there is a need for researchers, authorities and Indigenous and local people to work together to record, predict and adapt to environmental change. Over the last two years the Siberian Environmental Change Network of Tomsk State University, The Government of the Yamal-Nenets Autonomous District, the UK Science and Innovation Network, and the EU INTERACT trans-national access programme together with other international partners and senior Indigenous peoples’ representatives have brought together interested stakeholders to put in place effective monitoring which addresses the needs and skills of local people and researchers, most recently in the context of winter weather and climate extremes. The Abstract will present the findings from the last two practical workshops; suggest a range of promising approaches; identify emerging good practice; and set out the next steps. Attendees will see how international cooperation is combining with local knowledge to create meaningful practical action and important research.
Glaciological Changes on the Northern Antarctic Peninsula

Thorsten Seehaus¹, Sebastian Marinsek², Alison Cook³, Jan Melchior van Wessem⁴, Matthias Braun¹
(matthias.h.braun@fau.de)
¹Friedrich-Alexander-Universität Erlangen-Nürnberg, Geography, Erlangen, Germany, ²Instituto Antártico Argentino, Buenos Aires, Argentina, ³Durham University, Geography, Durham, United Kingdom, ⁴Utrecht University, IMAU, Utrecht, Netherlands

During the last decades the climatic conditions along the Antarctic Peninsula have undergone significant changes. Consequently, the glacial systems along the Antarctic Peninsula reacted with widespread retreat, surface lowering as well as variations in flow speeds. Moreover, numerous ice shelves along the Antarctic Peninsula retreated, started to break-up or disintegrated completely. The aim of this work is to study the reaction of glaciers at the northern Antarctic Peninsula to the changing climatic conditions and the readjustments of tributary glaciers to ice shelf disintegration, as well as to better quantify the ice mass loss and its temporal changes.

We analysed time series of various satellite sensors (ERS-1/2, ENVISAT, RADARSAT-1, ALOS, TerraSAR-X/TanDEM-X, ASTER, Landsat) to detect changes in ice dynamics of glacier along the northern Antarctic Peninsula (< 65°). Intensity feature tracking techniques were applied on data stacks from different SAR satellites over the last 20 years to infer temporal trends in glacier surface velocities. In combination with ice thickness reconstructions and modeled climatic mass balance fields regional imbalance were calculated. The detailed multi-mission time series analysis of glacier changes supports the interpretation of the ongoing processes in this region and allows multi temporal imbalance estimates.

First Detailed Quantification of Glacier Elevation Changes on South Georgia

David Farías¹ (david.farias@fau.de), Christian Sommer¹, Thorsten Seehaus¹, Philipp Malz¹, Gino Casassa², Matthias H. Braun¹
¹Friedrich Alexander-Universität Erlangen-Nürnberg, Institute of Geography and Geosciences, Erlangen, Germany, ²Universidad de Magallanes, Punta Arenas, Chile

Glaciers are frequently regarded as indicators of climate change, several studies indicate that most of the glaciers worldwide are retreating. In the Southern Hemisphere glacier mass balance information is scarce. Therefore, this gap of information generates an uncertainty about the current status of glaciers. South Georgia is the largest subantarctic islands, lying south of the Antarctic polar front. About 56% of the surface is glacierized. Previous studies carried out on South Georgia have shown heterogeneous pattern of glacial advance and retreat over time. However, mass balance data is lacking for this region. Our focus in this study is to derive glacier surface elevation changes using SRTM-C band and TanDEM-X bistatic SAR-data for the period 2000-2012/13. This information is used to obtain the first detailed quantification and interpretation of glacier elevation and mass change on South Georgia.
In this poster we present glacier velocities (by remote sensing and field data) as well as ice thickness measurements (by an airborne 25 MHz ground penetrating radar) on Gourdon Glacier (James Ross Island, Antarctica).

James Ross Island is located east from the northern Antarctic Peninsula in a region which has undergone considerable changes in the last decades with the retreat or disintegration of several ice shelves. The glaciers of James Ross Island have shown predominantly retreat over the last decades while some glaciers showed also advance. In this context, we investigate the glacier dynamics and mass changes on James Ross Island using different approaches: geodetic glacier mass balances and the flux-gate approach (input-output method).

A comprehensive set of field observation (surface mass balance, time lapse camera, automatic weather stations, permanent GPS recorders) is run over several years. Additionally, a detailed remote sensing data analysis of the temporal evolution of velocities is carried out.

In order to improve the ice flux estimates we started a comprehensive airborne ground penetrating radar (GPR) campaign on Gourdon Glacier in February 2017. Ice thickness and elevation data were collected on more than 50 km of profiles with ice thicknesses of up to 350 m. Further measurements are planned for February 2018 and will include repetitions of profiles flown by previous ice thickness surveys in order to evaluate potential changes in the accumulation area.
Since the very first global atmospheric reanalysis projects in the early 1990s, handling the ever-changing observing system has proved an important and recurring challenge to producing temporally consistent reanalysis datasets. The problem has been exacerbated over Antarctica and the Southern Ocean by the data scarcity characteristic of these regions. Important changes in the type and/or availability of observations (most notably the massive input of satellite data in the late 1970s) have produced major artifacts in the reanalysis time series in high southern latitudes. Reanalysis projects going back to the early 1900s have sought to achieve greater temporal homogeneity in the observing system by assimilating only a limited set of conventional observations. In these instances, however, the prescription of unrealistic sea-ice conditions prior to 1979 and the rapidly decreasing density of surface observations poleward of 60°S prior to the 1980s have again resulted in significant inhomogeneities and spurious trends in the time series. Overall, these issues have severely reduced the usefulness of reanalysis products for Antarctic and Southern Ocean studies prior to 1979 and limited our understanding of long-term climate changes in these remote regions. Here, we reassess the skills of global reanalyses in high southern latitudes, take stock of recent improvements, and offer some recommendations for addressing some recurring issues and ultimately helping bridge the 1979 barrier.
Recent studies have concluded that overall warming trends in Western Antarctica since the 1950s, as well as the cooling in more recent years, are within the bounds of natural variability. We want to provide a more comprehensive and widespread picture of how surface temperatures are changing throughout recent decades across much of the Southern Hemisphere mid- and high-latitudes. The study includes station observations from the entire Antarctic continent, mid-latitude island stations, South America, South Africa, southern Australia, and New Zealand. Using seasonal and yearly temperature anomalies, our goal is to determine the trends and their statistical significance and then investigate the drivers behind them, using time periods of various lengths to determine the longevity of said drivers. Teleconnections being considered include the Southern Annular Mode and the El Niño Southern Oscillation, due to their known influence on the Southern Hemisphere climate.
It is well-known that the isotopic composition of the ice cores is a proxy for the temperature change at the drilling site. However, several studies showed that there are many other factors influencing the ice cores data. One of these factors is the isotopic composition of water and water vapour at the site of the airmass formation. In order to separate these factors we carried out continuous measurements of the isotopic composition of water vapor over the ocean surface during the Antarctic Circumnavigation Expedition (ACE) 2016/17. For the measurements on board of the ship, two water vapor isotope analyzers (Picarro L2120-i and Picarro L2130-i) were used equipped with two types of calibration devices. This helped to obtain robust and accurate results. As a by-product result we present comparative characteristics of different types of equipment. This data is also combined with the previously published results (see review in Galewsky et al., 2016). Here we present the results of these data analysis combined with the meteorological observations and air mass trajectories calculations.

The research was possible due to funding from EPFL, Swiss Polar Institute and Ferring Pharmaceuticals. We thank Picarro Inc. for providing us with the Picarro L2130-i and Standard Delivery Module.
Lake Bonney High Resolution 3D Structure using an Autonomous Underwater Vehicle

Robert Spigel¹, Peter Doran² (pdoran@lsu.edu), John Priscu³, Maciej Obryk², William Stone⁴
¹National Institute of Water and Atmospheric Research (NIWA), Christchurch, New Zealand, ²Louisiana State University, Baton Rouge, United States, ³Montana State University, Bozeman, United States, ⁴Stone Aerospace, Austin, United States

We used an Environmentally Non-Disturbing Under-ice Robotic ANtarctic Explorer (ENDURANCE) to make measurements of conductivity and temperature in Lake Bonney, in Taylor Valley. The lake is divided into two lobes - East Lobe Bonney (ELB) and West Lobe Bonney (WLB), each with unique temperature and salinity profiles. Most of our data were collected in November 2009 from WLB to examine the influence of the adjacent Taylor Glacier on the structure of the water column. Temperatures adjacent to the glacier face between 20-22 m were 3°C colder than in the rest of WLB, due to latent heat transfer associated with melting of the submerged glacier face and inflow of cold brines that originate beneath the glacier. Melting of the glacier face into the salinity gradient below the chemocline generates a series of nearly horizontal intrusions into WLB that were previously documented in profiles measured with 3 cm vertical resolution in 1990-91. WLB and ELB are connected by a narrow channel through which water can be exchanged over a shallow sill that controls the position of the chemocline in WLB. A complex exchange flow appears to exist through the narrows, driven by horizontal density gradients and melting at the glacier face. Superimposed on the exchange is a net west-to-east flow generated by the higher volume of meltwater inflows to WLB. Both of these processes can be expected to be enhanced in the future as more meltwater is produced.
Seasonal Dynamics in the Extreme Arctic: Ward Hunt Lake, Canada

Paschale N. Bégin¹ ² (paschale-noel.begin.1@ulaval.ca), Yukiko Tanabe³, Warwick F. Vincent¹ ²
¹Centre d’Études Nordiques (CEN), Quebec City, Canada, ²Université Laval, Biology, Quebec City, Canada,
³National Institute of Polar Research, Tokyo, Japan

Lake ecosystems occur along the far northern coast of the Canadian High Arctic, but almost nothing is known about their seasonal dynamics. Ward Hunt Lake is Canada’s northernmost lake, located on Ward Hunt Island (lat. 83 °05’N, long. 74 °10’W), off Ellesmere Island, Nunavut. The lake is oligotrophic, and given its extreme northerly location, is a potentially sensitive indicator of global climate change. Our aims were to determine the structure and functioning of this remote aquatic ecosystem, and to better understand the nature and implications of ongoing change. A mooring installed at the deepest point of the lake (10m) recorded temperature, oxygen, chlorophyll fluorescence and underwater irradiance. This information was coupled with images from an automated camera system to track the seasonal variations in ice cover from July 2016 to July 2017. The annual chlorophyll \(a\) maximum coincided with open water conditions in September when there was increased light availability and water column mixing. Contrary to expectation, oxygen concentrations dropped rapidly after ice-up, and anoxia was recorded in the bottom waters in December. The oxygen and temperature records also revealed an internal wave pattern during the period of ice-cover. These high-resolution measurements indicated large-amplitude temporal variations in biogeochemical processes despite the low-nutrient status of this High Arctic ecosystem.
Increased meltwater is a feature of nearly all models of Antarctica’s future, and underpins analysis of environmental and biological domains. We characterised surficial occurrences of water, or ice re-frozen from meltwater, throughout the Ross Sea Region (RSR) using two important new datasets: (1) a GeoMAP GIS defining exposed bedrock and glacial cover sequences, including 869 seasonal meltwater accumulations; (2) an Antarctic-wide datacube of daily land surface temperatures (LST) from 2003-2015, detected by MODIS instruments at 1 km resolution.

Local temperature statistics were assigned to water occurrences to derive empirical thresholds for melting. Water is only observed where average annual LST is > -35°C, but with significant regional differences in conditions of meltwater occurrence. Growing degree days (GDD) above a temperature threshold, albedo and % rock are key factors strongly correlated with meltwater. Probability that water is present or absent is modelled across the RSR using a variety of environmental covariates weighted by correlation strength in a training dataset. Environmental conditions were then adjusted and models re-run to forecast future conditions under a warmer climate (LST +2°C, GDD +30%). As well as defining where surficial water can be expected in future, the study highlights the importance of regional-scale datasets to characterise cryosphere-lithosphere interactions, and role geology may play on the melting of Antarctica.
The most luxuriant vegetation is found in freshwater lakebeds as thick phytobenthic mats in East Antarctica. Photosynthetic activities of phytobenthic mats are measured well in many lakes on Antarctica during summer, whereas little is known about it for a period from autumn to spring. We collected phytobenthic mat samples from Lake West Ongul (69°01′S, 39°33′E) in Sōya Coast, East Antactica once or twice per month throughout the year except June, and from nine freshwater lakes (69°14′S-69°30′S, 39°33′E-39°47′E) in Sōya Coast, East Antactica in both summer and early-spring, of which two lakes were a target of continuous monitoring of PAR (photosynthetically active radiation) and temperatures underwater by installing mooring systems. Then, we measured photosynthetic characteristics using a chlorophyll fluorescence instrument (Phyto-PAM, Walz) as soon as possible after arrival in the base, and rest of the samples were frozen in the dark at -20°C for analyzing the pigments composition as an index of light-utilization and photo-community composition. The photosynthetic activities changed seasonally and are quite different between spring and summer, in addition to this, the community compositions contributing to photosynthesis of the benthic mats changed depending on the season.
Glacial meltwater streams are often characterized by diel fluctuations or cessation of flow, especially in regions where the energy balance of the source glacier is alternately positive and negative throughout a day. These characteristics drive a highly dynamic physical environment, in which stream sediment undergoes periodic inundation and drying as channel flow varies. The role of long-term (i.e., seasonal to inter-annual) sediment drying-rewetting on biogeochemical cycles has been studied extensively in temperate systems characterized by wet and dry seasons. However, these relationships have remained understudied in systems characterized by short-term (i.e., sub-daily to weekly) flow intermittency, as often occurs in glaciated environments. To advance understanding of how short-term variations in physical conditions alter nutrient cycling (specifically, inorganic nitrogen availability), we present preliminary findings on the spatiotemporal variability of pore-water chemistry during diel pulsing in an ephemeral glacial meltwater stream (McMurdo Dry Valleys, Antarctica). We present these results in the context of a laboratory rewetting experiment, high- and low-frequency stream nitrate concentration data from the MDV Long-Term Ecological Research Project, and results from prior studies in Arctic and Antarctic streams. Our results will inform understanding of sediment-channel interactions that control nutrient transport and retention in polar and alpine ephemeral streams.
Within the North American Arctic, the effects of climate change have led to more pronounced temperature change in the west, with substantially more warming in Alaska and the Northwest Territories than along the eastern coast of Nunavut. Though records of increased temperatures and increased occurrence of permafrost degradation have been noted, widespread and long-term assessment of freshwater biotic responses to the changing climate have been lacking in North America. Assessment of trends across the North American Arctic presents the opportunity to investigate biotic responses to different rates of warming (west to east) with relatively little interaction from anthropogenic effects, compared to more developed regions of the circumpolar Arctic. The biodiversity of fish, benthic macroinvertebrates, and algae in lakes and rivers was evaluated along latitudinal transects from west to east, and biotic patterns were related to trends in abiotic descriptors to characterize environmental drivers of change in these communities. Through the analysis of spatially- and temporally-distributed data for the North American Arctic, this study aims to assess the current status and historical trends in freshwater biodiversity in response to physical and chemical habitat shifts related to climate change.
Modeling Vulnerability to Thermokarst Disturbance in Boreal Alaska

Helene Genet¹ (hgenet@alaska.edu), Mark Lara², Anthony David McGuire³, William Robert Bolton⁴, Eugénie Euskirchen¹, Vladimir Romanovsky⁴
¹University of Alaska - Fairbanks, Institute of Arctic Biology, Fairbanks, United States, ²University of Illinois, Urbana-Champaign, Department of Plant Biology, Urbana, United States, ³U.S. Geological Survey, Alaska Cooperative Fish and Wildlife Research Unit, Fairbanks, United States, ⁴University of Alaska - Fairbanks, International Arctic Research Center, Fairbanks, United States

Recent climate change is driving permafrost degradation, threatening to mobilize vast reservoirs of ancient carbon previously protected from decomposition. Although large scale, progressive, top-down permafrost thaw has been well studied and represented in high-latitude ecosystem models, the consequences of abrupt and local thermokarst disturbances (TK) are less well understood. To fill this gap, we conducted a detection analysis characterizing 60 years of land cover change in a major wetland complex subject to TK disturbance in Interior Alaska, using aerial and satellite images. We observed a nonlinear loss of permafrost plateau forest associated with TK disturbance and driven by precipitation and forest fragmentation. The results of this analysis were integrated into a state-and-transition model that simulates land cover change associated with TK disturbance. By 2100, the model predicts a mean decrease of 7.4% (sd 1.8%) in permafrost plateau forests associated with an increase in TK fens and bogs. We evaluated the consequences of TK-related land cover change on the regional carbon balance using a process-based biogeochemical model. We used long-term field observations of vegetation and soil physical and biogeochemical attributes to develop new parameterizations for TK wetlands and permafrost plateau forest land cover types. Preliminary simulations suggest a 7.5% (sd 3.5%) decrease in Net Ecosystem Exchange associated with TK-related land cover change by 2100.
Validating Approaches to Determine Biodiversity Attributes of Arctic Freshwaters

Michael Power\textsuperscript{1} (m3power@uwaterloo.ca), Joseph Culp\textsuperscript{2,3}, Milla Rautio\textsuperscript{4}, Guillaume Grosbois\textsuperscript{5}
\textsuperscript{1}University of Waterloo, Biology, Waterloo, Canada, \textsuperscript{2}Wilfrid Laurier University, Biology, Waterloo, Canada, \textsuperscript{3}Environment and Climate Change Canada, Waterloo, Canada, \textsuperscript{4}Université du Québec à Chicoutimi, Chicoutimi, Canada, \textsuperscript{5}Université du Québec à Chicoutimi, Biology, Chicoutimi, Canada

Improved understanding of how human-induced changes in Arctic freshwater ecosystems, e.g. climate change and resource development, may impact the health of northern freshwater resources and the provision of ecosystem services, e.g., sustainable fisheries, is essential. Here we discuss a research template consistent with the Circumpolar Biodiversity Monitoring Program to determine how aquatic ecosystem function and structure varies with spatial scale to support juvenile fish production, the diversity of other resident organisms, and the habitats upon which fisheries health and sustainability depend. The study also aims to measure cumulative impacts on aquatic ecosystem structure (e.g., biodiversity loss, reduced fish harvestability). Research focuses on the Lake Greiner Watershed, Victoria Island Nunavut, is multi-trophic and will expand beyond simple, single study of lake ecosystems to include landscape-level, watershed attributes such as tributary streams that provide important rearing and connectivity habitats for fish. The study is timely and necessary as it has been more than 40 years since such investigations were last conducted in the Canadian Arctic. The work will establish and validate monitoring protocols for aquatic ecosystems in the north, thereby providing tools to government agencies for the continued routine monitoring of Arctic freshwater systems and a means to assess the accumulation of future ecosystem impacts (e.g., climate change, development).
Characterizing Microhabitats at Relevant Scales for Polar Terrestrial Biota

Peter Convey¹ (pcon@bas.ac.uk), Stephen J. Coulson²,³, Anna Sjöblom⁴
¹British Antarctic Survey, Cambridge, United Kingdom, ²UNIS - University Centre in Svalbard, Longyearbyen, Norway, ³Swedish University of Agricultural Sciences, Uppsala, Sweden, ⁴Uppsala University, Uppsala, Sweden

Ground temperatures in the top few centimetres of the soil profile are key in many processes yet remain very poorly documented, especially in the polar regions or over longer timescales. They vary greatly at various scales across the often heterogeneous polar landscapes. Meteorological air temperature records provide a poor proxy for soil temperature profiles, while at present no biological microclimate datasets exist that are of sufficient duration to allow comparison with large-scale climate trends. Responses of soil-associated biota both to existing climate and to projected change cannot be understood without improved description of these microclimates. We introduce and provide an overview of multi-annual temperature records at biologically-relevant scale from 20 High Arctic (Svalbard) and maritime Antarctic sites. General features that are likely to have important influences on polar terrestrial biology include
(a) summer ground and sub-surface temperatures vary much more than those of the air;
(b) winter ground temperatures are generally uncoupled from atmospheric temperatures;
(c) the ground thawing period may be considerably shorter than that of positive air temperatures;
(d) ground freeze-thaw event patterns differ between Arctic and Antarctic;
(e) rates of ground temperature change are generally low;
(f) accumulated thermal sum in the ground usually greatly exceeds air cumulative degree days.
To predict changes in the future, we need to identify links between parameters in the ecosystems, such as food supply to the benthos, composition of benthic communities and effected functions. Comparative experiments can be used to distinguish different causes for effects, particularly in regions differing in environmental conditions such as sea-ice cover. Here we show results from benthic chamber incubation experiments, in which the same method was applied in (i) Arctic shelf and deep seas and (ii) Arctic and Antarctic shelf seas.

Our results show that the comparative approach can point to challenging global assumptions such as the largely diffusion-driven oxygen consumption rates in the deep sea and the biodiversity-driven rates of ecosystem functions (here: remineralisation rates). We argue that experiments manipulating the biological system (e.g. species) or environment in contrasting regions such the Arctic and Southern Ocean can elucidate physico- and biochemical mechanisms crucial for a better state description and prediction of processes in marine and polar ecosystems.
Ecological Role of Arctic Squid *Gonatus fabricii* Inferred using Stable Isotopes

Alexey Golikov¹ (golikov_ksu@mail.ru), Filipe Ceia², Rushan Sabirov¹, Zarina Zaripova¹, Martin Blicher³, Denis Zakharov⁴, José Xavier²,5  
¹Kazan Federal University, Department of Zoology, Kazan, Russian Federation, ²University of Coimbra, Marine and Environmental Sciences Centre, Coimbra, Portugal, ³Greenland Institute of Natural Resources, Greenland Climate Research Centre, Nuuk, Greenland, ⁴Polar Research Institute of Marine Fisheries and Oceanography, Laboratory of Coastal Research, Murmansk, Russian Federation, ⁵British Antarctic Survey, Natural Environment Research Council, Cambridge, United Kingdom

*Gonatus fabricii* is the most abundant (and the only one species of) squid, living in the Arctic throughout its life cycle. Its detailed ecological role was assessed using stable isotope analysis of its beaks in the Arctic: Western Greenland, Eastern Greenland and the Barents Sea. The values of both $\delta^{13}C$ and $\delta^{15}N$ were not sex-related, despite ontogenetic differences in life cycle. $\delta^{13}C$ showed low ontogenetic increase while having significant geographical differences: more eastern areas had lower values, more western areas had higher ones. Such pattern in $\delta^{13}C$ values, despite of not reported previously, was spotted in many taxa in the Arctic. $\delta^{15}N$ showed no geographical variation, while having significant ontogenetic increase (9.99‰ $\delta^{15}N$; 2.8 trophic levels) from epipelagic forms (1.4-2.6 trophic levels) to bathypelagic ones (2.2-4.2 trophic levels), being comparable with the largest fishes, seals and whales. Consequently, *G. fabricii* is considered the top predator invertebrate in the Arctic, with the widest trophic niche. *G. fabricii* had the highest values of $\delta^{15}N$ ever recorded in cephalopod beaks, 14.85‰. Its trophic level was surpassed only by the Antarctic colossal squid, *Mesonychoteuthis hamiltoni*: seems like in polar ecosystems squids occupy higher positions, than in the rest of the World Ocean. As the maximum recorded mantle length of *G. fabricii* is 389 mm (257 mm in the studied ones), its trophic level and predatory role would increase as our research develops.
Regional Variation of Antarctic Krill Lipids and their Fatty Acid Composition

Nicole Hellesey¹,²,³ (nicoleh3@utas.edu.au), Jessica Ericson¹,²,³, Peter D Nichols², Stephen Nicol¹, So Kawaguchi³,⁴, Nils Hoem⁵, Patti Virtue¹,²,³

¹Institute for Marine and Antarctic Studies, Hobart, Australia, ²Commonwealth Science for Industry Research Organisation, Oceans and Atmosphere, Hobart, Australia, ³Antarctic Climate & Ecosystems Cooperative Research Centre, Ecology, Hobart, Australia, ⁴Australian Antarctic Division, Kingston, Australia, ⁵Aker BioMarine, Oslo, Norway

Antarctic krill are an important trophic link between phytoplankton and higher organisms. Knowledge of their lipid (oil) biochemistry can assist in understanding and predicting potential ecological changes and can also inform the fishery on sustainable practices, optimising krill harvest. This study examined how the lipid and fatty acid content and composition of Antarctic krill varied between the three major ocean basins surrounding Antarctica (Indian, Atlantic and Pacific). Lipids were analysed from krill collected by a commercial krill fishery, along with samples collected on the K-Axis and ACE voyages.

Krill were staged, sexed, weighed and measured before undergoing lipid and fatty acid analysis. The digestive glands and stomachs were dissected out of samples so that a clear dietary signal could be attained and compared to the signal detected from samples of whole krill. Fatty acid signatures from the digestive glands and stomachs serve to show the immediate differences in diet between these regions, whilst the fatty acids of the whole krill show which lipids are being retained by the krill between regions.

These analyses serve as a baseline of the differences at a regional scale for lipid levels, energy usage and budgeting of krill. Knowing how krill diet and energy budgets vary around Antarctica will ensure an accurate measurement of krill production and energy flow in ecosystem models as well as helping to ensure the krill fishery is sustainable into the future.
Moss communities dominate the terrestrial vegetation in Antarctica, and thus are disproportionately important for the preservation of ecosystem services and biodiversity continent-wide. Understanding physical drivers of moss-community-level processes in Antarctica is a key challenge due to difficulties associated with sampling at temporal and spatial scales relevant for moss. Further, the ability to predict future impacts of climate change on Antarctic vegetation has been hampered by a scale mismatch between coarse scale climate models and scales biologically relevant for moss communities. Modelling at a scale appropriate for the study of mosses will lead to novel insights into how microhabitats are distributed across micro-topography, what impact microclimates have on community assemblages and productivity, and what changes may occur in the future. We surveyed microclimates in 10 quadrats (1m x 1m) in maritime Antarctica in January 2017 and 2018. Microclimatic variations were captured under different weather conditions, and moss-bed surfaces were digitised at a 1cm resolution using structure from motion. These data were used to parameterise a novel empirically calibrated mechanistic model that predicts moss-bed microclimates on a centimetre scale. This model allows us to scale-down from coarse climate data to determine how processes affecting moss composition, health and physiology vary in different microhabitats and how these might be altered under future climate scenarios.
The amphipod *Gondogeneia antarctica* is one of species predominating shallow Antarctic coastal macrobenthic communities. *G. antarctica* has been considered a key component of nearshore Antarctic food web, preyed by a high number of predators, and relying on various food sources over a year. In order to investigate its trophic preferences, *G. Antarctica* and its potential food (Suspended Particulate Matter and macroalgae) were collected, from intertidal water at King Sejong Station (Feb-Nov 2015). The C and N stable isotopes were analyzed in the potential food and the body of amphipods. We found similar $\delta^{13}C$ values of *G. antarctica* during the year (e.g. -19.4‰ ± 0.8: summer, -20.2‰ ± 0.5: winter), being close to those of red algae analyzed (*Iridaea cordata* -21.1‰ ± 3.2, *Gigartina skottsbergii* -22.6‰ ± 1.5, *Palmaria decipiens* -19.9‰ ± 0.7), indicating that the macroalgae were a primary food source, and SPM (-25.4‰ ± 1.2) the secondary one. The digestive tract contained organic matter (summer) and macroalgae (winter) confirming the isotopic results. The range of $\delta^{15}N$ values (5.6 to 7.7‰) of the amphipod indicated omnivory when food is relatively abundant in summer, though they generally appeared to be primary consumers in the other seasons. This seasonal trend was consistent among different sizes & reproductive status. We further discuss about the relevance of this seasonal shift with environmental parameters, such as seawater temperature, salinity, Chlorophyll a and sea ice cover.
Patterns in epibenthic community distribution and composition are regulated by a variety of environmental and biotic drivers. The multiscale nature of these fundamental cause-effect relationships, albeit generally known to be very important for the understanding of ecological processes and development of conservation and environmental management practices, has very rarely been explicitly addressed in marine polar research. To tackle this issue, we performed an ecological survey of epibenthic communities in three regions off the northern Antarctic Peninsula (northwestern Weddell Sea, southern Bransfield Strait and southern Drake Passage) by means of high-resolution seabed images (n=2799 taken with the Ocean Floor Observation System (OFOS)). We used Moran's eigenvector mapping of the epibenthic composition data to extract spatial scales at which communities are structured (700 m to 30 km) by physical and biological environmental factors, such as sea-ice dynamics, primary production, and water depth. The analysis indicates that at different spatial scales the community structure is driven by different environmental variables. However, the small-scale variability in epibenthic composition was not sufficiently explained by the measured environmental factors, very likely because it is primarily driven by biological interactions. Our study underpins the necessity to assess the relationship between environmental drivers and biological assemblages across a range of scales.
Dynamic Growth Model of Antarctic Macroalgae in a Fast-changing Environment

Charlène Guillaumot¹ (charleneguillaumot21@gmail.com), Antonio Aguera¹, Bruno Danis¹, Dolores Dereigibus², Maria Liliana Quartino², Leonardo A Saravia³
¹Université Libre de Bruxelles, Bruxelles, Belgium, ²Instituto Antártico Argentino, Buenos Aires, Argentina, ³Universidad Nacional de General Sarmiento, Buenos Aires, Argentina

Understanding communities functions and trophic interactions between Antarctic species has been the focus of a lot of research over the past few years. Modeling approaches help integrate increasing information about these communities using ecological network frameworks. Within these networks, macroalgae, as primary producers, are strong drivers in benthic ecosystem functioning. Characterising relationships between macroalgae growth performance and environmental parameters is an interesting approach to assess potential ecosystem responses to fast-changing environments. In this context, we build a dynamic growth model for Antarctic macroalgae that describes biomass changes in time and predicts macroalgae growth according to forcing environmental variables like: light intensity, water turbidity, current speed, ice cover. Our objective is to define a mathematical model structure that can encompass the environments observed in the Western Antarctic Peninsula, we will obtain parameters from published studies mainly from Potter Cove, King Georges Island (South Shetlands). After defining it we study the existence of alternative stable states with respect to environmental variables that could produce regime shifts in these Antarctic ecosystems.
Antifouling Activity in Sessile Antarctic Invertebrates by in situ Experiments

Carlos Angulo-Preckler¹ (carlospreckler@hotmail.com), Mariana Postigo², Critina Cid², Conxita Avila¹
¹University of Barcelona, Evolutionary Biology, Ecology and Environmental Sciences, Barcelona, Spain, ²Center of Astrobiology, Microbial Evolution Laboratory, Madrid, Spain

Competition for space is a remarkable ecological force, comparable to predation, which produces a strong selective pressure on sessile benthic invertebrates. The settlement of organisms on the surfaces of living organisms can be either advantageous or disadvantageous to the host. To obtain protection, many benthic marine invertebrates, including sponges and bryozoans, contain secondary metabolites with antibacterial properties. Here, extracts from five sponges and two bryozoans from Antarctic waters, have been shown to exhibit selective antibacterial activity. Three replicates of each fraction treatment were tested submerging the plates in the sea during one lunar cycle (28 days). Amplification from environmental DNA was performed searching for bacteria, eukaryota, and archaea. Different levels of bacterial and eukaryotic activity were found in the tested extracts when compared to controls. An important activity against eukaryotic fouling were detected. The hydrophylic fractions of Mycale tylotornota and Cornucopina pectogemma completely inhibited the growth of eukaryotic organisms, one of the early succession stages involved in biofouling. Thus, although chemical defenses may be quite species-specific in their ecological roles, these results suggest that different chemical strategies exist to deal with space competition, reinforcing the importance of marine organisms in the production of bioactive substances.
Disentangling the Coupling between Sea Ice and Tundra Productivity in Svalbard

Marc Macias-Fauria¹ (marc.maciasfauria@ouce.ox.ac.uk), Bruce Forbes², Stein Rune Karlsen³
¹University of Oxford, School of Geography and the Environment, Oxford, United Kingdom, ²University of Lapland, Arctic Centre, Rovaniemi, Finland, ³Northern Research Institute - Norut, Tomsø, Norway

The rapid decline in Arctic sea ice poses urgent questions concerning its ecological effects, such as on tundra terrestrial productivity. However, reported sea ice/terrestrial productivity linkages have seldom been constrained, and the mechanism governing them remains elusive, with a diversity of spatial scales and metrics proposed, at times in contradiction to each other. In this study, we use spatially explicit remotely sensed sea ice concentration and high-resolution terrestrial productivity estimates (Normalised Difference Vegetation Index, NDVI) across the Svalbard Archipelago to describe local/sub-regional and large-scale components of sea ice/terrestrial productivity coupling. Whereas the local/sub-regional component is attributed to sea breeze (cold air advection from ice-covered ocean onto adjacent land during the growing season), the large-scale component might reflect co-variability of sea ice and tundra productivity due to a common forcing, such as large-scale atmospheric circulation (North Atlantic Oscillation, NAO). Our study clarifies the range of mechanisms in sea ice/terrestrial productivity coupling, allowing the generation of testable hypotheses about its past, present, and future dynamics across the Arctic.
Elemental Stoichiometry Drives Nematode Life History and Genome Evolution

Byron Adams¹ (bjadams@byu.edu), Bishwa Adhikari², Xia Xue³, Breana Simmons⁴, Becky Ball⁵, Jeb Barrett⁶, Diana Wall⁷

¹Brigham Young University, Department of Biology, Provo, United States, ²University of Arizona, Tucson, United States, ³Brigham Young University, Provo, United States, ⁴East Georgia State College, Swainsboro, United States, ⁵Arizona State University, Glendale, United States, ⁶Virginia Tech, Blacksburg, United States, ⁷Colorado State University, Fort Collins, United States

The presence of bioavailable phosphorus (P) differs significantly across the Transantarctic Mountain (TAM) landscape where it is highly correlated with age of exposure and the composition of glacial tills. Terrestrial habitats with very old surface exposures have relatively little bioavailable phosphorus whereas as younger tills typically are much more phosphorus rich. Thus, provenance and weathering play an instrumental role in patterns of distribution and abundance of this important nutrient in the TAM. Phosphorus is the most limiting element in DNA transcription and translation such that P availability is directly coupled to high demands for the protein synthesis that is required for organismal growth and development. Using field and laboratory approaches we show that conspecific TAM nematodes from high versus low bioavailable P environments contain greater somatic P concentrations and have evolved 1) faster growth rates, 2) earlier reproduction, 3) shorter reproductive cycles, 4) smaller body size, 5) increased rates of transcription, and 6) increased rRNA gene copy number. These findings have important implications on the evolution of organismal life history traits and ultimately the development of trophic complexity in terrestrial ecosystems.
The combination of partial least square regression (PLSR) and soil visible (VIS) and near infrared (NIR) spectroscopy measurements can be used to predict soil properties and assist estimating the spatial characteristics of soil properties from the pedon to regional scales. VIS-NIR spectroscopy was successfully used to describe, estimate and further map the spatial patterns of soil properties in unknown locations using PLSR in R program. The parameters such as oxalate and dithionite extracted iron, aluminum and manganese oxides and (hydr-)oxides, soil organic carbon and total N concentrations, and pH were investigated in this research. Moreover, the geostatistical methods (e.g. Moran’s I: spatial autocorrelation) can be used in order to better understand the pedogenic processes pertaining to permafrost thaw. This research illustrates how VIS-NIR spectroscopy can be implemented in order to improve the global soil spectral library as well as assist in up-scaling of soil properties and processes in cold climate regions.
In the ultraxerous region of the Dry Valleys of Antarctica, the very cold and dry climate ensure that dry soils overlie icy permafrost; a characteristic unique to this region, but is the norm on Mars. Here, we present summary of our work in University Valley, upper Dry Valleys. In University Valley, mean annual air temperature approximates mean annual ground surface temperature (ie, surface offset ~ 0°C); however, mean annual relative humidity (45.5 ± 14%) is much lower than mean annual ground surface relative humidity (varying from 100 to ~ 85%ice). The ice table depth increase with distance from the glacier: from < 1 cm to ~ 60 cm, indicating that despite being a cold and dry region, ground ice is pervasive. Excluding the two bodies of buried glacier ice, volumetric ice contents ranged from 0 to 93%. These high ice contents suggest the cold temperatures and low precipitation in the upper Dry Valleys are likely not limiting factors to the development of ice-rich permafrost. Based on D-18O measurements, the ground ice has different origins: vapor-deposition, freezing of evaporated snow meltwater or burial of glacier ice. We modeled the net water vapour flux, ice table depths and D-18O of ground ice using the conditions measured in the valley. When ground surface conditions are used (instead of those measured in the atmosphere), our modeling predicts that the measured ice table depths in the valley are likely in equilibrium with contemporary conditions.
Quantification of Holocene Nivation Rates on James Ross Island, Antarctica

Michaela Knazkova¹ (michaelaknazkova@gmail.com), Daniel Nyvlt¹, Filip Hrbacek¹
¹Masaryk University, Faculty of Science, Department of Geography, Brno, Czech Republic

Nivation encompasses a breadth of slowly operating landscape modelling processes, which have been studied only very little in the recent years. In the semi-arid polar continental climate of James Ross Island with annual precipitation of 300-500 mm and strong redistribution of snow by wind that causes the formation of snow-patches, meltwater from the late-lying snow-patches is not only capable of transporting fine particles downslope and slope profile shaping, but also controls the presence of vegetation in the landscape. The area for this study is located on Cape Lachman. The deglaciation of this area took place 12.9 ± 1.2 ka ago. The study site consists of ca 2 km long and 200 m wide semi-circular depression. Snow accumulations on the lee slopes last throughout the summer and the long-term downslope transport of fine particles by meltwater has caused significant remodelling of the slope profile. dGPS measurements on 20 transects have been used for comparison between transects which have been affected by nivation processes and those which have been not. Besides, a digital terrain model was constructed to quantify the scarp retreat and slope profile change along the depression margin due to nivation and to calculate the rate of these changes since the deglaciation, i.e. for the whole Holocene. Furthermore, grain-size changes of material in studied profiles support the removal of fine-grained particles by meltwater from the slope and their accumulation on the depression floor.
When studying fluvial transport in Antarctic streams, an obvious question arises: where does the material come from? The sources of bedload and suspended load generally differ in most catchments. Chemical composition of suspended material transported in Bohemian and Algal streams on Ulu Peninsula, James Ross Island (eastern Antarctic Peninsula) didn’t bring any clear answer (Kavan et al., 2017). Here we test the hypothesis that an important source of material for fluvial transport is the material brought by strong barrier winds transporting material from relatively vast ice-free areas of Ulu Peninsula. Two sets of passive aeolian samplers were installed on upwind and downwind sides of Bohemian Stream braidplain with respect to prevailing southerly to westerly barrier winds. The material was sampled for 23 days (29/01/2017-20/02/2017) without an occurrence of significant wind storm during the period. Nevertheless, samplers ahead of the braidplain did collect 41.66 g/m² in average, whereas only 29.09 g/m² were sampled behind the braidplain. This suggests a significant part of wind-blown material (>30%) was lost from aeolian transport and was stored in braidplain being available for subsequent fluvial transport. The redistribution of aeolian material through fluvial systems causes spatially unequal input of fine-grained material to coastal marine environment and shapes significantly the Antarctic coastline.
How do rocky boulder pavements and oriented boulder landforms form atop dust and ice? How do they persist through orbital/spin-axis-induced climate change? We describe silt-dominated inflated soil textures in the McMurdo Dry Valleys of Antarctica and evaluate a class of potentially similar martian landforms on Mars referred to as “boulder halos.” Boulder halos are circular arrangements of clasts present at martian middle to high latitudes. They are thought to result from impacts into a boulder-poor surficial unit that is rich in ground-ice and/or sediments and that is underlain by a competent substrate. To determine the distribution of boulder halos and to evaluate mechanisms for their formation, we mapped boulder halos over 4,188 HiRISE images located between 50-80° north and south latitude. Boulder halos are about three times more common in the northern hemisphere than in the southern, and have size-frequency distributions suggesting recent Amazonian formation (tens to hundreds of millions of years). In the north, boulder halo sites are characterized by abundant shallow subsurface ice and high thermal inertia. Spatial patterns of halo distribution indicate that surface processes such as inflation either promote boulder halo preservation in the north or destroy boulder halos in the south.
Investigations of Patterned Ground in Antarctic Permafrost as a Mars Analogue

Emanuele Forte¹, Rossana Raffi², Hugh French³, Mauro Guglielmin⁴ (mauro.guglielmin@uninsubria.it)
¹Università degli Studi di Trieste, Trieste, Italy, ²Università degli Studi Roma La Sapienza, Roma, Italy, ³Ottawa University, Ottawa, Canada, ⁴Università degli Studi dell’Insubria, DISTA, Varese, Italy

The results of a combined geophysical and geomorphological investigation of thermal-contraction-crack polygons in Northern Victoria Land (Antarctica) are reported. An area of ~30,000 m² characterized by random orthogonal polygons was investigated using 10 GPR and 2 ERT surveys. The terrain consists of Holocene-age raised beaches. The polygons are well developed only on beaches that are >14 m above current sea level. Uplift curves for the region suggest the beaches formed between 4.2 and 6.3 ka BP. Sections were excavated through two of the fissures that form the polygons. There was good correlation between field observations and GPR (250 Mhz) data. It is concluded that the polygons are composite in nature because the shallow linear depressions that outline the polygons are underlain by fissures that can contain both sandy gravel (i.e., sand wedges) and foliated gravelly ice (i.e., ice wedges) in the same polygon network. Generally, the ice infill is less common than the sandy gravel infill. While thermal-contraction-cracking is the principle mechanism for polygon formation, it is suggested that local micro-site conditions, mainly snow distribution, leads to the different type of fissure infill.
Microbial Communities in the Brines of Two Antarctic Frozen Lakes (Boulder Clay)

Maurizio Azzaro¹, A Conte², M Papale², A.S Cabral³, G. Caruso³, E. Crisafi³, M. Dalle Fratte³, E. Forte³, Rosa Bruna La Ferla³ (rosabruna.laferla@iamc.cnr.it), A. Lo Giudice¹⁻², G Maimone³, R Paranhos³, A.C. Rappazzo³, C Rizzo², S. Savoca², N. Spanò², Mauro Guglielmin⁴

¹National Research Council of Italy, Institute for Coastal Marine Environment (IAMC), Messina, Italy, ²University of Messina, Messina, Italy, ³Federal University of Rio de Janeiro, Rio de Janeiro, Brazil, ⁴University of Insubria, Varese, Italy, ⁵University of Trieste, Trieste, Italy

During a GPR survey, two lenses of liquid brines were found at different depths in two adjacent frozen Boulder Clay lakes (Lake-1: 2.5 m; Lake-2: 2.0) with a different salinity (0.2 and 3.6 mS/cm, respectively) and pH (8.17 and 8.76, respectively). Brines were analyzed for bacterial diversity by Ion Torrent DNA and cDNA sequencing, microbial abundances (by image analysis and flow cytometry) and metabolic activities (by Biolog-Ecoplate™ and potential rates of ectoenzymatic activities determinations). The analysis of DNA sequences generally showed the predominance of Bacteroidetes, followed by Proteobacteria and Actinobacteria. The highest percentage (6.0 vs 1.7%) of active bacteria (by the analysis of RNA sequences; mainly Bacteroidetes) was observed in Lake-1. This latter harboured microbial populations characterized by higher prokaryotic cell abundances, volumes, biomass and virus abundance than Lake-2. Diverse cell morphotypes were observed in the two lakes. Different metabolic responses were also determined, with higher numbers of respiring cells and higher rates of ectoenzymatic activities, as well as the ability to better utilize carbon sources, in Lake-1 than in Lake-2. Results highlighted differences in the analyzed cryoenvironments in terms of diversity, abundance and metabolism, suggesting that Antarctic lakes might possess distinct microbial features in spite of their spatial proximity.
Two distinct hypersaline brine pockets (TF4 and TF5) separated by a 12 cm-thick ice layer were sampled from Tarn Flat, an unexplored Antarctic perennially frozen lake. Samples were analyzed for prokaryotic (Bacteria and Archaea) diversity (Ion Torrent sequencing), microbial abundances (image analysis and flow cytometry) and metabolic activities (Biolog-Ecoplate™ and potential rates of ectoenzymatic activities). The two sites shared only 22 and 18% of OTUs for Bacteria and Archaea, respectively. Shannon diversity for archaeal and bacterial communities was higher in TF5 than TF4 (p value < 0.001). Both bacterial communities were dominated by Proteobacteria, followed by Bacteroidetes and Actinobacteria. The Archaeal community was mainly constituted by Euryarchaeota and Crenarchaeota. Prokaryotic and virus-like particle abundances were in the order of $10^9$ cells/l and $10^{10}$ VLP/l, respectively, in both samples, with slightly higher counts in TF4 than TF5. However, the VLP/PA ratio was 2.7 times higher in TF4 than in TF5. Larger cells were detected in TF5 (0.105 µm³) than TF4 (< 0.06 µm³) as well as higher values of physiological diversity, substrate richness, substrate evenness and equitability were determined in TF5 than TF4. The prokaryotic community hydrolyzed proteins rather than organic phosphates, and polysaccharide degradation was negligible in TF5 and high in TF4. Overall data revealed the occurrence of highly different microbial assemblages in the studied brines.
Rock glaciers in the Dry Valleys of Antarctica vary across the region in terms of origin and internal structure. Based on ground-penetrating-radar data and field excavations, rock glaciers in central Wright Valley are cored by ice-cemented sediments and recharged by meltwater, whereas those in Taylor and Pearse valleys often contain 3+ m of clean ice buried beneath sediments. Based on field observations, the latter type of rock glacier forms along the margins of cold-based glaciers as a mélange of glacial ice blocks, meltwater and sediments. These clean-ice rock glaciers often show evidence of complex formational histories and can therefore be used to map multiple glacial advances. Stable isotopic analyses of buried ice from a rock glacier in Pearse Valley support the presence of two distinct ice bodies:

1) one from a previous advance of East Antarctic outlet Taylor Glacier, possibly dating to Marine Isotope Stage 5 and
2) another from a modern alpine glacier which is still actively supplying ice and sediments.

This study outlines the environmental conditions that foster rock-glacier formation in cold deserts with implications for lobate flow features on Mars. The data also provide a baseline to study the geomorphic impacts of present and future climate change. Meltwater-fed rock glaciers, such as those in Wright Valley, may grow in response to warming, whereas clean-ice rock glaciers will likely experience degradation by thermokarst melting and stream erosion.
Weathering Rate Study in Maritime Antarctica Using Onsite Nondestructive Methods

Jeronimo Lopez-Martinez¹ (jeronimo.lopez@uam.es), Miguel Gomez-Heras¹, Luis Javier Lamban², Belen Oliva-Urcia¹, Jose A. Ortega-Becerril¹, Thomas Schmid³

¹University Autonoma of Madrid, Faculty of Sciences, Geology and Geochemistry, Madrid, Spain, ²Geological Survey of Spain-IGME, Zaragoza, Spain, ³Center for Energetic, Environmental and Technological Researches-CIEMAT, Madrid, Spain

Periglacial processes are highly active under the maritime environmental conditions of the South Shetland Islands. Weathering associated with such conditions influences soil and landform development. Dating of deposits and erosive surfaces in the region poses difficulties due to the scarcity of sedimentary elements adequate for dating. This is the case of one of the prominent geomorphological features in the studied region: raised marine features located up to 260 m a.s.l. The aim of this work is to explore the possibilities of discriminating exposure ages using a combination of measuring methods to study weathering. There are studies on the use of Schmidt hammer for relative dating glacial weathered surfaces; however, there are other onsite nondestructive techniques that could further improve the dating results. In this study, a range of techniques including Schmidt hammer, ultrasound pulse velocity, spectroscopy and surface temperature were applied to relatively date exposed rock surfaces in the South Shetland Islands. Measurements have included Holocene and pre-Holocene raised beaches containing pebble sediments, and marine erosive platforms located at different altitudes in Livingston and King George islands. In addition to onsite and laboratory measurements, the spectral signature of these features was determined in order to characterize the spectral information from satellite observations, which in turn can be extrapolated to further areas over a larger region.
The vertical distribution and controlling factors of the hydrochemistry of ground ice are critical to explore the mechanism of salt-moisture migration during the soil freezing-thawing processes, which are of great importance to understanding the hydrological cycles in cold regions. This study examined the characteristics of ground ice hydrochemistry using data from nine soil profiles investigated in permafrost regions of the central Qinghai-Tibet Plateau (QTP), which is called as the third pole. The isotopes and anion values of subsurface water on the QTP were higher than those in Arctic polygonal ground regions. The spatial tendency of anions was not obvious, while well-developed hydrochemical depth gradients were found within the soil profile, presenting depleted isotopes and increased anions with depth. Cl\(^-\) and SO\(_4^{2-}\) concentrations in soil water increased with depth, while NO\(_3^-\) concentration did not change obviously with depth. Freeze-out fractionation, self-purification, and desalination greatly impact soil hydrochemistry. Correlation analyses showed that the major controlling factors for the variations of soil water chemistry were soil moisture, air temperature, and active layer thickness. The results could provide fundamental framework to understand the ground ice origins and the salt-moisture migration pathways in the context of permafrost changes, and should be considered in establishing the process-based permafrost hydrologic models.
The Tibetan Plateau (TP), the highest and largest plateau in the world, with complex and competing cryospheric-hydrologic-geodynamic processes, is particularly sensitive to anthropogenic warming. The quantitative water mass budget in the TP is poorly known. Here we examine annual changes in lake area, level, and volume during 1970s –2015. We find that a complex pattern of lake volume change during 1970s–2015: a slight decrease of -2.78 Gt yr$^{-1}$ during 1970s–1995, followed by a rapid increase of 12.53 Gt yr$^{-1}$ during 1996–2010, and then a recent deceleration (1.46 Gt yr$^{-1}$) during 2011–2015. We then estimated the recent water mass budget for the Inner TP, 2003–2009, including changes in terrestrial water storage (TWS), lake volume, glacier mass, snow water equivalent (SWE), soil moisture, and permafrost. The dominant components of water mass budget, namely changes in lake volume (7.72 ± 0.63 Gt yr$^{-1}$) and groundwater storage (5.01 ± 1.59 Gt yr$^{-1}$), increased at similar rates. We find that increased net precipitation contributes the majority of water supply (74%) for the lake volume increase, followed by glacier mass loss (13%), and ground ice melt due to permafrost degradation (12%). Other term such as SWE (1%) make a relatively small contribution. These results suggest that the hydrologic cycle in the TP has intensified remarkably during recent decades.

Vapor Stable Isotopes in the Tibetan Plateau Record Moisture Transport Processes

Jing Gao1 (gaojing@itpcas.ac.cn), Tandong Yao1, H. C. Steen-Larsen2
1Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China, 2Niels Bohr Institute, University of Copenhagen, Copenhagen, Denmark

The water cycle in the southern Tibetan Plateau as a crucial region in the “Asian Water Towers” impacts water supply in downstream countries. Moisture transport processes determine the variation of regional water cycle directly. Water vapor stable isotopes (\(\delta^{18}O\) and \(\delta^D\)), as an integrative tracer of water phase-transition and diffusivity process provide the potential of enhancing our knowledge of the moisture transport processes from the moisture origins to the southern Tibetan Plateau. Continuous, in situ high-resolution measurements of atmospheric water vapor stable isotopes have been conducted at Lhasa, Motuo and Everest, southern Tibetan Plateau (TP), since October 2014, using the laser analyzers. Combined with local meteorological data, reanalysis data and simulations from the iso-GCMs model, the relationships between water vapor stable isotopes and atmospheric processes are explored at daily and seasonal scales. The changing of vapor stable isotopes is resulted from the moisture transport processes, especially the transfer from the westerlies to the Indian summer monsoon. Our results will improve the implications of stable isotopes in ice cores and understanding of water cycle in this region.
Characteristics of Wet Season Precipitation Gradients on the Tibetan Plateau

Lan Cuo\textsuperscript{1} (lancuo@itpcas.ac.cn), Yongxin Zhang\textsuperscript{2}

\textsuperscript{1}Chinese Academy of Sciences, Institute of Tibetan Plateau Research, Beijing, China, \textsuperscript{2}National Center for Atmospheric Research (NCAR), Research Applications Laboratory and Climate and Global Dynamics Laboratory, Boulder, United States

The Tibetan Plateau (TP) with its vast land mass and high elevation affects regional climate and weather. More importantly, the TP is the headwater of 9 major Asian rivers that provide fresh water for 1.65 billion people and many ecosystems, with wet season (May - September) precipitation being the most critical component of the fresh water. Using station observations and ERA-Interim reanalysis for 1979 - 2015, we show that wet season precipitation on the TP displays distinctive regional variations in vertical gradients (i.e., changes with elevation). The variations can be largely explained by considering those of vertically integrated moisture, convective available potential energy and condensation level. The increase of precipitation with elevation for all groups is predominantly the result of combined increasing CAPE and decreasing LCL with elevation that cancel out the decreasing vertically integrated moisture with elevation. Below 4000 m and excluding desert, precipitation change with elevation is mainly determined by the effects of energy and condensation level. Above 4000 m and in the desert, condensation level dominates over energy.
Hydrogeochemical Characteristics of the Gandaki River Basin in Central Himalayas

Fan Zhang1 (zhangfan@itpcas.ac.cn), Ramesh Raj Pant1, Faizan Ur Rehman1, Guanxing Wang1
1Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China

Hydrogeochemical Characteristics of the Gandaki River Basin of Central Himalayas was analyzed based on 165 river water samples taken during pre-monsoon, monsoon and post monsoon seasons from 55 sampling sites. The pH, EC and TDS were measured on site while major ions (Ca2+, Mg2+, K+, Na+, Cl-, SO42-, NO3-) and Si were analyzed in the laboratory following the standard procedures. The results revealed mildly alkaline pH with the pattern of average ionic dominance: Ca2+>Mg2+>Na+>K+ for cations and HCO3->SO42->Cl->NO3- for anions. Gibbs plot and ionic relations displayed the predominance of carbonates weathering processes which is supported by geochemical facies of water in Piper plot as Ca-HCO3 (83.03%), mixed with Ca-Na-HCO3 (12.73%) and Ca-Cl (4.24%). Strong spatiotemporal heterogeneity was observed between upstream and downstream segments in terms of distinct precipitation, meltwater, local geogenic sources and anthropogenic interferences. Suitability analysis of river water for drinking as well as irrigation purposes revealed that the river has mostly retained its natural water quality. However, increasing anthropogenic interferences could be serious threats for water quality and ecological integrity of the river basin in the future.
Coordinated Regional Climate Downscaling Experiment (CORDEX) Activity in Asia

Likun Ai1 (aili@itpcas.ac.cn)

1Institute of Tibetan Plateau Research, Chinese Academy of Sciences, International Programme Office, Third Pole Environment, Beijing, China

CORDEX is a sub-project under WCRP (World Climate Research Program). From 2013, APN (Asian-Pacific Network for Global Change Study) funded a regional project to support the CORDEX development in Asia. The objective of this joint CORDEX activity for Asia is to set up a more enhanced, open, efficient, and shared collaborative platform for climate downscaling groups in Asia. In last 4 years, re-grouped and re-designed 3 sub-domains for CORDEX Asia have been conducted, which are South Asia, East Asia and Southeast Asia. This project has set up the mechanism of sharing the data, experiences and techniques on climate downscaling with all the CORDEX groups in Asia. This APN project has also supported setting up the ESGF nodes (RCM data sharing) in Asia by collaboration with WCRP-ESGF core group. The CORDEX Asian Empirical-Statistical Downscaling (ESD) group was established to support the application of climate downscaling products to end-users. The science-policy dialogues platform focusing on climate adaptation during the workshops was built up. This project has trained more than 130 young scientists from developing countries in Asia.
Third Pole Environment (TPE) Programme: History, Achievements and Future Plan

Likun Ai¹ (aili@itpcas.ac.cn)
¹Institute of Tibetan Plateau Research, Chinese Academy of Sciences, International Programme Office, Third Pole Environment, Beijing, China

After the North and South Poles, the Third Pole is the highland core of Asia, and includes the Hindu-Kush, Karakorum, Himalayas, Tibetan Plateau and all the mountain ranges that surround it. This region provides the water resource and ecosystem services to billions of people in Asia. It is well accepted that the regional environmental change will have huge implications for millions of people living in the Third Pole region and downstream areas.

Formally launched in 2009, the Third Pole Environment (TPE) program is to understand the mechanisms of the earth system multi-sphere (atmosphere, cryosphere, hydrosphere, lithosphere, biosphere and anthroposphere) interactions in the Third Pole region. This Poster will give brief introduction of history, achievement, ongoing activities and future plan of TPE.
Debris is one of the unavoidable components of Himalaya glaciers and having a critical role in glacier dynamics. Contrasting to normal ablation pattern over glaciers, debris covered glaciers of this region has experienced inverse ablation rate due to significant control of debris cover. Considering complex nature of debris materials, surface temperature becomes crucial factor to estimate thermal resistance of debris to calculate ablation under debris covered glacierized area. In this investigation, an attempt has made to quantify the thermal resistivity of supraglacial debris of Chandra basin by using heat flux method. The ablation and temperature (surface and subsurface) data was obtained from stake networks and T-data logger installed over glaciers in different altitude ranging from of 4100 to 5100 m.a.s.l. during year 2016-17. The Chandra basin has 702 km² glacierized areas and almost ~22% of this area is covered by debris with various thicknesses (10-150 cm). The major components of the debris in this basin are Quartz, Phyllite, Mica, Slate, Gneiss and feldspar. Observation revealed lower temperature at the debris surface and debris-ice interface during November to May and vice versa during June to August. There is significant diurnal variation in thermal resistance of debris, higher during day than night may be caused by variation in vapour pressure in the debris layer under the saturated water pressure condition.
Wed_110_CR-3_908
Multi-sphere Hydrological Modeling over the Third Pole Region

Lei Wang1 (wanglei@itpcas.ac.cn)
1Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China

For improved predictive ability of regional water resources and water-related disasters in the Third Pole region (Tibetan Plateau and its surrounding area), in recent years, we aim at developing a multi-sphere hydrological modeling system that is applicable to the high-elevation environment. The major achievements of our work can be summarized as follows.

(1) A distributed land surface hydrological model (WEB-DHM) was developed in 2009, which can consistently describe the exchanges of water, energy, and CO2 fluxes in the land-atmosphere interactions at the basin scale. The model has been widely applied into dozens of watersheds in Asia, Africa, North America, and South America, to serve their integrated water resources management.

(2) Key cryosphere processes (e.g., snow, frozen soil, glacier) have been significantly improved under the framework of the distributed land surface hydrological model WEB-DHM, and the physically-improved multi-sphere (atmosphere-hydrosphere-cryosphere-biosphere) hydrological model have been extensively applied into cold river basins for addressing critical water issues in the Third Pole Region (e.g., Floods, Droughts, Lake area changes, and so on).
As an important sensitive factor of global climate change, the surface snowmelt in Tibet Plateau, Greenland and Antarctica is a key factor impacting the free water resources in world. Understanding the spatio-temporal variation of snowmelt in the three areas is very important to change of water resources. Many studies for surface snowmelt have been conducted already, but most of them only focused on one of three areas. The climate conditions of Tibet Plateau, Greenland and Antarctica differ, and local characteristics are diverse within their regions as well. However, linkages through atmosphere, ocean and another climate system make local climate change in the three areas correlated. Therefore, in order to understand precisely the impact of snowmelt on Tibet Plateau, Greenland and Antarctica to water resources, the variation of snowmelt on the three areas should be studied as a whole system. Spaceborne earth observation provides an efficient means of measuring snowmelt dynamics in a long term. Therefore, based on spaceborne microwave radiometer datasets from 1978 to 2014 by using improved freeze-thaw detection algorithms and new proposed snowmelt index, we investigate the snowmelt change on Tibet Plateau, Greenland and Antarctica in this paper by addressing the following three questions: What is difference between the snowmelt change on the three areas? How is the snowmelt change on whole three areas? What is relationship between the snowmelt change in on the three areas?
Spaceborne passive microwave remote sensing (e.g. SSM/I, AMSR-E) and its relationship with physical properties of the snowpack has been widely studied in the last decade. Furthermore, AMSR-E measurements from Level 2A (L2A) product, are three times more sensitive than EASE-Grid for mountainous regions. In spite of this, advantages of passive microwaves remote sensing technologies are still unexplored for the Andean Region, such as the Upper Maipo basin (about 7562 km²) located in the Central Andes of Chile. The aim of this study is to examine passive microwave brightness temperature (Tb) at 36.5 GHz from L2A (14 x 8 km), and its relationship with the snow water equivalent (SWE) in the Upper Maipo. For this, Tb observations were processed at basin and point scales, and a recent SWE reanalysis, with a spatial resolution of 0.05°, were used in this study. There is a high negative correlation (R=-0.80) between the minimum Tb (nighttime) of each hydrological year (2002/03 - 2011/12) with the concurrent SWE for basin scale, and significant higher coefficients of determination (R²>0.75) for cells above ~3500 m.a.s.l. Nevertheless, there is a high spatial scattering between Tb and SWE due to different spatial scales of each product and other variables involved in the radiative transfer of the snowpack. Finally, it was shown that Tb observations are sensitive to SWE in the Central Andes of Chile, with a high empirical correlation during the accumulation period.
Native nothofagus forests in the mid-latitude regions of the Andes Cordillera are notorious biodiversity hotspots, uniquely situated in the Southern Hemisphere such that they develop in snow-dominated reaches of this mountain range. Spanning a comparatively smaller surface area that similar ecosystems in the northern hemisphere, the interaction between vegetation and snow processes in this ecotone has received relatively little attention in the scientific literature. Here, we present the first systematic study of snow-vegetation interactions in the nothofagus forests of the Mediterranean Andes, focusing on the interplay between interception, climate and energy exchange in determining patterns of snow water equivalent variability. The Valle Hermoso experimental basin, located in Nevados de Chillan, was fitted with eight continuously measuring snow depth sensors, located at varying elevations, aspect and forest cover. Also, manual measurements of snow properties and canopy parameters as distance to canopy, leaf area index and total gap area were obtained during end-of winter and spring seasons during three years, 2015 through 2017. We find that interception implied a 22% - 32% reduction in snow accumulation in forested sites compared with clearings. Differences in snow duration were not statistically significant between forested and clearing sites, indicating that long-wave energy exchange is unable to overcome the shading induced by the forest canopy, even in deciduous forest.
Water budgets of glacialized basins are difficult to constrain, despite the significant potential to undergo change as ice coverage decreases and rain becomes the dominant form of precipitation. Wolverine Glacier (WG) is a coastal mountain glacier in southcentral Alaska that has experienced 27 m w.e. a-1 mass loss since monitoring began in 1966. A basic water budget was calculated for the WG basin using meteorological, glacier surface mass balance, and stream discharge data from water years 2011 through 2017. The water budget was partitioned into on-glacier and off-glacier components in order to quantify how different hydrologic components contribute to annual stream discharge. Our results indicate the dominance of on-glacier fluxes and a large and temporally-variable residual that likely accounts for unmeasured variables. As the glacier continues to retreat, off-glacier components will become more important as new vegetation expands into previously ice-covered regions, altering timing of water delivery, storage, chemistry, and evapotranspiration. Understanding the water budget of glacierized basins will become increasingly important, as they provide delivery of freshwater and nutrients to downstream habitats. Water source (on versus off glacier), timing, and magnitude of basin runoff will be critical to predict impact on these diverse and economically significant ecosystems.
A Framework of Remote Sensing Products for Three Pole Studies

Rongxing Li\textsuperscript{1,2} (rli@tongji.edu.cn), Yinsheng Zhang\textsuperscript{3}, Hansheng Wang\textsuperscript{4}, Fei Li\textsuperscript{5}, Xiaohua Tong\textsuperscript{1,2}
\textsuperscript{1}Center for Spatial Information Science and Sustainable Development Applications, Tongji University, Shanghai, China, \textsuperscript{2}College of Surveying and Geo-Information, Tongji University, Shanghai, China, \textsuperscript{3}Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China, \textsuperscript{4}Institute of Geodesy and Geophysics, Chinese Academy of Sciences, Wuhan, China, \textsuperscript{5}Chinese Antarctic Center of Surveying and Mapping, Wuhan University, Wuhan, China

The Three Poles play an important role in the earth system and global change studies. Much of research efforts have been made in studying the individual poles and their immediate and intermediate surroundings, while research results of three poles as non-separate entities have been less published. We present a framework of remote sensing product generation which will establish a collection of maps and databases to support integrated three poles studies. These products will geographically cover all three poles and have a range of cryospheric and hydroospheric attributes, including permafrost, sea ice, snow, albedo, ice sheets and glaciers (mass balance, ice flow speed etc.) and others. Existing products will be evaluated and updated considering their consistencies, errors, and spatial and temporal changes. New products will be generated to fill gaps or to improve the quality as new data and technology become available. Models can be used to guide observations and data collections, as well as to demonstrate the capability of uncertainty reduction of predictions. The remote sensing products are expected to support a focused set of science applications including the anomaly change trend of some local and regional glaciers in Tibet Plateau, change and instability of polar ice sheets vs. sea level changes, and global sea ice change trend.
In order to clarify effects of glacial meltwater discharge on surface water carbonate chemistry and air-sea CO2 flux, observational studies were carried out in the Bowdoin Fjord in northwestern Greenland during the summer of 2016 and 2017. Due to the freshwater supply from the melting glacier, surface water salinity was low down to 6.5 near the calving front of the glacier as compared to that in the outer side of the fjord (Salinity=30.5). The dissolved inorganic carbon (DIC) and total alkalinity (TA) in surface water were also low near the calving front while they were high in the outer side of the fjord. A relationship between salinity and DIC/TA in surface water indicates high correlations, suggesting that variations of DIC and TA in surface water are explained mainly by the dilution effect due to the discharge of the pure glacial meltwater. The partial pressure of CO2 (pCO2) in surface water estimated from DIC and TA was low, especially near the calving front down to 100 µatm as compared to that in the atmosphere (about 400 µatm). Therefore, the surface water affected by the glacial meltwater acted as a sink for atmospheric CO2. Present results indicate that the discharge of glacial meltwater draws down the pCO2 in surface water and enhances the air-to-sea CO2 flux.
The Subglacial Recovery Lake: New Insights from Airborne Radar Data

Anja Diez¹, Kenichi Matsuoka¹ (kenichi.matsuoka@npolar.no), Tom Jordan², Jack Kohler¹, Fausto Ferraccioli², Hugh Corr², Arne Olesen³, René Forsberg³

¹Norwegian Polar Institute, Tromsø, Norway, ²British Antarctic Survey, Cambridge, United Kingdom, ³Technical University of Denmark, Copenhagen, Taiwan, Republic of China

The Recovery Region, with its largest glacier Recovery Glacier, was identified as the biggest contributor to sea level rise from East Antarctica in future. Active subglacial lakes along the glacier suggest an active hydraulic network controlling the enhanced ice flow of Recovery Glacier. Four giant lakes (Lake A–D) were identified at the onset of the enhanced ice flow from satellite data. Their stability and potential hydraulic link to the downstream lakes is unknown. We conducted an extensive radar survey over these lakes in 2015/16, complementing radar data from the region from 2013/2014. We analyze this new radar data together and compare it to previously collected data from 2008/2009. Hence, we show that the two southern lakes, Lakes C and D do currently not contain significant amounts of water. Within the originally-proposed area of Lake A and B we identify one Lake/Swamp area and estimate its current area to be about 4320 km². Water leakage from the western boundary of this lake triggers the fastest enhanced ice flow branch of Recovery Glacier. We suggest that this Lake is part of the system of active subglacial lakes further downstream within the Recovery trough, affecting their multi-year cycle of filling and draining.

Water Balance and Thermal Regime of Lakes in Antarctic Oases

Elena Shevnina¹ (elena.shevnina@fmi.fi), Ekaterina Kourzeneva¹, Daniela Franz², Yuriy Dvornikov³
¹Finnish Meteorological Institute, Helsinki, Finland, ²Johann Heinrich von Thünen Institute, Berlin, Germany,
³Earth Cryosphere Institute, Russian Academy of Sciences, Saint Petersburg, Russian Federation

Connection between thermal regime and water balance for lakes in the Antarctic oases was studied. The study
based on observation on 18 lakes located in the King George Island, the Larsmann Hills and the Schirmaher
oasis in summers 2011-2018. The role of evaporation in the seasonal water balance of the Antarctic lakes are
discussed. The latent heat flux or the evaporation rate was evaluated from the lake model FLake simulations
forced by standard meteorological observations. Also, the evaporation was estimated from the empirical
equations. The sensitivity of the different methods to calculate evaporation, by the Dalton-type empirical
equation and by the atmospheric surface layer block of the FLake model, was studied. For endorheic lakes, the
sensitivity appeared to be large, up to 47% of the total seasonal water volume change, which assumes that
FLake has the potential to be used in hydrological applications to calculate evaporation.
Böeckella Lake, located in Hope Bay, northern Antarctic Peninsula, is a thermo-karstic lake surrounded by morainic deposits. The area has continuous permafrost with 80-100 m mean depth. This is a relevant location from the ecological point of view, containing one of the main Adelie penguin’s colonies. The natural lake recharge came from glacial melting water, direct precipitation and underground circulation from the surrounding moraines. The lake discharge from the lake was mainly by underground flow in the northern sector to the Böeckella stream. The lake has been the source of fresh water for the Argentinean Esperanza Base for more than 30 years. In order to increase the volume of stored water in the lake, its level was artificially increased by means of construction of a wall in the natural drain sector. During the 2009-2010 austral summer the closure of the lake broke, due to permafrost melting, and in a few hours the lake water discharged to the sea. The lake was replaced by a dry surface containing five ponds corresponding to the main natural lake depocenters. In this work, the causes and consequences of the mentioned event are analyzed, including the effects in the vegetation and animal colonies around the lake. Broader effects discussed are those connected with exposure to the atmosphere of stored organic matter, which started an oxidation process and CO₂ transference to the air.
Realistic, accurate estimates of future availability and vulnerability of water resources across the High Asia region are not possible without a better understanding of the current hydrologic regime. The amount, timing and spatial patterns of snow and ice melt play key roles in providing water for downstream irrigation, hydropower generation, and general consumption. Separating the specific contribution of seasonal snow (renewable) versus glacier ice (non-renewable) melt is the main goal of the Contribution to High Asia Runoff from Ice and Snow (CHARIS) project that focuses on the Ganges, Brahmaputra, Indus, Amu Darya and Syr Darya basins. Our methodology involves the application of MODIS-derived remote sensing products to calculate separately daily melt from snow and glacier ice. Using an automated partitioning method, we generate daily maps of:
1) snow over glacier ice,
2) exposed glacier ice, and
3) snow over land.
These are inputs to a temperature index (TI) model that yields melt water volumes contributing to river flow. Here we present a high-level summary of our overall methodology as well as preliminary results for the five full CHARIS basins. The western regions of High Asia are heavily reliant on snow and ice melt sources for summer dry season flow when demand is at a peak (15-20% specifically from glacier ice melt) whereas monsoon rainfall dominates runoff during the summer period in the east (< 5% from glacier ice melt).
Tibetan Plateau (TP) is referred as “Asian Water Tower” for the large amount of water storage and the wide-range influence on the downstream countries through a large network of rivers. In the water cycle, energy released from the phase change of water during precipitation is part of the elevated thermal effect on the weather and climate over the Northern Hemisphere. The study presents the relative contribution of internal and external water vapor to the precipitation based on basin-scale analysis over the TP. The result shows that the water vapor transportation varies depending on the circulation and terrain complexity. Overall, the atmosphere conveys about 60% of the water vapor condensation into the precipitation over the TP, whereas the local evapotranspiration contributes the rest 40%. Noted the reanalyses produced excessive precipitation over the TP, we also compare the water cycles in several reanalyses. The result could give some light on the errors of the reproducing the water cycle processes in reanalyses and be helpful to improve the performance of the model over TP.

Oxygen Stable Isotope Variability on the Pine Island Glacier Ice Divide

Ronaldo Torma Bernardo¹ (ronaldo.bernardo@ufrgs.br), Franciele Schwanck¹, Jefferson Cardia Simões¹, Douglas Introne²
¹UFRGS, CPC, Porto Alegre, Brazil, ²University of Maine, CCI, Orono, United States

This work reports the δ18O variability in the upper 45 m of a 92 m firn-ice core recovered from the West Antarctic Ice Sheet in the 2008/09 austral summer. The core site, called Mount Johns, is at 79°55'S; 94°23'W, 2122 m a.s.l., the 12 m temperature is -33 °C. The core was melted in a continuous melter system and the first 300 samples analyzed by IRMS at Climatic Change Institute, University of Maine. Further, 1500 samples were measured by laser spectroscopy at the Centro Polar e Climático Isotopes Laboratory. The medium value for these 1800 samples is 36.4 ± 1.9‰, ranging from -42.7 to -30.3‰, covering about 105 years of accumulation (i.e., about 0.21 m in water equivalent per year). The isotopic profile recorded at Mount Johns shows a warming trend similar to the ones observed in others West Antarctic Ice Sheet sector (WAIS) since the 1990s. These changes are directly linked to variations in the regional atmospheric circulation, we discuss these stable isotope ratios in term of changes in the moisture source areas.
The study aims in estimation of role of permafrost-related processes in runoff generation in continuous permafrost in Eastern Siberia. Terrain is elevated plain (100-500 m a.s.l.) with occasional uplands. The climate is cold and dry. Mean air temperature varies from -9 to -11°C, precipitation ranges from 270 to 310 mm/year. Main land cover types are slopes, uplands and thermokarst areas. Studied 18 river basins with areas 80 - 65400 km² were classified into three groups with distinct behavior:
1) with flow larger 100 mm/year and variation coefficient (Cv) lower 0.4;
2) transitional;
3) with flow lower 24 mm/year and Cv larger 1.1.
Rivers of the 1st group do not freeze up to the bottom and do not dry. Rivers of 2nd group freeze up to the bottom in winter but flow every year in warm season. Rivers of 3rd group could be frozen and/or dry for the whole year. Precipitation does not explain spatial and temporal variability of flow. Land cover analysis showed that rivers with high and stable flow have less than 4% of the watershed area subject to thermokarst. More than a half of basin areas of rivers with low and unstable flow are occupied by thermokarst. Study showed that permafrost conditions could play a larger role in runoff generation than hydroclimatic factors.

The study is partially supported by Russian Foundation for Basic Research, projects No 17-05-00926.
Glacier-climate interaction and its spatial variability over the Tibetan Plateau is still poorly understood. We present a new distributed glacier mass balance model applied on two glaciers of the Tibetan Plateau: Parlung No. 4 Glacier, 11.7 km², a temperate-maritime glacier, and Zhadang Glacier, 2.0 km², a sub-continental glacier. Enthalpy, rather than temperature, is used in the energy budget equations to simplify the computation of latent heat fluxes from water phase changes and the movement of liquid water in the snow. Two novel methods are used to distribute near-surface air temperature and wind speed from a set of Automatic Weather Stations (AWS). Further, we apply a new method to discriminate between solid and liquid precipitation based on daily mean air temperature, relative humidity, and elevation. Model results are evaluated by in-situ mass balance observations of the Parlung No. 4 Glacier and remote sensing products.

Our aims are to:

i) develop a novel enthalpy-based model and test its performance on the distributed simulations of glacier mass balance and energy budget;

ii) compare the physical processes typical of the summer season on two different types of glaciers on the Tibetan Plateau;

iii) identify the key model sensitivities at both study sites.

We present the interplay of precipitation thresholds, albedo and net radiation at these different glaciers and discuss their implications for future mass balance modelling on the Tibetan Plateau.
Stable water isotope content is widely used in paleo-climatolgy, glaciology and hydrology as a proxy of the precipitation formation conditions, water origin etc. In particular, the concentration of heavy isotopes is applied in hydrology for mass-balance studies, to assess contribution of different water sources and other issues. Understanding the isotopic transformations of water during the hydrological cycle requires precise knowledge of the fractionation coefficients. While for deuterium and oxygen 18 these coefficients are known within satisfactory uncertainty, this is not the case for the oxygen 17 fractionation coefficients.

In this study, we use a unique opportunity provided by the hydrological system of Antarctic subglacial Lake Vostok, where the lake water is slowly frozen in equilibrium conditions to form the accreted lake ice underneath the Antarctic ice sheet. We have precisely measured the isotopic composition (including oxygen 17 concentration) in the accreted lake ice and water, which for the first time allowed us to directly obtain robust values of oxygen 17 fractionation coefficients during water freezing. It has been demonstrated that the ratio between 17O and 18O fractionation coefficients during water freezing differs significantly from the value known for evaporation and sublimation processes. We use these new findings to re-assess the characteristics of Lake Vostok water mass balance.
Impact of Topography on Snowfall, Assessed by a Dual-pol Radar

Nikola Besic¹² (nikola.besic@epfl.ch), Franziska Gerber¹²³, Daniele Nerini², Yvan Chevalley¹, Loris Foresti², Jordi Figueras i Ventura², Marco Gabella², Urs Germann², Michael Lehning¹²³, Alexis Berne¹

In this contribution we analyse the impact of topography on snowfall, in terms of variability and microphysics, by interpreting polarimetric radar data. The former is related to the dynamics i.e. growth and decay analysis of the snowfall precipitation field, while the latter is related to the 3D hydrometeor classification in precipitation. The analysis focuses on the region around the Weissfluhgipfel (WFG) radar, in the vicinity of Davos, Switzerland.

The growth and decay analysis is based on the advection (semi-Lagrangian scheme) of the snowfall field and the comparison with the following actual measurement. Basically, we shift the precipitation field as if it was not affected by the local topography and then compare it with the measurement which obviously accounts for the micro-scale influence.

The applied hydrometeor classification is a semi-supervised approach, adapted to the technical specificities of a radar, capable of distinguishing between 9 different hydrometeor classes, among which rimed ice particles, aggregates (AG), crystals (CR) and vertical ice.

Links of both variability (snowfall growth) and microphysics (intense riming + AG/CR co-occurrence) observation to the local topography are assessed through multi-scale wavelet analysis. The analysis shows an interesting correspondence between the zones of snowfall growth on one side and the zones of relatively more intense riming and AG/CR co-occurrence on other side.
Liquid and solid precipitation are important climatic variables in the Arctic that are expected to have undergone significant changes in the past and will undergo further changes due to the changing climate. However, only a few in situ data sets of these variables are currently available in the Arctic. Due to the long history of monitoring activities Ny-Alesund, Svalbard offers the possibility to generate a quality-controlled data set that may serve as a reference of precipitation for the analysis of the impact of a changing climate on the hydrological cycle, on cryospheric processes, on atmospheric chemistry, or on the properties of the soil. However, it is well known that standard gauges to measure precipitation can strongly be biased especially in the case of solid precipitation. We will present our recent work on the correction of observed precipitation in Ny-Alesund for arctic conditions and how these corrections modify the recorded data. Moreover, the uncorrected and corrected precipitation time series will be analyzed regarding parameters like total accumulation, number of events, modification of precipitation phase, and strength and frequency of extreme events.
Glacial lake outburst floods are among the most serious natural hazards in the Himalayas. Such floods are of high scientific and political importance because they exert trans-boundary impacts on bordering countries. The preparation of an updated inventory of glacial lakes and the analysis of their evolution are an important first step in assessment of hazards from glacial lake outbursts. Here, we report the spatiotemporal developments of the glacial lakes in the Poiqu River basin, a trans-boundary basin in the Central Himalayas, from 1976 to 2010 based on multi-temporal Landsat images. Studied glacial lakes are classified as glacier-fed lakes and non-glacier-fed lakes according to their hydrologic connection to glacial watersheds. We found that lakes connected to glacial watersheds (glacier-fed lakes) significantly expanded from 1976 to 2010, whereas lakes not connected to glacial watersheds (non-glacier-fed lakes) remained stable during the same period. This contrast can be attributed to the impact of glaciers. Retreating glaciers not only supply meltwater to lakes but also leave space for them to expand. Compared with other regions of the Hindu Kush Himalayas (HKH), the lake area per glacier area in the Poiqu River basin was the highest. This observation might be attributed to the different climate regimes and glacier status along the HKH. The results presented in this study confirm the significant role of glacier retreat on the evolution of glacial lakes.
Persistent organic pollutants (POPs) are chemicals with long-lifetime in the environment, and therefore have the potential to be transported over long distances.

As the environmental behaviour of POPs depends on complex interaction of many factors, any significant environmental alteration is likely to affect their distribution and fate; temperature as well as many other mechanisms are known to influence their distribution in the environment.

Sea ice, as well snow melting, can be well considered an indicator of climate change and it is also a significant POPs reservoir, and influences the contaminant dispersion through the sea ice trajectories.

Kongsfjorden is situated in the northern part of Spitsbergen island (Norwegian Arctic). Surface and depth water, as well as sediments, were collected at four sites during three sampling campaigns between June and September 2012, which means before, during and after ice and snow melting. The sampling stations were characterized by different degrees of glacial “runoff” and different anthropogenic impact.

The present investigation reveals the results of the analysis of the samples for their PAH, OCP and PCB content. Twelve of 16 studied PAHs, seven of 29 PCBs and four of 14 OCPs were determined in the sea waters. Total PAH, PCB and OCPs concentrations in the sea waters were from 50 to 500 ng/L, 5 to 30 ng/L and 10 to 150 ng/L respectively.
An Assessment of the MAR Regional Climate Model over High Mountain Asia

Melissa Linares¹ (melinares2@gmail.com), Marco Tedesco¹,², Steve Margulis³, Jeyavinoth Jeyaratnam¹,⁴, Patrick Alexander¹, Xavier Fettweis⁵

¹Lamont-Doherty Earth Observatory Columbia University, New York, United States, ²NASA Goddard Institute of Space Studies, New York, United States, ³UCLA, Department of Civil and Environmental Engineering, Los Angeles, United States, ⁴City College of New York, New York, United States, ⁵Université de Liège, Department of Geography, Liège, Belgium

The lack of ground measurements has made the use of remote sensing, atmospheric reanalysis and modelling tools over the High Mountain Asia (HMA) pivotal for understanding the impact of climate change on the hydrological cycle and on the cryosphere. Here, we show the results of the analysis of the assessment of the outputs of Modèle Atmosphérique Régionale (MAR) model RCM over the HMA region as part of the NASA-project 'Understanding and forecasting changes in High Mountain Asia snow hydrology via a novel Bayesian reanalysis and modeling approach'.

We compared the MAR outputs with reanalysis data from ERA-Interim over the region bounded by the following coordinates: 66°E to 89°E and 21°N to 39°N. In particular, we evaluated the following parameters: surface pressure, snow depth, total cloud cover, two-meter temperature, wind speed, surface new solar radiation, skin temperature, surface sensible heat flux, and surface latent heat flux. The level of agreement between the RCM outputs and the reanalysis highly depend on the specific parameters. For example, in case of surface pressure the maximum percentage error is 13.24% while the 2-m air temperature has a maximum percentage error of 340.62%.

Lastly, we report results concerning the assessment of MAR surface albedo and surface temperature over the region through MODIS products. Next steps are to determine whether RCMs and reanalysis datasets are effective at capturing snow and snowmelt runoff processes.
Multiyear Observations on Stable Isotopes of Surface Snow along CHINARE Transect

Tianming Ma¹,² (matianming@pric.org.cn), Yuansheng Li², Li Li¹, Chunlei An², Guitao Shi², Hongmei Ma², Su Jiang²

Water stable isotopes from Antarctic surface snow have long been used to understand physical processes occurring in hydrologic cycle. In this study, a dataset including new measurements and previous observations is presented here for the determination of water isotopic composition along the traverse from Zhongshan Station to Dome A, East Antarctica. All 661 samples were collected in 7 field seasons by Chinese National Antarctica Research Expedition. The spatial distribution of δ¹⁸O and δD show significantly decrease tendency from coastal to inland regions, with a latitudinal gradient of -2.42 ‰/degree (r²=0.85), an altitudinal gradient of -1.02 ‰/100m (r²=0.85), a temperature gradient of 0.95 ‰/°C (r²=0.85). In addition, the accumulation, moisture source, transportation paths and post-depositional effects are also possible to have an association with spatial variability of water stable isotopic ratios. To disentangle the complicated influences on water isotopic composition of surface snow samples, the Hysplit trajectory model combining with MCIM model are used to calculate δ values during snowfall process. The results indicate that the moisture source of each region is completely different. Simulated experiments under various temperatures were conducted to reveal sublimation and isotopic exchanges between snow and air. This comparison suggests the isotopic composition of surface snow on coastal region may get a more impact by post-depositional processes than other regions.
This work investigates the concentrations the major ionic and the stable isotope variability in a 42.92 m firn core (called IC-2) collected at 88°01´21.3"S, 82°04´21.7"W (2,621 m a.s.l.) in the West Antarctic sheet, during a Chilean-Brazilian traverse in the 2004/05 Austral summer. We subsampled the core using a continuous melting system at the Climate Change Institute (CCI, University of Maine, USA) under a Class 100 room conditions. This process generated 1,755 samples (about 40 samples by meter) for ionic chromatography determination Na⁺, K⁺, Mg²⁺, Ca²⁺, MS (CH₃SO₃⁻), Cl⁻, NO₃⁻ e SO₄²⁻. We used a Picarro system (Wavelength-Scanned Cavity Ring Down Spectrometer, WS-CRDS) for determining the δ¹⁸O and δD in each sample. The mean δ¹⁸O is -46.45‰ (ranging from -50.77‰ to -41.40‰); while the mean δD is -369.68‰ (ranging from -408.18‰ to -323.85‰). The deuterium excess (d) varies from -5.84‰ to 9.23‰ (mean = 3.74‰). The first 800 samples (the upper 23 m) show a mean snow accumulation rate of 0.40 m y⁻¹ in eq. H₂O, corresponding to about 32 years of precipitation. The ionic analysis of the first 200 samples show a strong predominance of H⁺ (2.52 µEq L⁻¹), indirectly calculated through the ionic balance, indicating an acid contribution, and low concentrations of NO₃⁻ (68.52 ± 31.39 µg L⁻¹) (Lindau et al., 2016), probably resulting from post-depositional effects (glaze ice is observed in the area).
Spatio-temporal Variations of Firn Properties on the Western Greenland Ice Sheet

Regine Hock¹ (rehock@alaska.edu), Giovanni Corti², Federico Covi¹, Takao Kameda³, Jonny Kingslake⁴, Sasha Leidman⁵, Clement Miege⁵, Asa Rennermalm⁵, Steve Munsell⁶, Marco Tedesco⁴

¹University of Alaska Fairbanks, Geophysical Institute, Fairbanks, United States, ²Reed College, Portland, United States, ³Kitami Institute of Technology, Koencho, Japan, ⁴Columbia University, New York, United States, ⁵State University of New Jersey, Piscataway, United States, ⁶Prescott College, Arizona, United States

On the Greenland ice sheet a significant portion of surface melt percolates, refreezes, or is stored in porous firn. However thick (>5 m) ice layers in the ice sheet, now present at lower elevations, can seal off underlying porous firn, forcing meltwater to generate runoff instead of refreezing. Using five 20-26 m firn cores collected 40 to 100 km apart (1963 to 2355 m a.s.l.) in spring 2017 in addition to GPR data, automatic weather stations and ice temperature profiles, we investigate stratigraphy and spatio-temporal variation of firn properties in the Kangerlussuaq sector of the western Greenland ice sheet. We find significant spatial variability in firn properties on both large and small scales. For firn cores extracted at the lowest elevations thick (>1 m) ice lenses are present in the upper portion. The fraction of ice lenses for the upper 20 m of the cores ranged from 10% to 55%. A short core (5 m) drilled 16 m away from one of the longer cores shows significant small-scale variability in the distribution of ice lenses. Comparing 2017 core data to legacy data from 1989 at one drilling site shows a substantial increase in mean firn density and the size and number of ice lenses.
Analysis of IceCube and QualitySpec Trek Derived Snow SSA Measured in Sodankylä

Leena Leppänen1 (leena.leppanen@fmi.fi)
1Finnish Meteorological Institute, Sodankylä, Finland

Snow microstructure is important for microwave and optical remote sensing of snow. One parameter describing it is specific surface area (SSA), which is defined as volume to surface area ratio of snow grains. Several measurement methods are developed to measure it, including reflectance derived methods, as reflectance at NIR and SWIR wavelengths is sensitive to grain size and therefore SSA. IceCube (A2 Photononic Sensors, France) is developed to SSA measurements and it measures hemispherical reflectance of 1310 nm laser from the snow sample surface. Method is presented to be accurate (10 % error) but it needs removal of the snow from snowpack during the sampling. Recently developed hand-held QualitySpec Trek (QST, ASD Inc., US) measures spectral reflectance of 350-2500 nm with direct contact to the object.

The collected data set includes measurements of vertical snow profile with IceCube and QST during five days between February and April 2017 in Sodankylä in Finland at research station of Finnish Meteorological Institute. Some of the IceCube samples were measured also with QST. Preliminary results shows usability of QST for SSA observations, thus error seems to be larger than for IceCube. QST observations confirms also that reflectance measured from IceCube samples differs little from reflectance measured directly from the snowpack at the same height.
Wind-packing of Snow in Antarctica

Christian Sommer\textsuperscript{1,2} (sommer@slf.ch), Nander Wever\textsuperscript{1,2}, Charles Fierz\textsuperscript{1}, Michael Lehning\textsuperscript{1,2}
\textsuperscript{1}WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland, \textsuperscript{2}École Polytechnique Fédérale de Lausanne, School of Architecture, Civil and Environmental Engineering, Lausanne, Switzerland

A snowfall and subsequent drifting snow event were observed in Antarctica. The event was similar to recent wind tunnel experiments on wind-packing of snow and could therefore be used to compare wind-packing in Antarctica with those experiments. The results from Antarctica were similar to those from the wind tunnel. Drifting snow is necessary for wind-packing and the hardening is more efficient at wind-exposed surfaces than in wind-sheltered areas. The results show that the insight gained from the wind tunnel experiments are applicable in nature. Furthermore, it is demonstrated for the first time how fresh snow gets organized in Barchan dunes during subsequent drifting with significant increase in surface hardness at all locations on the dune. This quantitative analysis of surface and associated hardness change improves our understanding of Antarctic snow deposition.
The Challenge of Automatic SWE Measurements in High Altitudes

Christoph Marty¹ (marty@slf.ch), Charles Fierz¹, Alain Geiger², Franziska Koch³, Wolfram Mauser³, Ladina Steiner²
¹WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland, ²ETH / IGP, Zurich, Switzerland, ³LMU, Munich, Germany

Information about the available snow water equivalent (SWE) of a snow pack is valuable for many applications including the validation of remote sensing data, flood forecasting, designing buildings for snow loads and assessing changes in snow water resources in mountain catchments. The measurements of SWE are particularly important in mountain regions where measuring winter precipitation by conventional rain gauges is problematic due to wind under-catch. Manual measurements of SWE are time consuming and therefore often only performed on monthly time-intervals. The automatic measurement of SWE in Alpine terrain is not reliable despite the fact that some commercially available devices are on the market. These devices often need either regular calibration, complicated post-processing or are limited by a maximum SWE they are able to measure.

We use a multi-year data set from the high alpine experimental site Weissfluhjoch at 2540 m asl, where the mean maximum measured snow depth is 240 cm. On this site SWE has been measured manually in a snow pit and simultaneously by a snow pillow, a snow scale, a ground penetrating radar and GPS receivers.

We assess the different SWE measurement methods during the typical seasonal evolution of the snow pack and compare it with state-of-the-art parameterization and modelling approaches.

Synchronizing Borehole Depths to a Temperature Time Series

Jandyr Travassos¹ (wavefrontgeo@gmail.com), Mariusz Potokii, Jefferson Simoes¹, Pedro Carvalho¹
¹UFRJ, COPPE, Rio de Janeiro, Brazil, ²University of Maine, Climate Change Institute, Orono, United States, ³UFRGS, NUPAC, Porto Alegre, Brazil

The Plateau Detroit divides the warmer and moist west side from the colder and drier east side of the Antarctic Peninsula and has a very high deposition rate. We use hydrogen peroxide concentration with a high resolution sampling, averaging 36 samples/year from a 98m borehole as a robust seasonal marker. We found the hydrogen peroxide concentration to be well preserved in that high accumulation site. We have also estimated a daily temperature time series at the site by using daily records from four Antarctic Stations forming a polygon having the borehole in its interior. Both records, hydrogen peroxide concentration and daily temperature, follow the same seasonal variation, the passing of years, but in a different fashion. The former has a frequency scaling in relation to the former. As the temperature has a constant spectral contents we compensate the peroxide frequency scaling by a non–linear pairing transformation based on mathematical optimization, without human intervention. That pairing allows for the estimation of a relation of depth to time; a chronology for the borehole data chronology spanning from 01-Jan-1980 to 29-Dec-2010. The estimated borehole chronology suggests that at least the first 109.29m were accumulated within a time frame spanning a mere 30 years period. This points to a deposition rate of 2.7m(weq)/year, or 2.5 times the accumulation rate found at Gomez, further South.
Snow Microstructure Evolution in Presence of Mineral Dust

Marie Dumont¹ (marie.dumont@meteo.fr), Frédéric Flin¹, Pascal Hagenmuller¹, François Tuzet¹, Isabel Peinke¹, Philippe Lapalus¹, Anne Dufour¹, Jacques Roulle¹, Laurent Péizard¹, Sabine Rolland-du-Roscoat²
¹Météo-France - CNRS, CNRM/CEN, Grenoble, France, ²UGA - Grenoble INP - CNRS, 3SR, Grenoble, France

Light absorbing impurities in snow such as black carbon or mineral dust are known to decrease snow albedo. This engenders several positive feedbacks generally leading to an acceleration of snow metamorphism. Though many studies have been focused on measuring, modeling and quantifying the radiative impact of light absorbing impurities in snow, only a few have been focused on the non-radiative impact of such impurities and especially on the impact of the presence of impurities directly on snow metamorphism.

In this study we present ‘in vivo’ X-ray tomography monitoring of snow microstructure containing mineral dust (desert sand with size distribution centered at 1 micron) under several conditions and especially under temperature gradient metamorphism. Snow microstructure evolution along with the change in the spatial distribution and exact location of the dust particles observed during such an experiment are especially relevant to understand metamorphism/impurities interplays for arctic snowpacks that frequently undergo high temperature gradient metamorphism.
Rapid Measurements of the Snow Surface Specific Area using the ASSSAP Instrument

Laurent Arnaud¹, Ghislain Picard⁴ (ghislain.picard@univ-grenoble-alpes.fr), Eric Lefebvre⁴

¹Institut des Géosciences de l’Environnement, Saint Martin d’Hères, France

The surface specific area is a snow properties defined as the surface area of the air-ice interface per unit of mass. It has become in a decade a variable of choice to predict snow optical and microwave behavior and to quantitatively simulate snow metamorphism allowing significant progresses. The development of instruments and protocols to rapidly take accurate measurements of SSA in the field has greatly contributed to this emergence.

ASSSAP, the Alpine/Arctic/Antarctic Snow Specific Surface Area Profiler, is an instrument designed to measure profiles of SSA at 1 cm resolution in 1-2 meter long boreholes. It estimates SSA from measured snow reflectance at two wavelengths (1310 nm and 850 nm). It uses laser diodes and photodiodes as the sole optical elements and basic embedded electronics which is very robust and is able to operate at -40°C. It allows 4 modes of operation:

i) in-situ measurements of profiles in boreholes directly
ii) measurements on samples, in the field or in the lab, with a sampler holder compatible with IceCube
iii) in-situ nondestructive 1-2 meter long transects of SSA of the snow surface,
iv) measurements of profiles along 1-m snow cores in the lab.

The profiles and transects are measured in a matter of minutes, and are equivalent to about 100 independent measurements. Measurements on sample takes about 30 s. The accuracy has been shown to be around 15% in a well controlled experiment but our experience suggests that this depends on conditions.
Results from COST ES1404 Action for Harmonization of Snow Measurements in Europe

The COST Action ES1404 entitled “A European network for a harmonized monitoring of snow for the benefit of climate change scenarios, hydrology and numerical weather prediction” aims to enhance and harmonize the observations of European operational services and the snow research community. This presentation illustrates the results of the Action activities related to the harmonization of in situ snow observations and instrumentation, to establish quality-assured and comparable regional and global observation-based data on the variability of depth, structure and other physical properties of snow cover. Members of the Action designed a survey carried out among European institutions on measured snow parameters and applied instrumentation. It was answered by 125 groups from 38 European countries, providing a compilation of the measurement practices applied by different communities and in various environments and regions. In addition, the Action organized two field measurement campaigns in Turkey in March 2016 and in Iceland in February 2017 dedicated to the measurements of two essential snow variables, snow water equivalent (SWE) and snow depth (HS). The results contains the comparison of SWE and HS measurement techniques including error analysis aiming to develop instrument recommendations for range of environmental conditions. The Action included several workshops and Short term Scientific Missions that strengthened networking and co-operation among the participating countries.
In recent years, increasing melt on the Greenland ice sheet (GrIS) has caused significant changes in percolation regimes in GrIS’s firn. Aquifers have grown in some regions and impermeable ice slabs are forming in others, which directly affect runoff. The effects of refrozen melt water have been observed in firn cores, but continuous high-resolution data has not yet been available to document the nature of these changes as they happen. Very little is known about percolation depths, liquid water content, refreezing and seasonal mass fluxes, and vertical versus horizontal flow of water in areas where refrozen melt water is becoming the dominant regime in near-surface firn. To overcome this deficit and provide continuous data for model evaluations, we installed impulse radar systems at 3 locations in various glacier regimes: at the transition zone from accumulation to ablation (Swiss Camp), within the deep percolation regime where meltwater inputs are steadily increasing (Dye-2), and in the dry snow zone (Summit). For summer 2016, we compare monitored changes within snow and firn at these locations with spatial extent and duration of melt over the GrIS from remote sensing data. Such comparisons provide valuable information on water retention and percolation at certain glacier regimes of the GrIS. Linking the detail of in situ data at select sites with the spatial melt extent supports a more comprehensive interpretation of changes occurring within meltwater regimes over the GrIS.
Inter-comparison of Direct Observations of Snow Grain Size

Roberta Pirazzini1 (roberta.pirazzini@fmi.fi), Charles Fierz2, Teruo Aoki3, Henna-Reetta Hannula4, Leena Leppänen4

1Finnish Meteorological Institute, Meteorological Research, Helsinki, Finland, 2WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland, 3Okayama University, Graduate School of Natural Science and Technology, Okayama, Japan, 4Finnish Meteorological Institute, Arctic Research, Sodankylä, Finland

This work focuses on snow grain size data measured during the MicroSnow workshop held in March 2014 in Davos, Switzerland. The workshop was motivated by the recent development of new techniques to measure the snow microstructure, and aimed to quantify the differences among the various existing methods. The main objective of this study is to describe direct grain size measurements techniques, which include visual grain size estimation and calculation of the grain size from macro-photos using image processing software, and inter-compare the obtained measurements. Each of the inter-compared method applies a specific grain size metric, which is linked to the original application of the method: traditional visual estimations were developed by snow scientists to characterize the snowpack, e.g. for hydrological and avalanche forecast purposes. The Aoki grain size and the short skeleton metric are used to represent the optical properties of the snowpack when studying its interaction with the visible and near-infrared solar radiation. Finally, grain metrics that represent the dimension of the aggregated crystals are applied to represent the upper edge of grain size distribution in the simulation of the radiative transfer in the snow. In this work we assess differences between the used grain metrics, also in relation to other microstructure quantities such as specific surface area and optically equivalent grain size, evidencing merits and shortcomings of the applied methods.
Water isotopic composition from ice core is a key proxy for past climate reconstructions. In particular, the longest climatic records from ice core are obtained from the low accumulation areas of the East Antarctic Plateau. Still, the low accumulation which enables long term records implies a longer exposure of the surface snow to the atmosphere, and thus, a more significant role of post-deposition processes. This limits the interpretation of isotopic composition from ice core records, specifically at short time scales.

Here, we compare series of surface snow isotopic composition from East Antarctica to grain index satellite observations, highlighting that during intense summer metamorphism events, the climatic signal in the surface snow isotopic composition is erased. Still, we observe a signature of these events left in surface snow $^{17}$O-excess. We compare the evolution of surface snow isotopic composition in between precipitation events to the first measurements of $^{17}$O-excess in the vapour in Antarctica to estimate the mass balance and the associated fractionation. These results provide new applications for $^{17}$O-excess as a tracer of post-deposition processes.
In order to better understand the relationship between the firn layer and the underlying ice, a seismic refraction experiment was carried out on the Amery Ice Shelf in Eastern Antarctica. The experiments aimed to reveal a detailed view of the subsurface structures and physical properties both in the direction of flow and perpendicular to it. Several surveys were carried out along and across the shear margin of two ice units that originated from the Lambert Glacier and the Mawson Escarpment Ice Stream. The firn is an important component of ice sheet dynamics, as the firn’s anisotropy provides an indication of where the ice is undergoing deformation.

Seismic velocity is directly related to mechanical properties. An increase of anisotropy leads to differences in seismic velocity when measured in different directions. We use this to determine the degree of anisotropy for the surveyed area. The seismic velocities is calculated by applying the 1D inversion algorithm of Wiechert-Herglotz-Bateman to the data. We find that the seismic velocity of the firn exhibits anisotropic behaviour in both surveyed directions:

The degree of anisotropy decreases in flow-direction (along the shear margin). Across the margin (across-flow) the degree of anisotropy is higher on the ice unit closer to the ice shelf boundary, with the highest values being found above the shear margin. The ice unit further away from the ice shelf boundary exhibits only small anisotropic behaviour.
Modeling the surface mass balance (SMB) from long-term climate simulations with Earth System Models (ESMs) remains a major challenge, specifically due to the required downscaling from coarse resolution atmospheric data onto high-resolution topographies. We present a sophisticated energy balance model (EBM) to calculate and downscale the SMB for multi-millennial simulations. The EBM accounts for changes in the snow albedo due to varying snow properties (age, depth, melting and refreezing of water) and cloud cover, as well as key physical processes like percolation and refreezing of melt water. The atmospheric forcing is obtained from simulations with the Max-Planck Institute Earth System Model (MPI-ESM).

To evaluate its performance, the EBM is used to calculate the SMB based on the MPI-ESM CMIP6 historical simulation and shows good agreement with reconstructions from regional climate modeling (RACMO and MAR). To estimate the SMB changes throughout the last deglaciation, the EBM is forced with a transient simulation with MPI-ESM in coarse resolution. For the latter, MPI-ESM is run with prescribed ice sheets and topography and accounts for changes in river directions, ocean bathymetry and land sea mask due to the retreating ice sheets and isostatic adjustments. In this presentation, we not only depict the challenges of modeling the SMB from coarse resolution climate data but also highlight the benefits of using a sophisticated EBM for long-term simulations.
Snow avalanches are a persistent risk for Alpine infrastructures. Cost-effective strategies for risk mitigation invariably require avalanche forecasting tools, based upon the knowledge of the physical parameters of the snow cover (depth, density, liquid water content, etc.). Currently, the most common measuring method for these parameters is the manual analysis of snow cover, through in-situ excavation of snow pits. This method, although time-consuming, is usually very accurate, but for safety reasons it cannot be applied when and where most needed (along critical slopes, under bad weather conditions).

To get around these constraints, systems based on microwave radars have been proposed. Such systems can deliver a rapid, non-destructive, and possibly automatic analysis of the snow structure. While very promising, standard radar architectures cannot deliver, without external aids, measures of the snow depth and physical parameters at the same time, thus strongly limiting the accuracy and applicability of this approach.

This paper presents a novel radar architecture, called SNOWAVE, capable of simultaneously measuring the propagation distance and wave speed, and possibly also attenuation in the medium. This way, snow depth, density, and possibly liquid water can be estimated at the same time. Experimental results from field test at elevations above 2500 m in the Italian Alps (Valle d’Aosta) are also presented to show the feasibility and potential of this innovative approach.
The marginal zone is of importance for accumulation and melt of the Greenland Ice Sheet. We measured snow water equivalent (SWE), snow depth and snow stratigraphy along a transect of 100 km length between Crawford Point 1 and Swiss Camp. The transect extended from the edge of the dry zone to the ablation facies (Benson, 1962). We measured the snow stratigraphy every 5 km by a high-resolution penetrometer (SnowMicroPen), besides to conventional snow pit records every 10 km. In addition, a ground-penetrating radar (GPR) system (1.3 GHz) was towed by skis to resolve the spatial variability of seasonal SWE along the transect. We found that end-of-winter SWE slightly decreased from about 500 mm to 400 mm along the transect. More surprisingly, we found quite large fluctuations of SWE between 350 and 550 mm along the GPR-record which we analyzed by variograms. We propose that point SWE-measurements in this zone should be complemented with GPR-measurements to arrive at unbiased SWE estimates and its spatial variation. In addition, SnowMicroPen measurements are found to be essential to keep track of the rather complex stratigraphy.

Sensitivity Experiments for the Impact of Metamorphism on Signals in Polar Snow

Matthias Jaggi1, Henning Löwe1 (loewe@slf.ch), Martin Schneebeli1, Ghislain Picard2, Laurent Arnaud2, Amaelle Landais3

1WSL Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland, 2Institut des Géosciences de l’Environnement, Saint Martin d’Hères, France, 3Laboratoire des Sciences du Climat et de l’Environnement, Gif-sur-Yvette Cedex, France

Under prevailing temperature gradient metamorphism in near-surface snow, the ice matrix may undergo full recrystallization via sublimation-deposition cycles, with potential consequences for the formation of climatic signals in polar snowpacks. Polar field studies naturally focus on the in-situ evolution of snowpacks, thereby facing unavoidable difficulties of discerning controls from stratigraphy, spatial variability or the atmosphere. In contrast, ex-situ laboratory studies on metamorphism are able to reasonably constrain the forcing, but were hitherto limited to small, homogeneous samples which hinders an understanding of stratigraphic variability. To bridge the gap between typical lab and field conditions we developed a portable rack of macroscopic metamorphism boxes in which large (0.4 x 0.4 x 0.3 m³), stratigraphically heterogeneous snow blocks can be subjected to different temperature forcing under sealed conditions after excavation from the natural snowpack. The experimental setup enables to conduct ex-situ sensitivity experiments for the evolution of signals (microstructure, isotopes, etc) if combined with an a posteriori comparison to the concurrent in-situ dynamics. In this contribution we present the design of the experiment and report preliminary results from the first deployment at Dome C during the Antarctic Summer 2017/2018 to detail the role of metamorphism within the project “Snow properties evolution in a changing climate in Antarctica”.
The delta O-18 records of ice cores are used as a proxy for temperature fluctuations. However, the processes leading to the final embedding of the measured ratio of O-18 to O-16 are not completely understood: Snow with a certain delta O-18 is deposited on the ground during snowfall. Snow close to the surface is exposed to high temperature gradients and therefore metamorphoses by high water vapor fluxes. These fluxes alter the ratio of stable water isotopes after deposition. It has also been shown that advective fluxes (wind) contribute to a change in isotope ratio. Therefore, it is of high importance to better understand these processes for the interpretation of ice core data. We investigated these effects in the upper snowpack at a field site above Davos, Switzerland. From January to May 2017 we sampled weekly the top 20 cm of the snow. Monthly, we sampled the complete profile of delta O-18 with a vertical resolution of 6 cm. In parallel, we continuously measured the delta O-18 signal in the air. In addition, the full energy balance is known, as well as microstructural properties of the snow (density, SSA). First results showed that delta O-18 in the surface snow is generally lower than in the simultaneously measured air. This can be explained by equilibrium fractionation of the snow. Some events also showed an enrichment in the snow surface in absence of precipitation. We assume this is due to predominant fractionating sublimation.
Continuous Sensing of Snow Water Equivalent Using Natural Gamma Radiation

Jaakko Mäkinen¹ (jaakko.makinen@nls.fi), Arttu Raja-Halli¹, Heikki Virtanen²

¹Finnish Geospatial Research Institute, Masala, Finland

Since 2014 we have been using the Campbell CS725, an instrument based on the attenuation of the natural gamma radiation of the soil to record the water equivalent of snow (SWE) at the Metsähovi Geodetic Research Station, Kirkkonummi, near Helsinki, Finland. The snow in this area is seasonal, the snow cover lasting 4 months with peak SWE of 100 mm on the average (1981-2010). The purpose of the measurements is to provide a correction for the attraction of the snow mass to the continuous record of variation in gravity of the superconducting gravimeter (SG) at the site. The SG has sensitivity better than 0.1 ppb for step-type changes in gravity, corresponding to the attraction of a water layer of 2 mm. However, the presence of the laboratory building modifies considerably the response as there is no snow under the SG and instead the snow stays on the roof producing a component in the direction opposite to the attraction of the snow on ground. We compare the record of the gamma device with manual sampling using the Korhonen-Melander snow sampler and meteorological observations, and discuss whether the gravity record in turn could be used to infer changes in SWE.
Despite contributing up to 50% of atmospheric aerosol concentration (Jimenez et al., 2006), detection and understanding of organic compounds in ice cores is not as well developed as their inorganic counterparts. Two groups of organic compounds emitted from the marine and terrestrial biosphere, fatty acids and terpene secondary oxidation aerosols (SOAs), display characteristics suitable for ice core paleoclimate reconstruction. Emission rates depend on ambient atmospheric conditions and/or plant species, compounds survive long-distance transport in the atmosphere to high latitudes (Fu et al., 2013, Pokhrel et al, 2016, among others), and some compounds are shown to survive in ice layers up to 450 yrs old (Kawamura et al., 1996).

Contamination potential for these organic compounds, from various media used in the core drilling and analysis process, is quantified. A single, robust method of quantification for trace levels of compounds is developed, including preconcentration of samples and analysis with high resolution liquid chromatography - mass spectrometry (HPLC-MS).

These methods are finally used to test shallow snow and ice core samples representing both dominant terrestrial and marine aerosol input locations (identified using back-trajectory analysis). We present a first inventory of chemicals found in detectable amounts in locations including the Altai Mountains (Russia), Antarctic Peninsula, and sub-Antarctic island cores collected on the recent ACE Expedition.
Santiago, Chile is a South American mega-city with very high levels of air pollution despite the introduction of contamination reduction measures in the past 20 years. The city relies heavily on glacier and snow melt for its supply of fresh water during spring and summer. However, it is unclear how much of an impact the Santiago pollution plume has on nearby high-altitude glaciers.

We have identified the major sources of air contamination, their chemical profiles, and their temporal evolution since 1998 through analysis of urban air filters. Since 2016 we have collected tree samples from the mountain slopes and firn cores from the glaciers on top of the mountains. The comparison of anthropogenic contaminant profiles in tree and firn samples allows an estimation of the altitudinal reach of the Santiago pollution plume.

Here we show contaminant measurements from several firn cores drilled in glaciers downwind from Santiago between 4000 and 5200 m. We show that urban contaminants do reach the highest peaks near Santiago. However, the very high recent summer temperatures produce surface melt that mixes with underlying layers in all but the highest mountain glacier above 5000 m. We therefore compare only this high-altitude firn core record with contaminant time series from urban air filters and mountain slope dendrochemistry measurements.
The “Isotopic Constraints on Past Ozone Layer in Polar Ice” (ISOL-ICE) project is investigating the variability of past ultraviolet radiation and the ozone layer over the past 1000 years using a combination of ice cores, atmospheric measurements and numerical models. The ultraviolet radiation proxy, based on stable isotopes of nitrate, is being applied to a new 120 m ice core that was recovered from Dronning Maud Land, Antarctica in the 2016-17 Antarctic field season. During the field season, continuous atmospheric measurements of nitrogen oxides, turbulent flux and down-welling irradiance were also made. The first step to apply the new ultraviolet radiation proxy to the ice core record is to evaluate the regional air-snow transfer and post-depositional changes in nitrate and its stable isotopic composition. Here we present the nitrate isotopic composition and concentration of daily aerosol and surface snow from Dronning Maud Land throughout January 2017. We compare these observations to existing data sets in Terre Adelie and Dome C, another low accumulation region on the high elevation East Antarctic Ice Sheet.
Ancient air trapped in ice core bubbles is a key source of information about past climate and atmospheric composition. Before air bubbles become isolated in ice, the atmospheric signal is altered in the firn column by transport processes such as advection and diffusion. However, the influence of impermeable layers and barometric pumping (driven by surface pressure variability) on firn air transport is not well understood and cannot be captured in conventional 1-dimensional firn air models. Here we present a 2-dimensional (2D) trace gas advection-diffusion-dispersion model that accounts for discontinuous horizontal layers of reduced permeability. We find that layering and barometric pumping individually yield too small a reduction in gravitational settling of trace gases to match observations. In contrast, a combination of both processes strongly supresses gravitational fractionation. Layering focuses airflows in the 2D model and thus amplifies the dispersive mixing resulting from barometric pumping. Hence, the representation of both factors is needed to match the well-known observation of an interval of zero gravitational settling in the lock-in zone. Moreover, we find robust scaling relationships between kinetic isotope fractionation of different noble gas isotope and elemental ratios. These relationships may be used to correct for kinetic fractionation in future high precision ice core studies.

²National Centre for Antarctic & Ocean Research, Polar Sciences, Vasco da Gama, India

Atmospheric dust is known to be a significant influence to the global climatic variability. The present study uses a high-resolution dust flux record of an ice core retrieved from the central Dronning Maud Land of East Antarctica to identify the factors controlling the dust flux during the last century (1905-2005 AD). The results show that there was a nearly 2.5 fold increase in the dust influx (from an average of 2.5 to 37.0 mg m⁻² yr⁻¹) to the East Antarctica between the early to late 20th century, which was similar to the elevated dust fall over the West Antarctica. Such dramatic changes within the spatially distinct sites of Antarctica support the spatial extent and temporal consistency attributed to regional climate variability. A common source for the concomitant deposition of dust across the Antarctica appears to be the desert storms originating from the southern parts of the South America (SSA). The dust influx showed significant correlations with relative humidity, soil moisture, wind speed since the 1980’s compared with air temperature of Patagonia region supporting their the dominant role in production and transport of dust in Southern south America. The significant correlation of dust flux in Antarctica with the anthropogenic forcing (from CCSM4/CMIP5 model) indicates significant impact of the anthropogenic factors on the dust deposition and vice versa in Antarctica.
Environmental Signals from the Dust in a High Altitude Tropical Ice Core

Filipe Gaudie Ley Lindau¹ (filipelindau@hotmail.com), Jefferson Cardia Simões¹, Barbara Delmonte²
¹Universidade Federal do Rio Grande do Sul / INCT da Criosfera, Centro Polar e Climático, Porto Alegre, Brazil,
²University Milano-Bicocca (UNIMIB), Department of Environmental Sciences, Milano, Italy

High altitude ice cores from Central Andes are sources of information on the mechanisms leading the intense mid-tropospheric warming of the last decades, and also provide high-resolution data for a better understanding of the tropical-polar teleconnexions. In order to provide a proxy for atmospheric circulation variability over tropical South America during the last century we determined the dust size and concentration from the Illimani ice core (Bolivian Andes) recovered in 1999 at 6300 m. The content of particles with diameters from 0.7 to 20 µm was measured using a Coulter Multisizer at the LGGE, Grenoble. The seasonal resolution register comprises the 1919 - 1998 period and is characterized by a pronounced increase in dust concentration during the austral winter (JJA), reaching concentrations up to 22 µg g⁻¹, which responds to the increase of westerly winds over the Bolivian Altiplano during the dry season. The mode of the size distribution also increases during JJA, sometimes ranging from 6 to 10 µm which indicates an important local dust contribution. The dust concentration record suggests a slight increasing tendency as higher peaks are more frequent in the most recent years of the time series. These highest dust peaks, however, do not correspond to the same years of the main El Niño events. Additional methods are needed to separate the local dust from the regional/continental environmental signal in order to obtain significant correlations with atmospheric parameters.
Major incentives for developing lightweight drilling systems are: 1) cost reduction of field operations, and 2) accessibility of high altitude glaciers. A new approach to field operations is use of the Ultralight ice coring systems (ULICS), commercial flights and regular transportation in complex logistic regions instead of charter carriers. It also allows deployment of the ULICS equipment and ice cores to and out of a drilling site by small group of researchers. The minimal deployment total weight of the ULICS drilling equipment including power source, fuel and shelter is about 60 kg. Operation of the ULICS requires 2 persons.

The ULICS logistics based around small ice core diameter. This implementation relies on low power drilling equipment and lightweight high-efficiency power sources. Small diameter ice cores can be stored in portable freezers on a drill site or/and base camp.

The ULICS prototype is built at the Cryosphere Research Solutions LLC. Current model of the ULICS equipped with thermal-electric drill capable of producing 42 mm ice core. Estimated total deployment weight of the ULICS capable of recovering ice cores down to 150 m depth at about 4 m h⁻¹ production drilling rate is 25 kg. It includes custom high altitude power generator. A suit of electro-thermal and electro-mechanical drills suitable for the same lightweight rig to recover ice cores of 15-82 mm in diameter in temperate and polar glaciers is currently in development.
Shape and Size Constraints on Ice Core Dust Optical Properties

Marco A.C. Potenza\textsuperscript{1} (marco.potenza@unimi.it), Barbara Delmonte\textsuperscript{2}, Samuel Albani\textsuperscript{3}, Giovanni Baccolo\textsuperscript{2}, Valter Maggi\textsuperscript{2}, Llorenç Cremonesi\textsuperscript{1}

\textsuperscript{1}University of Milano, Physics, Milan, Italy, \textsuperscript{2}University Milano-Bicocca (UNIMIB), Milan, Italy, \textsuperscript{3}LSCE/IPSL, Gif-sur-Yvette, France

Mineral dust aerosol influences global climate. It changes the radiative properties of the atmosphere through scattering and absorption of solar (shortwave) and terrestrial (longwave) radiation. Paleoclimate modeling studies generally assume a spherical shape for dust particles, an assumption that implies a significant deviation of light scattering from scattering properties of real particles. Through the novel Single Particle Extinction and Scattering (SPES) method applied to East Antarctic ice core samples from the last glacial period and the Holocene we were able to derive information about dust particle shapes, which is critical to determine the intrinsic optical properties of dust.

We consider the first-order impact of different sets of optical properties derived from SPES analyses on atmospheric dust Aerosol Optical Depth (AOD), based on dust mixing ratios simulated by the Community Earth System Model (CESM), tuned to match size and deposition at Dome C. We derive that the net effect of considering the actual variability in particle shape can contribute to changes in AOD up to \approx 10\%. Actually, spatial and temporal variations in dust load, particle size distribution and shape combine together to determine the net effects on atmospheric extinction.

Given the importance of modeling light scattering by non-spherical particles, we recommend the use of the novel SPES technique to ice core analyses for an improved understanding of the role of dust in past climate change.
Internal Bubble Pressures and Bubble Trapping Function in Ice Cores

Ruzica Dadic¹ (ruzica.dadic@vuw.ac.nz), Martin Schneebeli², Mareike Wiese², Nancy Bertler³, Andrey Salamatin⁴, Thiemo Theile², Richard Alley⁴, Vladimir Lipenkov⁵

¹Victoria University of Wellington, Antarctic Research Centre, Wellington, New Zealand, ²WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland, ³Kazan Federal University, Kazan, Russian Federation, ⁴Pennsylvania State University, State College, United States, ⁵Arctic and Antarctic Research Institute, St. Petersburg, Russian Federation

Ice core data recorded significant and abrupt past climate changes that are associated with large and rapid changes in atmospheric greenhouse gases, such as methane. Due to the gradual close-off of gas bubbles, even a stepwise increase in air composition is spread out into a ramp in the data, because laboratory analysis of gases only considers the mean of all bubbles across one sample. The convolution of the distribution of trapping ages with the history of atmospheric composition smears the measured gas record in each sample. We propose to use the shape of the trapping function derived from bubble-pressure-distribution and site characteristics to deconvolve bubble close-off history from the atmospheric composition record. Here, we first present a non-destructive method that can simultaneously estimate pressure-distribution in all bubbles in a sample, not only for present conditions, but back through time under varying atmospheric conditions. The method uses temperature-driven air-bubble-migration as a proxy for the pressure of individual bubbles and thus the gradual close-off of gas bubbles. We then use the pressure-distribution to model the gas trapping functions and to constrain the age distribution of air bubbles for past conditions, which are preserved at different depths. The trapping functions will help us to obtain a more accurate gas signal in the future that is less attenuated through the age distribution of the gas during the close-off process.
Reconstruction of Early Holocene Environmental Conditions from the RICE Ice Core

Lukas Eling1,2 (lukas.eling@vuw.ac.nz), Nancy Bertler1,2, James Lee3, Robert McKay1,2, Rebecca Pyne2
1Victoria University of Wellington, Wellington, New Zealand, 2GNS Science, Lower Hutt, New Zealand, 3Oregon State University, Corvallis, United States

As part of the Roosevelt Island Climate Evolution (RICE) project, a deep ice core was drilled at Roosevelt Island, an ice rise situated at the north-eastern edge of the Ross Ice Shelf, a major drainage pathway of the marine based West Antarctic Ice Sheet (WAIS). The RICE records provide new insights into our understanding of the stability of the Ross Ice Shelf in a warming world and associated sea-level rise contributions of WAIS. Here we present high precision (low to sub ppb concentrations) Ion Chromatography data from discrete samples of the RICE core representing the Early Holocene from ~ 10.5 ka BP to ~ 7.5 ka BP in high resolution (sub-annual to 3-5 years). This record permits the reconstruction of sea ice extent and marine primary production in the Ross Sea Polynya using MSA− and the ratio of Na+/SO₄²⁻ to estimate the frost flower contribution. Additionally atmospheric circulation patterns are reconstructed based on K⁺, Mg²⁺ and NO₃⁻, which have a continental source and are therefore related to katabatic winds, and Na⁺, Cl⁻ and Ca²⁺ which are marine aerosols and are associated with cyclonic activity. This detailed picture of Early Holocene atmospheric conditions, sea ice and marine productivity in the Ross Sea is used to link changing environmental conditions to the retreat of the Ross Ice Sheet/ Shelf, which may have been largely complete by the mid-Holocene as suggested by recent results from marine studies, combined with ice sheet modelling experiments.
Spatiotemporal Variations of Monocarboxylic Acids in Snow in Eastern Antarctica

Chuanjin Li1 (lichuanjin@lzb.ac.cn)
1State Key Laboratory of Cryospheric Science, Northwest Institute of Eco-Environment and Resources, Chinese Academy of Sciences, Lanzhou, China

The spatiotemporal distributions of formate and acetate in snow layers along a transect from Zhongshan Station to Dome A are presented here. In the snow pit samples, the concentrations varied between 0.47 ± 0.14 ng g⁻¹ and 3.12 ± 4.24 ng g⁻¹ for formate and between 5.31 ± 1.55 ng g⁻¹ and 13.29 ± 4.64 ng g⁻¹ for acetate. Spatially, the concentrations of both acids featured negative trends with increasing elevation and distance inland for the initial 600 km of the transect, which implies that marine sources from the coastal oceans dominate the acid supply. Different distribution styles of the acids in the interior section (600-1248 km) suggest that different source region and transporting mechanism may be responsible for the acid deposition in the interior regions. Seasonal variations in the amounts of acid in a coastal snow pit (29-A) indicate highervales in the summer and lower amounts in the winter. An enlarged source region and intensified production and transport mechanisms were primarily responsible for the higher values in summer. Longer records from the interior snow pits (29-L and 29-M) indicate elevated values in the 1970s and lower values in the 1980s and early 1990s. The increases in the monocarboxylic acids since 1999 in snow pit 29-L and since 2005 in snow pit 29-M were temporally coincident with Chinese expedition activities in the area, suggesting that human activities were responsible for the increases in the acid load during recent decades.
The last interglacial period, also known as Eemian (ca. 132-116 ka BP), characterized by global temperatures and sea level higher than today, has been found in six East Antarctic ice cores: Vostok, Taylor Dome, Dome F, EPICA Dome C, EPICA Dronning Maud Land and TALDICE. Here we present a new deuterium excess record obtained from the TALDICE ice core analysing the high-resolution samples obtained from the 5 cm cuttings between 1384 and 1414 m, corresponding to the 115-130 ka BP period. Talos Dome is a peripheral dome of East Antarctica, located in the Ross Sea sector where the TALDICE deep ice core (1620 m) has been retrieved. A previous study has shown that the $\delta^{18}O$ records obtained from the East Antarctic deep ice cores depict a quite homogeneous pattern during the present and last interglacials. However, regional differences, particularly important in the case of the TALDICE ice core, may be related to both elevation and regional atmospheric circulation changes. The north-western drainage area of Talos Dome is mostly below sea level (Wilkes Subglacial Basin) and could be more sensitive to climatic and sea level fluctuations than other sectors of the East Antarctic Ice Sheet, possibly causing a distinct $\delta^{18}O$ signal in the TALDICE ice core. The $\delta^{18}O$ and deuterium excess records will be compared to high resolution ssNa and nssCa records as well as to the EPICA Dome C isotopic records to understand the regional differences highlighted by this site.
Atmospheric Contamination on the Top of the Himalaya over the Last 500 Years

Paolo Gabrielli\textsuperscript{1,2} (gabrielli.1@osu.edu), Anna Wegner\textsuperscript{1,3}, Roxana Sierra\textsuperscript{1}, Beaudon Emilie\textsuperscript{1}, Joel Barker\textsuperscript{1,2}, Lonnie Thompson\textsuperscript{1,2}
\textsuperscript{1}Ohio State University, Byrd Polar and Climate Research Center, Columbus, United States, \textsuperscript{2}Ohio State University, School of Earth Sciences, Columbus, United States, \textsuperscript{3}Alfred Wegener Institute, Bremerhaven, Germany

The Dasuopu ice core was drilled in 1997 at 7200 m altitude in the Himalaya and provides the highest elevation ice core climate record ever obtained. Due to its high altitude this site has the potential to have a large spatial significance including long distant pollution from Europe and climatic signals influenced by the North Atlantic. This area is heavily influenced by the monsoon regime providing seasonally and highly variable annual snow accumulation rates. The preservation of annual layers in this low latitude - high altitude ice core has allowed for the possibility to obtain a detailed snow accumulation record that can be used to calculate chemical fluxes to the central Himalaya. Here we present the results of a new trace element record from the Dasuopu ice core spanning the period between 1500 and 1993 AD. Crustal enrichment factors are used to discriminate between the terrigenous and non-crustal contributions (e.g. anthropogenic origin). In this study we focus on two research topics:
(1) determine the onset and origin of the earliest anthropogenic contamination from trace elements at high elevation (7200 m) in the Himalaya and
(2) determine annual, intra-annual, and decadal variations of atmospheric trace element fluxes.
Thanks to ice cores the history of the dust cycle and its tight connections with the climatic system were reconstructed. Here we present an update of the current research on the atmospheric dust content of the TALDICE ice core (Ross Sea sector, East Antarctica). Thanks to the application of different techniques it was possible to characterize the mineral particles deposited in the last 150 kyr. New constraints on provenance during the last climatic cycle will be given, showing that peripheral and inner sites, well coupled during glacial stages, present differences in relation to the different atmospheric evolution occurred during the last climatic transition. In addition the analysis of the elemental composition of dust allowed preparing a first and preliminary inventory of the elemental depositional fluxes in Antarctica. This is the first step to define a robust reference to assess the current impact of human activities on Antarctic glaciochemistry. But important results were also achieved looking at the deep disturbed part of TALDICE. For the first time significant weathering affecting particles entrapped in deep ice was appreciated and quantified. Chemical and physical processes alter the composition and aggregation state of dust below a critical depth. Future projects focused on the retrieval of very ancient ice, will need to take into account such phenomena.
A wide range of methods are available in studying ice cores nowadays. Nevertheless, most of them have a lot of disadvantages related to destruction of samples and their melting during the analyses, which may prevent the future sample processing.

X-ray computed tomography (CT) is a well-known and common method to obtain cross-sectional images using X-rays. The primary use of CT doesn't affect further processing of samples. Another advantage of method is its promptitude: the analysis cost is low, while the amount of information obtained is very substantial.

The shallow ice cores from Elbrus region were analyzed with the help of X-Ray CT scanner. RCT-180 scanner is able to scan cores with a length of 1 m and with a diameter of 10 cm. Scanner has a 150-180 µm spatial resolution and 100x100x1000 mm active area. For supporting the natural conditions of ice, a special cryothermos was created, which allows to keep the sample frozen during the survey.

This method permitted us to define the inner structure of full length ice cores, to find the core disturbances; to obtain a 3D pattern of ice density which appears to provide much more information than the visual observation of the axial ice cutting; to obtain 3D stratigraphy for subsequent correlation; to reveal and calculate the typical layers with contrast density and to find total porosity and individual pores.

The research was supported by the Russian Science Foundation (project no. 17-17-01270).
Here we accurately determine the phasing between East Antarctic temperature and atmospheric CO₂ variations during the last deglacial warming based on Antarctic ice core records. We build a stack of East Antarctic temperature variations by averaging the records from 4 ice cores (EPICA Dome C, Dome Fuji, EPICA Dronning Maud Land and Talos Dome), all accurately synchronized by volcanic event matching. We place this stack onto the WAIS Divide WD2014 age scale by synchronizing EPICA Dome C and WAIS Divide using volcanic event matching, which allows comparison with the high resolution CO₂ record from WAIS Divide. Since WAIS Divide is a high accumulation site, its air age scale, which has previously been determined by firn modeling, is more robust. Finally, we assess the CO₂ / Antarctic temperature phasing by determining four periods when their trends change abruptly.

We find that at the onset of the last deglaciation and at the onset of the Antarctic Cold Reversal (ACR) period CO₂ and Antarctic temperature are synchronous within a range of 210 years. Then CO₂ slightly leads by 165 ± 116 years at the end of the Antarctic Cold Reversal (ACR) period. Finally, Antarctic temperature significantly leads by 406 ± 200 years at the onset of the Holocene period. Our results further support the hypothesis of no convective zone at EPICA Dome C during the last deglaciation and the use of nitrogen-15 to infer the height of the diffusive zone.
Volcanic eruptions are an important component of climate forcing, and an essential component of the long-term budget of carbon dioxide in the atmosphere. However, establishing the past frequency of eruptions of various magnitudes is challenging. The record of episodic sulfate deposition in Antarctic ice offers the opportunity to establish such frequencies for larger eruptions. Here, we build on recent work that has synchronised records back to 200,000 years, between the East Antarctic sites of Dome C, Dome Fuji and Vostok. In each record, and for each volcano, we can estimate the amount of sulfate deposited above the background across the years following an eruption; in some cases we will use electrical conductivity data as a surrogate for sulfate. For some eruptions we will measure the profile of mass independent fractionation of sulfur isotopes to establish whether the eruption reached the stratosphere. By using the three records together we can for the first time place uncertainty estimates on the amount of sulfate deposited for each eruption. We will then use (and test) methods we have developed for making an assessment, unbiased by diffusion and thinning, of the frequency of eruptions above a given magnitude (in terms of sulfate deposition). Initial work suggests that the frequency of large eruptions is rather constant through the glacial and interglacial stages of two glacial cycles, but we hope to have fully tested this by the time of the meeting.
Taylor Glacier Ice Core Shows Dynamic Taylor Dome Accumulation during MIS 5-4

James Andrew Menking1 (menkingj@oregonstate.edu), Sarah Shackleton2, Ed Brook1, Jeffrey Severinghaus2, Rachael Rhodes3, Joe McConnell4, Aron Buffen1, Michael Dyonisius5, Thomas Bauska3, Vasilii Petrenko5
1Oregon State University, College of Earth, Ocean and Atmospheric Sciences, Corvallis, United States, 2Scripps Institution of Oceanography, University of California, San Diego, La Jolla, United States, 3Cambridge University, Department of Earth Sciences, Cambridge, United Kingdom, 4Desert Research Institute, Reno, United States, 5University of Rochester, Department of Earth and Environmental Sciences, Rochester, United States

A new ice core retrieved from the Taylor Glacier blue ice area (McMurdo Dry Valleys, Antarctica) contains a well-preserved record of the marine isotope stage (MIS) 5/4 transition. Methane and $\delta^{18}O_{\text{atm}}$ measurements were used to build a gas age scale for the new core by tying to preexisting, well-dated ice core records. Measurements of particle concentration (dust) were used similarly to build an ice age scale for the new core. The ice age-gas age difference approaches 10,000 years during MIS 4, suggesting very low precipitation or high wind scouring at the Taylor Glacier accumulation zone near Taylor Dome. Revised gas age and ice age models spanning the MIS 5/4 transition in the Taylor Dome ice core indicate a delta age $\approx$ 3000 years during MIS 4, which in conjunction with the Taylor Glacier data implies large spatial gradients in accumulation and/or wind scouring across Taylor Dome. Curiously, the delta age relationship between Taylor Glacier and Taylor Dome at the MIS 5/4 transition is reversed relative to the last glacial maximum (Baggenstos, 2015). This could be due to changes in the trajectory of paleo storm tracks that effectively reversed spatial gradients in accumulation across Taylor Dome at different times in the past (e.g., Morse et al., 1998).
Aerosols Preserved in a High-accumulation Dome Ice Core, Southeast Greenland

Yoshinori Iizuka¹ (iizuka@lowtem.hokudai.ac.jp), Ryu Uemura², Koji Fujita³, Sumito Matoba¹

¹Institute of Low Temperature Science, Hokkaido University, Sapporo, Japan, ²University of the Ryukyus, Faculty of Science, Okinawa, Japan, ³Nagoya University, Nagoya, Japan

On May 2015, we drilled a 90.45 m ice core in a high accumulation area of the southeastern Greenland Ice Sheet (SE-Dome; 67.18°N, 36.37°W, 3170 m a.s.l.). Then we measure physical and chemical properties of the SE-Dome ice core. First, we propose a dating method based on matching the δ¹⁸O variations between ice-core records and records simulated by isotope-enabled climate models. The close similarity between the δ¹⁸O records from the ice core and models enables correlation and the production of a precise age scale, with an accuracy of a few months. Second, we measured the major ion fluxes, and obtained records of annual ion fluxes from 1957 to 2014. From 1970 to 2010, the trend of non-sea-salt SO₄²⁻ flux decreases, whereas that for NH₄⁺ increases, tracking well with the anthropogenic SO₂ and NH₃ emissions mainly from North America. The result suggests that these fluxes reflect histories of the anthropogenic SO₂ and NH₃ emissions. In contrast, the decadal trend of NO₃⁻ flux differs from the decreasing trend of anthropogenic NOₓ emissions. We also find a high average NO₃⁻ flux (1.13 mmol m⁻² yr⁻¹) in the ice core, which suggests a negligible effect from post-depositional NO₃⁻ loss. Thus, the SE-Dome region is an excellent location for reconstructing nitrate fluxes. Over a decadal timescale, our NO₃⁻ flux record is similar to those from other ice cores in Greenland high-elevation sites, suggesting that NO₃⁻ concentrations records from these ice cores are reliable.
In Antarctica, a reasonable coverage of ice core records exist for the last couple of hundred years, however there is poor spatial coverage of high-resolution climate data over the last 2,000 years, particularly in East Antarctica (EA). Here, we use a range of high-resolution ice cores from EA covering the last 2,000 years from the IPICS array and PAGES Antarctic2k projects, and adding the recently recovered Aurora Basin North (ABN) ice core. The isotopic composition of snow and ice from this site is compared with other ice core isotopic records from Wilkes Land Coast and the transition region into the East Antarctic Plateau. The isotopic variability at ABN shows annual cycles in the upper 50 m and longer-term variability on decadal to centennial timescales. The ABN record shows no long-term isotopic trend over the ~2,700 year record length, whereas the isotopic ice core records used in EA regional composite show there is a long-term cooling over the last 2,000 years. A comparison of the preliminary dated ABN isotope record with the Law Dome (LD) isotopic record shows they are correlated, despite differences in site-specific influences. This correlation indicates a common climate signal at both sites and a spatial coherence in regional climate from coastal LD to the inland plateau of the ABN site. The isotopic records from ABN in conjunction with other EA high-resolution ice core records are used to explore, quantify and determine natural variability of key climate processes.
Development of a Method for the Measurement of $\delta^{15}$NH$_4$ in Ice Core Samples

Prisca Lehmann$^1$ (lehmann@climate.unibe.ch), Barbara Seth$^1$, Jochen Schmitt$^1$, Hubertus Fischer$^1$

$^1$University of Bern, Climate and Environmental Physics, Physics Institute & Oeschger Centre for Climate Research, Bern, Switzerland

Ammonium (NH$_4^+$) in Antarctic ice samples originates mainly from marine biogenic sources and is transported in aerosol form to the ice sheet, where deposition takes place. Due to the coupling of the biogeochemical cycles of nitrogen and carbon and isotopic fractionation, a dependence of the isotopic signature ($\delta^{15}$NH$_4$) of ammonium and the efficiency of nutrient turnover in the surface ocean is expected. The low concentration of NH$_4^+$ in ice and only small changes in the isotopic ratio make this analysis challenging. The basis of our new $\delta^{15}$NH$_4$ system is the well-established CFA system, which provides a continuous and contamination-free flow of meltwater containing ammonium. We are currently developing an interface that comprises four main steps: In a first step, the dissolved NH$_4^+$ is incorporated into an organic molecule and retained from the water phase by solid phase extraction. Secondly, this organic-N is quantitatively oxidized to N$_2$ using Cu/CuO as redox agents. In a third step, combustion side products (i.e. CO, CO$_2$, and H$_2$O) are separated using cryotrap and gas chromatography. In the last step, the $\delta^{15}$N of the purified N$_2$ is determined by isotopic ratio mass spectrometry. We already constructed and tested the lines for step 2-4 and the oxidative conversion works well for a NH$_3$ gas-standard and N-containing organic compounds. The coupling towards the ammonium-N in the water phase will be our next step and we present the current status of the analytical system.
Lead in the European Atmosphere from the Ortles Ice Cores, the Last 7000 Years

Michele Bertò¹ (michele.berto@psi.ch), Paolo Gabrielli², Andrea Spolaor², Jacopo Gabrielli³, Giuliano Dreossi³, Michela Segnana⁴, Carlo Barbante⁴,⁵

¹Paul Scherrer Institute, Energy and Environment Research Division, Zürich, Switzerland, ²Ohio State University, Byrd Polar and Climate Research Center BP, Columbus, United States, ³Ohio State University, School of Earth Sciences, Columbus, United States, ⁴CNR-IDPA, Venice, Italy, ⁵Ca Foscari University of Venice, DAIS, Venice, Italy

Four ice cores were recovered in 2011 from the Alto dell’Ortles glacier (3859 m, South Tyrol, Italy). This study presents the results from the analyses of the ice cores #1 (73.5 m) and #3 (74.83 m) performed at the University of Venice (Department of Environmental Sciences, Informatics and Statistics, DAIS) and at The Ohio State University (Byrd Polar and Climate Research Center, BPCRC) that cover the last 3000 and 7000 years, respectively. Core#1 and #3 were analyzed by Continuous Flow Analyses (CFA). The samples from core#1 were also measured discreetly. Trace elements analyses performed at DAIS were performed by using an ICP-MS (Agilent 7500), whereas those performed at the BPCRC by means of a ICP-SF-MS (Element2, Thermo).

The Ortles cores provide a detailed Lead contamination reconstruction of the past European atmosphere. A first Lead enrichment was found during the time of the Roman Empire, due to intense Lead and Silver mining activities. Afterwards Lead levels remained low except during the periods 1380-1500 AD and 1580-1680 AD, revealing an enhancement in European Silver mining activities. The highest Lead levels were determined during the last century, starting in the 1920s, mostly caused by leaded gasoline.

A comparison with other local archives corroborates the results of the Ortles ice cores. A comprehensive comparison with most of the available lead reconstructions allows obtaining a worldwide perspective of atmospheric contamination from this toxic metal.
Coupled Production of CH₄, C₂H₆, and C₃H₈ in Dust-rich Greenland Ice

Jochen Schmitt¹, Barbara Seth¹ (seth@climate.unibe.ch), James E. Lee², Jonas Beck¹, Jon S. Edwards², Edward J. Brook², Hubertus Fischer¹

¹Climate and Environmental Physics, Physics Institute, and Oeschger Center for Climate Change, University of Bern, Bern, Switzerland, ²College of Earth, Ocean, and Atmospheric Sciences, Oregon State University, Corvallis, United States

Air enclosures in ice samples are the only archive to reconstruct atmospheric trace gases and their isotopic composition beyond the time where firm air samples are accessible. Reconstructing the past atmospheric composition accurately requires that the respective trace gas is neither consumed nor produced in the ice. It is known for decades, that CO₂ production in Greenland ice compromises the atmospheric signal, and for trace gases like N₂O and methyl chloride production in dust-rich sections in Antarctic ice cores has been documented. Here, we show that for dust-rich Greenland ice samples production of short chain hydrocarbons (CH₄, C₂H₆, and C₃H₈) occurs in significant amounts to compromise accurate reconstructions of these gases. We found that the production of these hydrocarbons is tightly coupled to the dust concentration in these samples, which support results from independent experiments at Oregon State Univ. (presentation J. Lee). We further observed that these three hydrocarbon homologous occur in a stoichiometric ratio of about 20:2:1 for CH₄, C₂H₆, and C₃H₈, respectively, pointing to a shared production process, e.g. from an organic precursor molecule. With experiments we show that the production proceeds via a rather slow process in the water phase. With regard to the CH₄ produced in glacial Greenland ice, published results require a careful reevaluation of methane stable isotope records and reconstructions of the interhemispheric gradient during the glacial.
Towards Gas Measurements in Extremely Thinned Ice: The Mid-IR Laser Spectrometer

Bernhard Bereiter1,2 (bereiter@climate.unibe.ch), Béla Tuzson2, Philipp Scheidegger2, Lukas Emmenegger2, Lars Mächler3, Jochen Schmitt1, Hubertus Fischer1
1University of Bern, Physics Institute & Oeschger Centre for Climate Change Research, Bern, Switzerland, 2Swiss Federal Laboratories for Materials Science and Technology Empa, Dübendorf, Switzerland

The European Partnership in Ice Core Sciences (EuroPICS) plans to drill an ice core extending over 1.5 million years (Myr), nearly doubling the time span of the existing greenhouse record. The oldest section from 1-1.5 Myr is expected to be close to the bedrock and, due to glacial flow, extremely thinned. Thus, a 10,000 year glacial/interglacial transition can be compressed in 1 m of ice, reducing the sample vertical extent to cm-scales and its volume to 1-2 ml air STP, respectively, for a targeted century-scale temporal resolution. Within the ERC Advanced Grant “deepSlice” we aim to unlock such atmospheric archives in extremely thinned ice by developing a novel coupled semi-continuous sublimation extraction/laser spectroscopy system. Here we present the custom-made laser spectrometer developed in this context whose goal is to measure simultaneously CO2, CH4 and N2O concentrations and δ13C(CO2) isotope ratios in such small air samples without destructing it. The analytical approach is based on direct absorption using two Quantum Cascade Lasers emitting at 4.34 and 7.87 µm, respectively. The main challenge stems from the small sample volume which requires high precision and stability from the electronic and optical part of the system as well as low reactivity from the inner surfaces of the absorption cell. Preliminary results will be presented which show that the high-precision targets can be reached for all four parameters.
Alpine Ice Cores Indicate Persistently High Nitrate and Ammonium Concentrations

Margit Schwikowski1,2,3 (margit.schwikowski@psi.ch), Anja Eichler1,3, Theo M. Jenk1,3, Susanne Preunkert4, Michael Sigl1,3, Michel Legrand4
1Paul Scherrer Institute, Laboratory of Environmental Chemistry, Villigen PSI, Switzerland, 2University of Bern, Department of Chemistry and Biochemistry, Bern, Switzerland, 3University of Bern, Oeschger Centre for Climate Change Research, Bern, Switzerland, 4Université Grenoble Alpes, CNRS, Institut des Géosciences de l’Environnement (IGE), Grenoble, France

Ice cores from glaciers in the Alps are well suited to document the effects of anthropogenic emissions on air pollution, since they are surrounded by highly populated and industrialized countries in Europe. Concentration records of sulfate, nitrate and ammonium covering the 20th century until 2015 from Col du Dôme (4250 m asl, French Alps) and Colle Gnifetti (4450 m asl, Swiss Alps) ice cores agree well in absolute concentrations and temporal trends. Sulfate originating from fossil fuel combustion peaked in the 1970-80’s with a significant downward trend in recent decades, in agreement with results from atmospheric chemical transport modelling. In contrast to sulfate, in the case of nitrate related to traffic and energy production and ammonium to agricultural emissions, ice core data show persistently high concentrations, which do not correspond to the model simulations and/or data from Western Europe in the European Monitoring and Evaluation Programme network. The good agreement for sulfate indicates that transport and atmospheric chemistry is well simulated by the models. The discrepancy for nitrate and ammonium suggests uncertainties in the emissions estimates, which in the case of nitrogen oxides are possibly related to underestimated car emissions. Such uncertainties are also relevant for ammonia released from fertilizer use and animal husbandry, since it plays a significant role in secondary aerosol formation with a corresponding negative effect on human health.
Ice cores are used to reconstruct past changes in atmospheric methane. The stable isotopes of CH₄ enable us to draw conclusions about processes behind source and sink budget changes. By measuring δD(CH₄) on trapped gas from the NGRIP ice core over the period of Dansgaard-Oeschger (DO) events 7 and 8, Bock et al. (2010) ruled out the clathrate gun hypothesis, which calls upon the destabilization of marine CH₄ hydrates to explain the rapid CH₄ increases. However, for dust-rich Greenland ice there is evidence of excess CH₄ production during the melt extraction that calls into question previous results (presentations of J. Schmitt and J. E. Lee). New δD measurements using Antarctic ice from TALDICE show that the NGRIP δD values are likely affected by this process. The TALDICE δD values show only small variability over the two DO events, indicating no dramatic change in the CH₄ source mix. The new data are therefore still clearly in disagreement with the clathrate gun theory. Furthermore, we present new δD and δ¹³C data from the WAIS core covering a short-lived CH₄ excursion documented in the very high resolution CH₄ data by Rhodes et al. (2015) in Heinrich Stadial 4. Such rapid CH₄ excursions leave a characteristic imprint in both δ¹³C, from firn diffusion, and for δD, due to atmospheric imbalance effects, which are visible in our record. After accounting for these transient effects, the remaining isotope signal suggests a heavier source mix for δ¹³C, but little changes for δD.
Towards Gas Measurements in Extremely Thinned Ice: Sublimation Extraction

Lars Mächler¹ (maechler@climate.unibe.ch), Bernhard Bereiter¹,², Bela Tuzson², Lukas Emmenegger², Remo Walther¹, Jochen Schmitt¹, Hubertus Fischer¹

¹University of Bern, Physics Institute & Oeschger Centre for Climate Change Research, Bern, Switzerland, ²Swiss Federal Laboratories for Materials Science and Technology, Empa, Dübendorf, Switzerland

The European Partnership in Ice Core Sciences (EuroPICS) plans to drill an ice core extending over 1.5 Ma, nearly doubling the time span of the existing greenhouse record and covering the time period of the Mid Pleistocene Transition. The oldest section from 1-1.5 Ma is expected to be close to the bedrock and, due to glacial flow, extremely thinned. A century-scale temporal resolution reduces the sample vertical extent to cm-scales containing only 1-2 ml air STP.

Within the ERC Advanced Grant deepSlice project we aim to unlock such atmospheric archives by developing a novel coupled semi-continuous sublimation extraction/laser spectroscopy system. Sublimation is the only dry method that extracts 100% of all gas species avoiding potential issues with gas fractionation which showed to cause offsets between ice cores/different extraction methods. With the target of reducing ice waste and increase sample throughput, the development of our new gas extraction method aims at vertically sublimating an ice-core section with subsequent collecting the released air via cryo trapping in a dip tube. However, there remain several challenges: the heat transport within the sample could induce subsurface melting or lateral sublimation, inhomogeneity in the ice or of the radiation field delivering the heat could create inhomogeneity in the sublimation front, and CO₂ adsorption, a problem to all CO₂ extraction methods, particularly affects isotope ratios.
Growth of Air-hydrate Crystals in the Bottom Section of the EPICA DC Ice Core

Vladimir Lipenkov¹ (lipenkov@aari.ru), Andrey Salamatin², Jerome Chappellaz³, Gregory Teste³
¹Arctic & Antarctic Research Institute, Climate & Environmental Research Laboratory, Saint Petersburg, Russian Federation, ²Kazan (Volga Region) Federal University, Kazan, Russian Federation, ³University Grenoble Alpes, IGE, Grenoble, France

The post-formation growth (Ostwald ripening) of air-hydrate crystals occurs in polar ice sheets due to the diffusion of air molecules through the ice matrix from smaller crystals towards larger ones. The earlier studies of this phenomenon in the Vostok (Tsyganova & Lipenkov, 2011) and Dome Fuji (Uchida et al., 2011) ice cores have shown that, in the lower sections of these cores, the mean radii of hydrates increase linearly with their age. The existence of a robust linear relationship between the size and age of air hydrates in very old polar ice would imply that the geometrical properties of hydrate crystals could be used for estimating the age of ice in the near bottom layers of the ice sheets.

Here we present the preliminary results of a study of geometrical properties of air hydrates in the bottom section of the EDC ice core. The size distribution and the number concentration of hydrate crystals were measured at 23 depth levels between 2802 and 3258 m using the ice samples from the low-temperature collection stored in the undersnow cave at Concordia station. Experimentally determined correlation between the size and age of hydrates in the well dated part of the 800-kyr old EDC ice core is used to constrain the parameters of a mathematical model which describes the growth of air hydrates below the bubble-to-hydrate transition (Salamatin et al., 2003). The implication of the new data for dating the disturbed section of the old meteoric ice at Vostok is discussed.
An Extended Climate Archive from the Eastern Alps: The Mt Ortles Ice Cores

Giuliano Dreossi1 (iodio9@yahoo.it), Paolo Gabrielli2, Luca Carturan3, Barbara Stenni4, Michele Bertò5, Andrea Spolaor2, Jacopo Gabrieli2, Carlo Barbante1,4

1National Research Council for the Dynamics of Environmental Processes (IDPA-CNR), Venice, Italy, 2Byrd Polar and Climate Research Center, Columbus, United States, 3Department of Land, Environment, Agriculture and Forestry (TESAF), University of Padua, Padua, Italy, 4Department of Environmental Sciences, Informatics and Statistics (DAIS), Ca’ Foscari University of Venice, Venice, Italy, 5Paul Scherrer Institute, Villigen, Switzerland

Oxygen and hydrogen stable isotopes have been widely used in ice cores as temperature proxies for the last 50 years. In autumn 2011 three ice cores were drilled down to bedrock on the Alto dell’Ortles glacier (3859 m a.s.l.), Eastern Alps. The ice core chronology, based on lead-210 in the upper part and on carbon-14 measurements for the lower part, proves that this record is the most extended of the Eastern Alps and the second most extended ice core record from the Alpine region, extending beyond 7000 years BP. The long temporal extension of this glacial archive represents a unique opportunity to study the climate of the past in this part of the Alps, normally characterized by low-elevation shallow glaciers, whose have been particularly affected by the recent warming. The oxygen and hydrogen isotopic composition was measured for all the three cores and an isotope stacked record was created combining the three isotope profiles. The composite record shows a long warm period during the mid holocene, followed by a decreasing trend extending until the roman period. A large negative anomaly is present during the last 500 years, suggesting the presence of a colder period which was interrupted only in the XX century.
Wed_184_CR-8_2290
Dating the Aurora Basin North Ice Core with Seasonal Cycles and Volcanic Ties

Mark Curran$^{1,2}$ (mark.curran@aad.gov.au), Dating Team ABN$^{3}$

The aim of the Aurora Basin North (ABN) ice core drilling project is to provide a 2000 year climate record from a data sparse area of East Antarctica to add to the IPICS 2k array and the PAGES Antarctica2k projects. ABN is a 303m ice core from East Antarctica, 550km inland and about half way between the coastal Law Dome and inland Dome C sites. A combination of annual layer counting and volcanic ties was used to date the record. Annual peaks were found in many trace chemical species (e.g. sodium, sulphate, hydrogen peroxide) and other species such as black carbon. The ABN chronology has been established to ~1900 years before present (or 120 CE) through a combination of volcanic synchronisation to DSS and WAIS divide ice cores and layer counting between volcanic events. Below this date, annual layer counting becomes less certain and volcanic ties alone indicate the record extends to around 2700 years before present. We will present an update of the ABN results on this timescale for reconstructed temperatures, snow accumulation rate and aerosol concentrations, including volcanic sulphate concentrations and fluxes. These will be compared to other Antarctic ice core records.
Trace Elements Variation between ~600 kyr BP to ~800 kyr BP in Dome C Ice Core

Soon Do Hur¹ (sdhur@kopri.re.kr), Tseren-Ochir Soyol-Erdene², Chang Hee Han¹, Sungmin Hong³, Hee Jin Hwang¹, Carlo Barbante⁴

¹Korea Polar Research Institute, Incheon, Korea, Republic of, ²National University of Mongolia, Ulaanbaatar, Mongolia, ³Inha University, Incheon, Korea, Republic of, ⁴University of Venice, Venice-Mestre, Italy

Geochemical proxies were measured from the EPICA (European Project for Ice Coring in Antarctica) Dome C ice core, covering a period from ~600 kyr BP to ~800 kyr BP, by inductively coupled plasma sector field mass spectrometry (ICP-SFMS) and ion chromatography (IC) for trace elements and platinum group elements (PGEs) and major ions, respectively. The main trend of trace element and other proxy concentrations match well defined insoluble dust concentration profile. It shows that mineral dust was the dominant source of trace elements to East Antarctica whatever the period. PGE concentrations show a less difference between glacial and interglacial periods in comparison with crustal enriched elements and concentration ratios of Ir and Pt indicate that PGEs in Antarctica may be originated from non-crustal sources. These geochemical evidence suggest that changes in relative contribution of crustal dust, volcanic and extraterrestrial input to Antarctic ice during period from ~600 kyr BP to ~800 kyr BP.
Synchronizing Ice Core Chronologies: An Automated Method

Jai Chowdhry Beeman¹ (jai-chowdhry.beeman@univ-grenoble-alpes.fr), Frédéric Parrenin¹, Emmanuel Witrant², Amaelle Landais³

¹Université Grenoble Alpes / Institut des Géosciences de l’Environnement (IGE), CNRS - UMR 5001, Grenoble, France, ²Université Grenoble Alpes, GIPSA-Lab/CNRS, Grenoble, France, ³LSCE (UMR 8212 CEA-CNRS-UVSQ/IPSL), Université Paris Saclay, Gif-sur-Yvette, France

Ice cores can be synchronised to other ice cores, to paleoclimate records such as speleothems or marine sediment cores, or to orbital targets using time series measurements. Here, as part of the IceChrono dating model (Parrenin et al., 2015), we propose a generalized Bayesian synchronisation method, built on minimizing residuals between series using a parallelized Metropolis-Hastings simulation. We test the method on the gas phase synchronisation of the Epica Dome C and Fletcher Ice cores to the WAIS Divide chronology, using measurements of CH₄.

Our method is able to precisely synchronise the two gas records, introducing a level of reproducibility and objectivity unavailable in manual time series synchronisation methods. To guarantee an accurate estimate of chronological uncertainty, we present the chronologies we produce as ensembles of all the scenarios accepted in the Metropolis-Hastings simulation.
Astronomical Dating: An Inverse Method Applied to Antarctic Ice Cores

¹Université Grenoble Alpes / Institut des Géosciences de l’Environnement (IGE), CNRS - UMR 5001, Grenoble, France, ²LSCE (UMR 8212 CEA-CNRS-UVSQ/IPSL), Université Paris Saclay, Gif-sur-Yvette, France, ³Université Grenoble Alpes, GIPSA-Lab/CNRS, Grenoble, France, ⁴Arctic and Antarctic Research Institute, St. Petersburg, Russian Federation

The chronologies of deep polar ice cores are vital to our understanding of how climate variables and atmospheric greenhouse gas concentrations interacted over the last 800,000 years. The most recent chronologies of the deepest Antarctic ice cores rely in part on proxies that follow the periodicities of Earth’s insolation, defined by its rotational and orbital parameters, which can be calculated well into the past. The processes that link astronomical forcings to their proxies, on the other hand, operate on multiple spatial and temporal scales and are not well-modeled; and the synchronization between a proxy and its target can be ambiguous. This translates into significant uncertainty in astronomical chronologies. Since the alignment of proxies with their astronomical targets is typically performed visually, this uncertainty is difficult to formally address.

Here, we pose the synchronization of ice cores to astronomical targets as an inverse problem, based on the calculation of a cost function that takes into account residuals between proxy and target series. We compare the chronologies and respective uncertainties calculated by this method, using Total Air Content and d18O and dO2/N2 isotopic ratios as tracers of Earth’s astronomical parameters, to visual astronomical chronologies, and compare the results of the chronologies we produce using each proxy-target pair. We discuss the implications of our work for ice core chronologies, focusing on robust uncertainty estimation.
Exploring a New Proxy for Reconstructing Past Wind Strength in Ellsworth Land

Dieter Tetzner1,2 (dietet95@bas.ac.uk), Liz Thomas1, Eric Wolff2, Claire Allen1
1British Antarctic Survey, Cambridge, United Kingdom, 2Cambridge University, Department of Earth Sciences, Cambridge, United Kingdom

In the last decade, several efforts have been carried to assess the causes of the current rapid recent warming measured on West Antarctica and Antarctic Peninsula. The increase in wind strength and shifts in atmospheric circulation patterns have shown to play a key role in driving the advection of warm air parcels from mid-latitudes to high-latitudes. Winds are also responsible for driving basal and surface melting in the ice shelves by enhancing the removal of surface snow and by promoting the upwelling of deep warm water, respectively. All these combined have shown to produce substantial effects on environmental parameters, such as: sea surface temperatures, sea ice extension, air surface temperatures and precipitation.

Even though winds are fundamental components of the climatic system, there is a lack of past records which can help to understand completely the role that winds have played through time and the significance of the recent warming observed in the region.

In this work, we present a record of marine diatoms preserved in an intermediate depth ice core retrieved from the Amundsen Sea region. We explore the diatom abundance, species assemblages and total particulate content to assess the capacity of this record to represent the local/regional variability in wind strength and circulation patterns that influence the onshore northerly winds.
New Insights into Disruptions in the Isotopic Record from the Ronne Ice Shelf

Dieter Tetzner1,2 (dietet95@bas.ac.uk), Francisco Fernandoy3
1British Antarctic Survey, Cambridge, United Kingdom, 2Cambridge University, Department of Earth Sciences, Cambridge, United Kingdom, 3Universidad Andrés Bello, Facultad de Ingeniería, Viña del Mar, Chile

In the last decades, the Filchner-Ronne Ice Shelf (FRIS) region has emerged as an important location to study the response of the West Antarctic Ice Sheets and Ice Shelves in a climate change context. Recent research has highlighted the sensitivity of this region to current changes in the climatic conditions. Instrumental records from this remote region are short and scarce. However, several environmental parameters can be interpreted from proxy records preserved in ice cores. These records can be used to produce accurate chronologies of variations in meteorological parameters.

Even though these records are valuable tools to interpret climate trends, the lack of consistent annual cycles in a suite of chemical species, as well as the presence of peaks within the year cycle, can induce to errors in the production of age models. Identifying the presence of these peaks and understanding the processes behind their development is essential to improve chronologies.

In this work, we use meteorological observations, atmospheric reanalysis and stable water isotopes from firn cores to explore the relation between atmospheric processes and disruptions observed in the stable water isotope records from FRIS and inland. We assess the ability of synoptic scale events, atmospheric circulation modes and post-depositional processes to generate these sporadic patterns in the isotopic profiles.
Ice core records of methane are important indicators of the response of terrestrial biogeochemical cycles. Recent work has greatly enhanced the detail and precision in these records (Bock et al, 2010; Chappellaz et al, 2013; Baumgartner et al, 2014; Rhodes et al, 2015), but their interpretation depends on the fidelity of ice cores in preserving the paleo-atmospheric record. We review published data sets and observe enrichments of methane in samples from Greenland that are correlated with the abundance of dust in the ice (Steffenson, 1997). This is the first evidence of a non-atmospheric source of methane, which we refer to as "excess" methane, affecting ice core samples absent of melt layers or interaction with basal material. Enrichments of ~6 μmol CH₄ per mol Ca²⁺ in the sample were observed which corresponds to enrichments in concentration of several 10's of ppb and depletions in δD-CH₄ up to ~10‰. The release or production of excess methane was directly measured using a multiple melt-refreeze strategy on samples from the GISP2 Greenland Summit ice core and the North Greenland NEEM ice core. Enrichments of methane were absent in Antarctic ice core samples. Of several potential mechanisms, our results are best explained by the desorption of methane from dust particles during sample analysis. Ultimately, excess methane may be adsorbed onto the dust particles from emissions at the dust source or during methanogenesis within the ice sheet.
Water Isotope Characterization of the Styx Glacier Ice Core in East Antarctica

Yeongcheol Han¹ (yhan@kopri.re.kr), Songyi Kim¹ ², Sang Bum Hong¹, Soon Do Hur¹
¹Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of, ²Ewha Womans University, Seoul, Korea, Republic of

The Antarctic Northern Victoria Land (NVL) is adjacent to the Ross Sea and comprises the Transantarctic Mountains, which has both coastal and plateau environmental conditions. The Styx Glacier (SG) is a well-known snow accumulation area with least influence of katabatic wind in NVL and forms a flat surface with an area of >100 km². The field campaign, a part of the Korean Antarctic research program, drilled a 210.5 m long ice core, two firn cores and a snow pit at SG during the 2014-2015 summer season. Stable water isotopes (d¹⁸O, d¹⁷O and dD) were determined for the uppermost 100 meters of the ice core, a firn core and the snow pit. The results were combined with a firn densification model, electrical conductivity measurement data and firn air composition to establish a reliable depth-age relationship and to reconstruct the snow accumulation rate. The results were compared with ice core data from neighboring sites, and the spatial variability at the regional scale was investigated. Statistical approaches were applied to the water isotope time series to derive climate implications and to capture potential teleconnection influence.
Assessment of Fractionation Processes and Corrections for Noble Gas Thermometry

Sarah Shackleton¹ (sshackle@ucsd.edu), Christo Buizert², Jeffrey Severinghaus¹
¹University of California San Diego, Scripps Institution of Oceanography, San Diego, United States, ²Oregon State University, College of Earth, Ocean, and Atmospheric Sciences, Corvallis, United States

Noble gas thermometry allows reconstruction of mean ocean temperature (MOT) from the noble gas content (dKr/N₂, dXe/N₂, and dXe/Kr) of glacial ice. This technique promises to advance our understanding of past ocean heat uptake, potentially narrowing uncertainty in the climate sensitivity. Since the development of this proxy, improvements in the method have allowed for MOT reconstruction with unprecedented precision. These significant steps forward require us to reassess the validity and sensitivity of the assumptions that go into MOT reconstruction. Investigations into mechanisms that decouple the MOT proxies from ocean heat content have primarily focused on processes that affect atmospheric noble gas content. Here we address processes that decouple the noble gas content of air in glacial ice from the atmosphere and assess associated uncertainties in the interpretation of MOT records. We analyze modern firn air and surface ice samples from multiple polar sites, in which the air is young enough that the true atmospheric composition is known. We then correct them for gravitational, thermal and kinetic fractionation and gas loss using several approaches. From this we identify a ‘best method’ for correction of dKr/N₂, dXe/N₂, and dXe/Kr data, and quantify systematic error in MOT records. Using these findings we make suggestions for identifying and correcting potential bias in future MOT campaigns.
Dating of ice cores from high alpine glaciers is challenging due to limited glacier thickness, the complex bedrock geometry and strong annual layer thinning. Water Insoluble Organic Carbon (WIOC) in glacier ice has been used for radiocarbon dating for years [1]. However, this method is limited by the WIOC concentrations. The majority of the carbon containing matter in snow and ice is present as Dissolved Organic Carbon (DOC) [2]. To investigate the suitability of DO$^{14}$C dating, we develop a high efficient and low blank extraction system. Ice samples after cutting are further cleaned and melted under helium gas. WIOC is separated by filtration and Inorganic Carbon (IC) is removed via acidifying and degassing. The remaining DOC in the solution is oxidized by UV lamps. Produced CO$_2$ is quantified after cryogenic trapping and sampled to glass vials for $^{14}$C analyses. This setup has been applied to the Fiescherhorn ice core to estimate anthropogenic contribution of DOC to Alpine glaciers and establish the time boundary of applying DO$^{14}$C as a dating tool.

Today the building industry has a strong impetus and emphasis on sustainable building, a prevalent aspect of which is the use of endemic materials. What happens when the natural resources available aren't what is traditionally considered usable or practical? Throughout the history of building practices in Antarctica there has been minimal employment of materials that are available despite knowledge of the vernacular architectural practices in Arctic regions. Snow and ice are an ever present consideration in Antarctica, whether the structure interacts with drifting snow defensively, treating it as a negative quality, an impediment, or embraces it as a secondary building material and potential insulator. Recent research stations, in contrast to many of the older stations and huts, have been more cognizant of what impact they have on natural surroundings, which has resulted in more creative and innovative structures, including one proposal which incorporates snow as a primary building material. An interpretive-historical study of the building practices provides cultural and environmental insight into why this practice wasn't utilized more as well as the successes and failures.
Vulnerability of Ice-free Landscapes to Human Impacts, East Antarctica

Stephanie McLennan¹ (stephanie.mclennan@ga.gov.au), Tanya O'Neill², Duanne White³

¹Geoscience Australia, Environmental Geoscience Division, Canberra, Australia, ²University of Waikato, Earth and Ocean Sciences, Hamilton, New Zealand, ³University of Canberra, Canberra, Australia

Ice-free regions of Antarctica make up only a fraction of the continent but are often the site of intensive activity associated with national programs and tourism. Without the protection of permanent snow and ice, poorly consolidated sediments and fragile polar landforms can be easily damaged by human activities. Natural recovery processes in the cold, dry climate are slow and poorly understood. Over the next three years a collaborative project between Geoscience Australia, the Australian Antarctic Division, University of Waikato (NZ), and University of Canberra (AUS) will build on existing systematic methods for assessing impact and recovery. Through field experiments and geomorphology mapping, we will identify chemical and physical processes in ice-free landscapes that may influence recovery from disturbance. Preliminary remote landform mapping in the Vestfold Hills, East Antarctica, shows a variety of potentially vulnerable sedimentary landforms between bedrock outcrops, including muddy drainage depressions, ephemeral ponds, raised beaches, boulder fields, dunes, moraines, and gently undulating water-lain deposits. Salt efflorescence on the surface is common, particularly in areas with deeper sedimentary cover. We will link verified landform mapping to soil characteristics to reveal patterns of vulnerability, aid planning and environmental management practices and provide geoscience information to inform predictions of future environmental changes.
Study shows that chlorophyll-a concentration in 80% area of the South Ocean is lower than 0.5 ug/l. Incubation experiment has proven that addition of guano with high content of nutrients may efficiently improve production of chlorophyll.

In south bay of the Doumer island CTD cast data show fluorescent of Chlorophyll-a in upper 100m water are about 0.14-3.64 ug/l with average of 1.09 ug/l, and has a observable peak in depth about 20-30m with temperature of 0.97 °C. POC/PON in the bay is about 4.0-6.4 with average of 5.0, is remarkably lower than FOODBANCS C/N (5.9-7.8) in east of the Anvers Island and Palmer LTER C/N (7.1-9.2) in the west Antarctic Peninsula continent shelf, which may be explained that some guano debris are brought into the bay by melt water, redistributed by tidal current and deposit in coastal zone. These additional input of undissolved particulate guano reduce value of observed C/N, with a trend of being smaller in coast than inner bya. Moreover, low concentrations of coprostanol and cholesterol were detected in the surface sediments in center of the bay, which may be another indicators for penguin guano effect in this area.

It can be inferred that in circumstance of global warming, the historical penguin excretion may release much more nutrients to coastal water. These will stimulate phytoplankton community production and benefit krill resource in the Antarctic. More attentions should be exerted to understand guano role in ecosystem nutrient cycling.
Diversity and Ecophysiology of *Vaucheria* sp. in Coastal Tidal Flats of Svalbard

Claude-Eric Souquieres¹, Jana Kvíderová² (jana.kviderova@objektivem.net), Josef Elster¹,²

¹University of South Bohemia, České Budějovice, Czech Republic, ²Institute of Botany, Academy of Sciences of the Czech Republic, Třeboň, Czech Republic

The Arctic coastal zone, especially tidal flats, is the one most dynamic polar landscapes due to frequent disturbance of the seabed and random recolonization of very unstable fine sediment in temporary system of channels and lagoons. One of such unique areas where these processes occur is the Adventfjorden tidal flat, located near Longyearbyen (Svalbard). The microphytobenthos carpet covers large area of several hectares there, contributing thus significantly to tidal flat stabilization. The xanthophycean microalga *Vaucheria* sp. (Vaucheriaceae, Xanthophyceae) is dominant there in various habitats ranging from freshwater to marine ones. In summer seasons 2016 and 2017, we focused on morphological and molecular diversity of *Vaucheria* sp. with respect to the area distribution, impact of tide and distance from sea on *Vaucheria* sp. distribution together with chemical and physical water and sediment ecological properties. These ecological studies were followed by measurements of photosynthetic activity of *Vaucheria* sp. in two types of microcosmos as well in situ using variable chlorophyll fluorescence and gasometry approaches.
The North East Greenland National Park holds unique and sensitive ecosystems as well as archaeological heritage sites, but is also generally well protected. Nevertheless, the Greenland Sea hydrocarbon licensing round in 2011 opened up a new chapter in hydrocarbon exploration in Greenland, as previously all exploration licenses concerned the west coast of Greenland. Our current knowledge concerning the very remote North East Greenland coastal areas is generally poor, and thus decision support concerning emergency prevention, preparedness and response is challenged.

This project seeks to improve our understanding of the coastal response to oil spill, by assessing potential oil spill sensitivity and resilience. The project utilizes a remote sensing approach to map and characterize the coastal zone in NE Greenland. We develop a Digital Elevation Model covering more than 60,000 km² at a resolution of 8 meters, based on ArcticDEM data. In areas of special interest we further derive intertidal zones, shallow water bathymetry and shoreline types based on both commercial VHR imagery and publically available satellite imagery. Validation will be carried out by in situ measurements.

The obtained knowledge will enable the provision of informed planning and decision making by a number of stakeholders, to support a sustainable management regarding exploration and potential exploitation of hydrocarbon resources.
Here we summarize the results of several coastal research projects carried out along paraglacial coasts of Svalbard during the last decade. We reconstruct the post-Little Ice Age evolution of coasts in western, central and southern Spitsbergen to illustrate the highly variable coastal zone responses to both paraglacial and periglacial landscape transformation associated with deglaciation and intensification of extreme geomorphological processes.

Our results show the key role of climate changes in controlling sediment fluxes from deglaciated valleys to the coastal zone. Under intervals characterized by a warming climate, retreating local ice masses, a shortened sea-ice seasons and melting permafrost most of studied coastal systems rapidly responded to excess of freshly released sediments and experienced significant geomorphological changes leading to development of new coastal landforms (e.g. spits) and progradation of existing forms (e.g beach-ridge plains, barriers). We discuss our new data in the context of previously published coastal evolution studies from Svalbard. The study highlights the need for a greater understanding of the controls on High Arctic coastal systems, especially given the potential for future accelerated climate warming, decay of sea-ice, storminess and sea-level rise and rapidly growing human impact on Arctic resources and strategic locations.

This paper is a contribution to the NCN project UMO2013/08/S/ST10/00585.
Need for an Integrated Research & Development Center in the Alaskan High Arctic

Jasper Hardesty\(^1\) (joharde@gmail.com), Mark Ivey\(^1\), Darielle Dexheimer\(^1\), Catherine Cahill\(^2\), Erika Roesler\(^1\), Fred Helsel\(^1\)
\(^1\)Sandia National Laboratories, Atmospheric Sciences, Albuquerque, United States, \(^2\)University of Alaska - Fairbanks, Alaska Center for Unmanned Aircraft Systems Integration (ACUASI), Fairbanks, United States

Arctic research stations provide critical monitoring and research on climate change for conditions and trends in the Arctic to address gaps in observations, infrastructure, resource management, and emergency response. This poster proposes development of a permanent integrated US High Arctic Research Center (USHARC) at Oliktok Point, Alaska; taking advantage of assets and infrastructure, controlled airspace, an active UAS program and local partnerships.

To address research and technology gaps, USHARC is envisioned to partner stakeholders from science, safety and security to develop comprehensive solutions. The Station will offer year-round use, logistic support, access to varied ecological settings, and support testing of technologies; such as autonomous platforms, energy microgrids, and sensors.

We propose that USHARC, combined with Toolik Field Station and Barrow Environmental Observatory, will form a US network of Arctic Stations. Unique assets from USHARC include: access via land, sea and air; coastal and terrestrial ecologies; controlled airspaces (land and ocean); logistic support; atmospheric observations; connections to Barrow and Toolik; fiber-optic communications; and a University of Alaska Fairbanks UAS Test Facility with an airstrip and hangar.

World-class Arctic research requires year-round access and facilities. A US High Arctic Station network enables monitoring to better study, predict and understand impacts that affect people, communities and planet.
The Coastal Community Ocean Observers (C2O2) Program

Peter Winsor¹ (pwinsor@alaska.edu), Tuula Hollmen³, Seth Danielson²
¹University of Alaska - Fairbanks, Institute of Marine Science, College of Fisheries and Ocean Sciences, Fairbanks, United States, ²University of Alaska - Fairbanks, Fairbanks, United States

The Coastal Community Ocean Observers (C2O2) is a coastal science program that seeks to build a framework for long-term community-driven monitoring of oceanic environmental variables. The C2O2 program combines cost-efficient means for communities to collect environmental data with local interest, promoting mutually beneficial partnerships and relationships for collecting and sharing information. The C2O2 program is currently active in six Alaskan communities which have uniquely different climates, cultures, and local concerns, and represents different oceans and environments. Using simple-to-operate conductivity-depth-salinity-fluorescence profilers, each of these communities have generated a large number of hydrographic data on weekly to months intervals which is reported in near-real time via a web interface and immediately available on the project website for community residents, scientists and stakeholders. Here we describe the C2O2 program, focusing on data collection, results and a build-out plan for the future, including implementation of a biological sampling component. C2O2 is interfacing with similar efforts in Canada, the Mosquito Fleet to the south and the CROW project to the north, to create a linked network of ocean observations in a south-to-north framework to detect and describe climate change propagation and its impact on local ecosystems and communities. We also discuss the possibility to build this to an pan-Arctic wide network of community observations.
Assessment of the vulnerability of Populated Sections of the Arctic Coast

Marek W. Jaskólski1 (marek.jaskolski@uwr.edu.pl), Matt C. Strzelecki1
1University of Wroclaw/ Institute of Geography and Regional Development, Department of Geomorphology, Wroclaw, Poland

The area of the Arctic is inhabited by about 4 million people, and the vast majority of human activity in the Arctic is focused on the coast. Over the past three decades, the climate of the Arctic has changed significantly, the observed increase in temperature was twice as high as the global average. Modern arctic coastal landscapes are strongly modified by accelerated degradation of permafrost and its thawing threatens the existing infrastructure, increases inflow of deglaciation sediments resulting in shallowing of the port basins and extending the period of open water, causing the increase of wave activity and hence increase of the erosive activity. The warming in the Arctic led to the acceleration and intensification of geomorphological processes that directly affect safety of human activities. Most available Arctic literature focuses on coastal zone changes in the local context. However, there is no overall assessment of the vulnerability of the Arctic coast in a global context, which focuses on threats for settlements at the arctic coast. The aim of our study is to show the variability of the vulnerability of human settlements (over 500 inhabitants) along the Arctic coastline and to identify the most endangered areas. Evaluation will be made using indexing methods, e.g. the adapted CVI index and remote sensing tools based on the ArcGIS geographic information system.

We describe a new ocean-sea ice-biogeochemical model, apply it to the Bothnian Bay in the northern Baltic Sea for the time period 1991-2007 and provide the first long-term mesoscale estimates of modelled sea-ice primary production in the northern Baltic Sea. After comparing the available physical and biogeochemical observations with the model results, we show the modelled spatial and temporal variability in sea-ice physical and biogeochemical properties and consider the main factors limiting ice algal primary production. Sea-ice permeability in the studied area was low compared with the polar oceans, which appeared to be a major reason for the generally low primary production rates. Although the sea ice was less saline in the northernmost parts of the basin, these parts were characterized by sea ice with a larger amount of habitable space, higher levels of photosynthetically active radiation and increased macronutrient availability near the coast, which favoured higher algal growth rates. Other parts of the southern central basin were mostly co-limited by less favourable light conditions and lower seawater macronutrient concentrations than in the coastal zones. Although a change towards milder winters was previously detected on a half-century timescale and could partly be seen here, analysis of the temporal evolution of sea-ice biogeochemical properties showed no significant trends over time, though these properties were characterized by large interannual variability.
Biogeochemistry of Antarctic Landfast Sea Ice and the Potential Role of Biofilm

Florian Deman¹ (florian.deman@vub.be), Arnout Roukaerts¹, François Fripiat², Jean-Louis Tison³, Bruno Delille⁴, Frank Dehairs¹
¹Vrije Universiteit Brussel (VUB), AMGC, Brussels, Belgium, ²Max Planck Institute for Chemistry, Climate Geochemistry, Mainz, Germany, ³Université Libre de Bruxelles, Laboratoire de Glaciologie, Brussels, Belgium, ⁴Université de Liège, Unité d’Oceanographie Chimique, Liège, Belgium

Antarctic landfast sea ice exhibits a large accumulation of biomass in the bottom few centimetres of the ice, with particulate organic carbon (POC) concentrations reaching 2 mmol C l⁻¹ during spring bloom. Surprisingly, fieldwork measurements (Adélie Land 2011, McMurdo Sound 2012, Prydz Bay 2015) of nitrate and phosphate concentrations show a simultaneous increase, with values exceeding those of underlying seawater, suggesting an intense remineralisation process within the ice. Such co-evolution of nutrients and biomass contradicts the classical view of nutrient consumption during the growth period followed by remineralisation after the bloom peak, and suggests an intense supply of N from the underlying water column. Results of a NPZD-model indicates that a second nutrient pool, in addition to the brine pool, is essential to successfully model and reproduce field observations. The presence of a biofilm attached to the ice walls could act as a water-retaining substrate forming microenvironments with chemical gradients within the brine channels. The effect of biofilm on nitrogen dynamics (concentration and isotopic composition) in sea ice will be discussed as well as potential implications for other parameters (phosphate, carbon, oxygen).
Cycling of DMS,P in Early-winter Ross Sea Pack Ice during the PIPERS Project

Gauthier Carnat¹ (gauthier.carnat@gmail.com), Bruno Delille², Fanny Van der Linden¹, Johannes de Jong³, Célia Sapart¹, Boris Wittek¹, Stephen Ackley⁴, Sharon Stammerjohn⁵, Jean-Louis Tison¹

¹Université Libre de Bruxelles, Laboratoire de Glaciologie, Brussels, Belgium, ²Université de Liège, Unité d’Océanographie Chimique, Liège, Belgium, ³Université Libre de Bruxelles, Laboratoire G-Time, Brussels, Belgium, ⁴University of Texas at San Antonio, Snow and Ice Geophysics Laboratory, San Antonio, United States, ⁵University of Colorado, Institute of Arctic and Alpine Research, Boulder, United States

Ice-algal assemblages are known to produce large amounts of the sulfur metabolite dimethylsulfoniopropionate (DMSP), and of its volatile degradation product dimethylsulfide (DMS). Sea ice DMS is subsequently released to the polar ocean and atmosphere where it plays multiple roles in the sulfur and carbon cycle, and mediates the formation of climate cooling sulfate aerosols. Previous studies on the cycling of DMS and DMSP in sea ice are mostly limited to the spring/summer seasons, when large blooms develop in first-year ice due to favourable light and nutrient regimes. In contrast, there is much less information about the production of DMS,P during the first stages of sea ice formation in light-limited early-winter. In this context, we carried out measurements of sea ice DMS,P concentrations in the Ross Sea from April until June 2017 in the framework of the PIPERS project. Multiple ice types and thicknesses were sampled (frazil, unconsolidated and consolidated pancakes, first-year ice) together with sea water and brine, in contrasted areas (marginal ice zones, polynyas, and the central Ross sea pack ice). Sea ice DMS,P concentrations (maximum of 95 and 492 nM) were lower than values typically reported during ice-algal spring blooms, but still significantly higher than sea water concentrations at the time of sampling (maximum of 3 and 15 nM). We present and discuss working hypotheses to explain how these concentrations build up through the different steps of sea ice formation.
Biogeochemistry at the Early Stages of Ice Formation: Insights from PIPERS

Bruno Delille1 (bruno.delille@uliege.be), Fanny Van der Linden1,2, Gauthier Carnat2, Céia Sapart2, Jeroen de Jong2, Marie Kotovitch1,2, Florian Deman3, Frank Dehairs2, Jean-Pierre Descy1, Daiki Nomura4, Sharon Stammerjohn5, Steve Ackley6, Jean-Louis Tison2

1Université de Liège, Chemical Oceanography Unit, Liège, Belgium, 2Université Libre de Bruxelles, Glaciology Unit, Bruxelles, Belgium, 3Vrije Universiteit Brussel (VUB), AMGC Department, Brussels, Belgium, 4Hokkaido University, Faculty of Fisheries Science, Hakodate, Japan, 5University of Colorado, Boulder, United States, 6University of Texas at San Antonio, Snow and ice Geophysics Laboratory, San Antonio, United States

The PIPERS cruise on N. B. Palmer into the early winter Ross Sea took place between April and June 2017. PIPERS was a unique opportunity to investigate biogeochemistry of pack ice during early stages of ice formation. We will present insights of the dynamics of sympagic microalgae assemblages, nutrients, particulate organic carbon and 2 potent greenhouse gases (carbon dioxide and nitrous oxide) during early ice growth. The comparison of CO2 fluxes over consolidated and unconsolidated ice show that
1) sea ice acts as a source of CO2 for the atmosphere
2) largest fluxes occur at the earliest sea ice growth stages (i.e. frazil ice, unconsolidated grey ice, pancake ice). Large fluxes are due to ongoing active rejection of impurities, high porosity of highly saline/high temperature young ice, and the absence of snow. Overall, snow appears to restrict CO2 fluxes. In some cases, fluxes over snow appears to be nil or even opposite to fluxes over bare ice. Therefore, while snow is often view as a transient buffer for air-ice gases fluxes, the role of snow appears to be more complicated. The new measurements of CO2 fluxes over young ice carried out during PIPERS potentially allow to complete a budget of CO2 fluxes over Antarctic pack ice by filling a significant gap.
Sea ice plays a significant role in the production and exchanges of climate active gases between the ocean and the atmosphere. One of them, dimethylsulfide (DMS), is a key precursor of sulfate aerosols which affect the Earth radiation balance. DMS is produced by the degradation of two algal metabolites: dimethylsulfoniopropionate (DMSP) and dimethylsulfoxide (DMSO), typically found in very high concentrations in sea ice. Little is known about the factors driving the production of these metabolites in the stressing environmental conditions (in particular low temperatures and high salinities) of the brine inclusions in which sea ice algae thrive. In this context, we present results from axenic cultures experiments with two emblematic species of the sea ice ecosystem: the diatom *Fragilariopsis cylindrus*, and the prymnesiophyte *Phaeocystis antarctica*. We discuss changes in DMSP and DMSO concentrations in response to gradual shifts in salinity and temperature corresponding to the typical seasonal variability encountered by these algae in the brine inclusions (from 4°C and salinity of 34, up to -18°C and salinity of 250). Globally, we show how the outcomes of this research project should improve our understanding and modelling capabilities of the sea ice sulfur cycle.
In the Arctic Ocean, continuing sea ice decline will increase light availability, but enhanced stratification could decrease nutrient supply to the euphotic zone. To investigate the effects of these factors on the taxonomic and trophic structure of planktonic and sympagic communities, we sampled environmental parameters, protists from the under-ice layer and from the water column, zooplankton and under-ice fauna in the Central Arctic Ocean in summer 2012. We identified
1) a 'Shelf-influenced' regime with decaying sea ice, high silicate concentrations and low NO\textsubscript{x} concentrations;
2) a 'Polar' regime with low silicate concentrations and low NO\textsubscript{x} concentrations; and
3) an 'Atlantic' regime with low silicate concentrations and high NO\textsubscript{x} concentrations. Across all communities, the taxonomic composition primarily responded to the variability of sea ice properties. The trophic structure of the communities, however, responded to NO\textsubscript{x} concentrations. The most heterotrophic taxa significantly dominated in the two NO\textsubscript{x}-depleted regimes compared to the NO\textsubscript{x}-rich Atlantic regime. The different nutrient regimes were also associated with differences in ecosystem functions, such as primary production, secondary production and carbon export. While changing sea ice properties will affect taxonomic composition at multiple size classes, low nutrient concentrations in the upper Arctic Ocean may induce a more heterotrophic food web, affecting key ecosystem functions.
Microalgal composition and production was studied in sea ice in Ryder Bay, West-Antarctic Peninsula. This area is the fastest warming oceanic region on earth; between 1979-2007 a 41% decline relative to the mean was recorded. The impact on biogeochemical cycles is poorly described. Development of microalgal sea-ice communities was studied from winter to summer during three years. Over the course of spring, modest surface communities developed with a Haptophyte pigment signature. Major biomass increases were recorded in the bottom layers and reached a maximum concentration of more than 700 µg Chl-a l\(^{-1}\) in December 2014. Early in the season, a mixed algal community inhabited the bottom layer. From November onwards, diatoms dominated the bottom community, with *Nitzschia, Fragillariopsis* and *Berkeley* sp. as the main species. The maximum electron transfer rate (ETR) as determined by PAM-fluorescence at the bottom gradually increased over spring from 3 to 30. At the same time, the slope of ETR versus irradiance (alfa) increased. The value for light saturation (Ik) hardly changed and measured ca. 150µmol photons m\(^{-2}\) s\(^{-1}\). Data will also be presented on production rates determined by means of C13-incorporation and on 13C-POC as a tracer for sea-ice microalgae. These times series provide unique patterns of community structure and photoacclimation in Antarctic landfast ice-algal communities.
DMSP Production and Conversion in Antarctic Landfast Ice

Jacqueline Stefels\textsuperscript{1} (j.stefels@rug.nl), Alison Webb\textsuperscript{1}, Mairi Fenton\textsuperscript{2}, Emily Davey\textsuperscript{2}, Maria van Leeuwe\textsuperscript{1}

\textsuperscript{1}University of Groningen, GELIFES, Groningen, Netherlands, \textsuperscript{2}British Antarctic Survey, Cambridge, United Kingdom

The marginal sea-ice zone around Antarctica is one of largest sources of the climate-active gas dimethylsulphide (DMS). DMS is produced from the enzymatic cleavage of dimethylsulphoniopropionate (DMSP), which is an osmolyte and cryoprotectant in ice algae. The release of DMS occurs mainly during springtime when the ice melts, but may also happen during brine drainage and when gap-layer communities form and mix with melting snow.

Here we present the development of DMSP in sea ice of Ryder Bay, during two winter seasons: 2014 and 2016. Ice cores were taken as soon as ice was accessible and continued until spring. Over winter only total and GF/F-filtered DMS+DMSP was taken, together with HPLC pigments for algal biomass analyses and classification. Bottom-ice concentrations of total DMS+DMSP increased during September/October and reached maximum values in December: generally between 1 and 2µM, but a maximum of 15µM was observed in December 2014. Internal- and surface communities regularly developed earlier in the season and also reaching µM-levels of DMS(P). High DMS(P) concentrations coincided with the presence of Haptophyte algae. In spring, ice cores were fully analyzed for DMS, DMSP and DMSO. Stable-isotope additions were used to calculate conversion rates within the sulphur cycle. In layers with high biomass, DMSP was quickly consumed: approximately 20% ended up in DMS. Other important pathways were uptake by organisms and demethylation.
The Arctic Microbiome During the Winter-spring Transition: Nitrogen-cycle Genes

António Gaspar Gonçalves Sousa1,2 (antonio.sousa@ciimar.up.pt), Maria Paola Tomasino1, Pedro Duarte3, Mar Fernández-Méndez3, Philipp Assmy3, Hugo Ribeiro1, Jaroslaw Surkont4, Ricardo Leite4, José Pereira Leal4, Luís Torgo5,6, Catarina Magalhães1,2

1CIIMAR/CIMAR - Interdisciplinary Centre of Marine and Environmental Research, Bioremediation and Ecosystems Functioning Research Group (EcoBioTec), Matosinhos, Portugal, 2Faculty of Sciences, University of Porto, Department of Biology, Porto, Portugal, 3Norwegian Polar Institute, Fram Centre, Tromsø, Norway, 4Instituto Gulbenkian de Ciência, Computational Genomics, Oeiras, Portugal, 5INESC Technology and Science, LIAAD - Laboratory of Artificial Intelligence and Decision Support, Porto, Portugal, 6University of Porto, Faculty of Sciences, Department of Computer Science, Porto, Portugal

Pelagic microbial communities are a key component of the Arctic Ocean when evaluating the ecological impact of the thinner Arctic icescape, as they constitute the basis of the marine food web and biogeochemical cycles. During the Norwegian young sea ICE expedition (N-ICE2015), that took place in drifting pack ice north of Svalbard between January-June 2015, seawater was collected at 5, 20 or 50, and 250 m depth on 9 March, 27 April and 16 June, together with environmental data. Illumina MiSeq paired-end reads from SSU rRNA amplicon and metagenomes were sequenced to study the composition, diversity and key nitrogen-cycling functions of the Arctic’s microbiome through the winter-spring transition. Results show that nitrifiers, aerobic ammonia oxidizers and nitrite oxidizers, mostly affiliated with *Thaumarchaeota* and *Nitrospinae*, are abundant in subsurface waters below the pack ice during winter-early spring (6.3-27.4%) but nearly absent in late spring (0.1-2.0%). Urease and ammonia monooxygenase encoding genes are positively correlated with total dissolved nitrogen (urea included) suggesting the coupling of ureolysis and ammonia oxidation. Urease encoding gene increases along depth meaning that distinct species of thaumarchaeotes, *Ca. Nitrosopumilus* and Marine Group I, found at different depths in the water column have different potential to carry out ureolysis. These results provide new knowledge about the nitrogen-cycling communities and pathways in the Arctic Ocean.
The contribution of sea-ice primary productivity to the Southern Ocean biological carbon pump is not well constrained. In this study, we partly address this gap and present concentrations of particulate organic carbon (POC) and nitrogen (PON), chlorophyll $a$ (Chl $a$), exopolysaccharides (EPS) and macro-nutrients in fast ice, pack ice and underlying seawater collected in the East Antarctic sector in late summer 2016-2017 (Dec-Jan). Very few sea-ice biological data exist for this time of the year where ocean-ice interactions are maximal due to ice melt and drift.

Chl $a$ concentration in late summer sea ice was up to 130 µg/L in fast ice and 95 µg/L in pack ice. Particulate organic carbon concentrations in the ice were high (up to 7000 µg/L), and C:N ratios were always higher than the Redfield ratio, suggesting carbon overconsumption in the ice. A loss of biomass during sea-ice melting and the production of EPS, which would have retained POC in the ice, could explain the high POC:Chl $a$ ratios (>7000 in fast ice and >1000 in pack ice) encountered in sea ice. Preliminary results also showed that ammonium was consistently enriched in the ice while nitrate+nitrite was predominantly depleted. Sea ice could have been acting as an organic carbon reservoir and recycling factory at this time of the year when the phytoplankton bloom is at its peak. These data also contribute to increase our understanding of the role of pack-ice biogeochemistry, which is less studied than fast ice.
Inter-comparison between Chambers for CO2 Flux Measurements over Sea Ice

Daiki Nomura1,2 (daiki.nomura@fish.hokudai.ac.jp), Bruno Delille3, Jean-Louis Tison4, Gerhard S. Dieckmann5

1Hokkaido University, Hakodate, Japan, 2Arctic Research Center, Hokkaido University, Sapporo, Japan,
3Université de Liège, Liège, Belgium, 4Université Libre de Bruxelles, Bruxelles, Belgium, 5Alfred Wegener
Institute, Bremerhaven, Germany

In order to validate the difference of air-sea ice CO2 flux measurements by different types of CO2 chamber, inter-comparison experiments were carried out on winter Antarctic pack ice in the Weddell Sea (R.V. Polarstern AWECS cruise, July-August 2013). Our ultimate goal is to understand the methodological gaps for the CO2 flux measurements between chamber and eddy covariance methods over sea ice as an activity for SCOR Working Group 152 (ECV-Ice). Two kinds of CO2 chamber systems were used: semi-automated CO2 chambers developed at Hokkaido University and automated long-term CO2 chambers (Li-8100A, LI-COR Biosciences, USA). These chambers were installed at the same ice/snow surface conditions within a 2-m × 2-m area. Based on the quantitative comparisons using least squares linear regression analyses, slope was 1.08, suggesting that the air-sea ice CO2 flux from two chambers were good agreement. Therefore, our inter-comparison experiments confirmed that there was no instrumental bias between two chambers, thereby the past data for air-sea ice CO2 flux obtained by each chamber’s group in the world polar oceans could be shared.
Observations over recent decades suggest that sea ice plays a significant role in global biogeochemical cycles, providing an active biogeochemical interface at the ocean-atmosphere boundary. However, a pressing need exists to perform methodological intercalibration experiments in order to obtain reliable measurements of basic biogeochemical properties, including many of the Essential Climate Variables of the Global Climate Observing System. With newly emerging techniques, and pressed by the rapid changes in sea ice, the time has come to evaluate and improve our approach to study sea-ice systems. In 2016, the Scientific Committee on Oceanic Research (SCOR) launched Working Group 152 on Measuring Essential Climate Variables in Sea Ice (ECV-Ice). This working group will synthesize past intercalibration exercises and design and coordinate new experiments. Our ultimate goal is to provide the international community with standardized protocols for processing sea-ice samples and collecting data for key variables, including CO₂ partial pressure, nutrients, algal biomass and production, and gas exchange. We will also establish the effectiveness of new techniques to address sea-ice heterogeneity (often referred to as “patchiness”). These tasks will directly benefit the long-term community goal of understanding the response of polar marine environments to ongoing climate change.
Water and ice samples were collected weekly in the Baltic Sea from October to May. Abundances of bacteria, virus-like-particles and nanoflagellates as well as chl a concentration were determined and environmental parameters were measured. The effects of environmental conditions and biological interactions on the organisms were examined with Pearson’s correlation test and a first order vector autoregressive model. All studied organisms had clear seasonal succession patterns and the sea ice microbial community had a wintertime succession independent of that of the water column. Accumulation of nanoflagellates and chl a were observed in ice. Bacteria were observed to have a key role in the trophic interactions in both ice and the water column. The results suggest that bacteria have a higher dependence on external factors than biological pressures. Viruses and nanoflagellates, however, seemed more responsive to changes in bacterial abundance. Our findings confirm that ice has an important role for biomass accumulation which is enhanced when the ice melts and carbon is released from ice. While examining the possible future changes of polar ecosystems, is is important to consider the extent to which the microbial food web during winter supports the water column and the benthos and affects ecosystem functioning throughout the year.
Sea ice is a key component of the Earth's climate system. Even though changes in sea ice extent and thickness are well documented, understanding processes that control climate in the polar regions back in time and over longer time scales requires proxy-based paleo reconstructions. Several highly branched isoprenoids (HBIs) have been used previously to investigate changes in sea ice extent in the past. However, the potential of these biomarkers - particularly their $\delta^2$H/1H ratios - to provide information about other parameters of sea ice such as ice thickness and/or snow cover have not been explored. This study focuses on investigation of $\delta^2$H/1H of HBIs isolated from the diatom Pleurosigma intermedium. We cultured this organism to test the hypothesis that $\delta^2$H values would reflect different levels of irradiance. The diatom culture was grown at different levels of light intensity in laboratory conditions. We observed $\delta^2$H-depletion in HBIs extracted from the cultures grown at higher light intensity. Improved understanding of the underlying mechanisms responsible for the isotopic differences in the diatom Pleurosigma intermedium would provide key insights for interpreting $\delta^2$H values of environmental samples from the polar regions. The goal is develop a new methodological approach that could be used to estimate ice thickness or/snow cover, which are among the key parameters with respect to sea ice albedo and heat exchange between the ocean and the atmosphere.
Ultraviolet radiation (UVR) is one of many sources of stress to surface-ocean microbial communities in high-latitude ecosystems. Polar phytoplankton divert a remarkably large fraction of their biomass into lipids that perform functions such as energy storage and cell structure, making these molecules particularly susceptible to UVR-induced degradation compared with lower-latitude species. While there is considerable evidence from the Arctic Ocean that lipids in sinking marine particles can be degraded photochemically, we present new evidence for lipid photooxidation in living plankton communities from the marginal ice zone (MIZ) in West Antarctica. We use a combination of environmental data, field experiments on natural microbial communities, and evidence from an abiotic liposome model designed to mimic the behavior of lipids in living cells to show that UVR exposure can increase the overall oxidation state of plankton living in the MIZ. We use high-resolution mass spectrometry and new lipidomics data analysis methods to identify a diverse suite of oxidized lipids and oxylipins that are produced under these conditions; many of these molecules have not been previously identified in the environment. Using contemporaneous data from the Palmer Long Term Ecological Research study, we show that the removal and modification of intact lipids by UVR exposure can represent a carbon flux equivalent to 22% of the strength of bacterial production in the same waters.
Arctic Sea Ice: Investigating the Origin of Nitrate using $\delta^{15}$N, $\delta^{18}$O and $\Delta^{17}$O

Sydney Clark1 (sydney_clark1@brown.edu), Andrea Mastorakis2, Julie Granger3, Ana Aguilar-Islas4, Meredith Hastings1
1Brown University, Earth, Environmental and Planetary Sciences, Providence, United States, 2Brown University, Chemistry, Providence, United States, 3University of Connecticut, Marine Sciences, Storrs, United States, 4University of Alaska - Fairbanks, College of Fisheries and Ocean Sciences, Fairbanks, United States

Atmospheric deposition (AD) is hypothesized to be the primary source of reactive N ($N_r$) to Arctic sea ice. While advection from the Pacific Ocean delivers a significant supply of $N_r$, it is unclear if AD (directly or from sea ice melt) supports primary production in the $N$-deplete western Arctic Ocean. Isotopes of NO$_3^-$ from sea ice cores provide an opportunity to understand whether melting sea ice represents an external supply of $N$ to the ocean; examination of snow provides an isotopic end-member for direct AD. Sea ice collected during the US Arctic GEOTRACES leg between 82 and 89°N exhibits NO$_3^-$ concentrations from 0.2-1.0 µM, while snow ranges from 1.1-3.7 µM. The isotopic composition of NO$_3^-$ ($\delta^{15}$N, $\delta^{18}$O, $\Delta^{17}$O) was measured on all snow and ice samples. The $\Delta^{17}$O ($\Delta^{17}$O=$\delta^{17}$O-0.52*\delta^{18}O≠0) is a diagnostic tool for atmospheric NO$_3^-$ compared to other NO$_3^-$ sources because only atmospheric NO$_3^-$ contains a nonzero $\Delta^{17}$O. Snow samples were characteristic of atmospheric NO$_3^-$ with generally negative $\delta^{15}$N (-5.9-2‰) and highly enriched $^{17}$O and $^{18}$O ($\Delta^{17}$O=27.1-33.5‰; $\delta^{18}$O=70.8-87.8‰). In contrast, sea ice samples were more enriched in $^{15}$N (-0.3-15‰) and depleted in $^{17}$O and $^{18}$O ($\Delta^{17}$O=0-12.4‰; $\delta^{18}$O=23.3-67.5‰). The presence of a $\Delta^{17}$O>0‰ occurs at various depths, indicating that atmospheric NO$_3^-$ is important in sea ice. However, low $\Delta^{17}$O and $\delta^{18}$O values and numerical modeling of isotope dynamics suggest that a majority of the NO$_3^-$ is derived from seawater/produced biologically in situ.
Biophysical Characterization of Arctic and Antarctic under Ice Environments

Giulia Castellani1 (giulia.castellani@awi.de), Benjamin A. Lange2, Kim Janka Müller3, Carmen David4, Fokje L. Schaaufsma5, Hauke Flores6, Jan A. van Franeker6

Sea ice is a highly inhomogeneous habitat varying on scales of meters to kilometers. The spatial variability of physical factors is reflected in the variability of sea ice microbial community and of sympagic fauna. Characterizing the biophysical environment of sea ice at scales of meters to kilometers is still a challenge. In this work we present data collected with a Surface and Under Ice Trawl (SUIT) during three Arctic and two Antarctic expeditions between 2012 and 2017. The SUIT is a relatively new net, which can catch organisms residing in close proximity to the sea ice underside. The SUIT is equipped with a sensor array from which we can retrieve key environmental properties: water salinity, temperature, chl a, sea ice thickness, under-ice light, and ice-algal chl a. An average trawl is about 2km long, it thus covers scales that can be hardly sampled with classic methodologies. In the present work we show results for sea ice thickness, ridges density, under ice light, and sea-ice chl a concentration derived from the SUIT sensor array. We investigate how the presence of ridges affect the light transmission through sea ice in both the Arctic and Antarctic region. We derive in-ice chl a based on under ice hyperspectral measurements to characterize the food standing stocks in both regions. We present a first habitat characterization on the kilometer scale. Moreover, this work represents the first Arctic-Antarctic comparison of under ice environmental characteristics.
In 2012, an unexpected CH₄ excess has been reported above open leads in the Arctic Ocean showing that sea ice plays a role in the ocean-atmosphere CH₄ dynamics. However, the processes involved there have not yet been identified.

We performed CH₄ stable isotope (d¹³C and dD) analyses on sea ice samples, as well as geochemical and physical measurements, to determine the possible pathways involved in CH₄ production/removal in or under sea ice. We present results from ice cores collected above the shallow shelf of Barrow (Alaska) from January to June 2009 as well as in the landfast ice of McMurdo Sound (Antarctica) from September to November 2012.

We found a clear difference in isotopic signature between the two sites. The McMurdo ice was supersaturated in CH₄ and showed isotopic signatures surprisingly enriched in heavy isotopes (d¹³C between -47 and -12 ‰ and dD between -87 and -350‰). No natural pathways have yet been identified with such isotopic signatures, but we suggest that aerobic CH₄ formation in or under the ice might be a candidate. In contrast, the CH₄ concentrations were much larger in ice overlying the shallow shelf of Barrow and there the origin of CH₄ was clearly biogenic (d¹³C between -48 and -68 ‰ and dD between -180 and -250‰), thus likely originating from the sediment. In the McMurdo ice, the seasonal evolution shows that CH₄ was becoming more enriched in heavy isotopes with time, suggesting the occurrence of aerobic oxidation processes in the ice.
RISE UP: Robotic Exploration Beneath the Ross and McMurdo Ice Shelves

Justin Lawrence¹ (jlawrence@gatech.edu), Britney Schmidt¹, Matthew Meister¹, Jennifer Glass¹, Jeff Bowman²

The NASA-funded RISE UP program (Ross Ice Shelf and Europa Underwater probe) is a three-season project to observe ice-ocean interactions and conditions beneath McMurdo Sound, the McMurdo Ice Shelf (MIS), and the Ross Ice Shelf (RIS) in Antarctica. In addition to traditional water column sampling and profiling methods, these observations are being made via the AUV/ROV Icefin, designed to conduct basal ice and benthic surveys through 30 cm boreholes in remote locations. During the 2017-19 austral summers, and in cooperation with the Antarctica New Zealand Ross Ice Shelf Programme (PI Christina Hulbe), RISE UP will provide insight into these largely unmapped and uncharacterized sub-ice environments.

RISEUP aims to autonomously characterize habitability and sample under-ice environments on broad spatial scales via robotic platforms. By combining data from Icefin’s sensors with CTD profiling, nutrient sampling, cell counts, and DNA extractions, we are mapping observations from the vehicle to the biologically relevant environmental parameters that support life. Across the gradient of field locations from the front of the RIS to the grounding zone, we can trace circulation, ice mass balance, nutrient flux, and sub-shelf biodiversity while refining the sensors autonomous vehicles can use to link environmental processes and habitability. Here, we present the results of this complementary water column sampling from the first season of RISE UP beneath the McMurdo and Ross Ice Shelves.

Several fjords on Svalbard are affected by glacier meltwater. We investigated the sea-ice carbonate (or CO2) chemistry in Tempelfjorden, a west-Spitsbergen fjord, and the influence of different processes such as ice-brine rejection, calcium carbonate precipitation and glacial meltwater during two winters in 2012 and 2013. The two contrasting years clearly showed that the influence of freshwater affected the chemical and physical characteristics of the sea ice. We found large variability of sea-ice total alkalinity (AT), total dissolved inorganic carbon (CT), pCO2, dissolved inorganic nutrients, oxygen isotopic ratio (d18O), and freshwater fractions, from the glacier front to the outer part of the fjord. Processes within the sea ice such as calcium carbonate formation (rikaite) and brine rejection also affected the sea-ice carbonate chemistry. The variability in the sea ice showed the lowest AT in 2012 near the glacier front coinciding with the highest freshwater fractions (glacial water). Relatively high AT in relation to salinity was observed mainly in 2012, which could either be a result of rikaite precipitation in the sea ice (dissolved during analysis) or calcite and dolomite minerals originating from the bedrock/glacial freshwater. We found crystals of rikaite, calcite and aragonite (forms of calcium carbonate) in the snow/frost flowers in 2013 as a result of to sea-ice processes.
Arctic is warming at a much higher rate than the rest of the globe. Several studies have pointed out dramatical changes in the Arctic atmosphere over the past few decades due to local as well as large scale changes in the atmospheric circulations. However, though not as rapid as in the case of atmosphere, the Arctic ocean and its surrounded counterparts have also been undergoing significant modifications in their role in determining the Arctic climate. Atlantic Water transported from the Nordic Seas through the Fram Strait and Barents Sea Opening are the major sources of oceanic heat to the Arctic Ocean. There are several evidences of warmer atlantic water intrusion in the arctic and surrounding oceans, popularly termed as 'Atlantification'. In this study we show that under the changing North Atlantic climate system, the transport of Atlantic water can be significantly modified through a defining contribution from the oceanic circulations. This has significant implications on the net oceanic heat transport towards the Arctic and also on the regional climate patterns. The teleconnections between North Atlantic climate and monsoon, Indian Ocean also indicates to the fact that tropical atmosphere-ocean dynamics can also indirectly influence the oceanic heat transport towards Arctic Ocean through changes in North Atlantic atmospheric dynamics.
Southern Ocean waves are the largest on Earth, but their interaction with sea ice is a particularly poorly understood feedback in the climate system. Limited observations of waves in the Antarctic marginal ice zone (MIZ) show that waves can travel hundreds of kilometers into the ice and that current representations of wave decay are inappropriate in a sea ice regime.

Waves induce floe break up, but the mechanisms of this process are poorly understood. Characterizing the wave field in the MIZ is fundamental to modelling wave motion through sea ice, and is crucial for estimating sea ice cover in this dynamic region. An observed southward shift in storm tracks over recent decades and a predicted increase in wave heights at the ice edge have implications for sea ice extent under changing climate.

Two Waves-In-Ice-Observing-Systems were deployed 1.5 km apart near 62.8 S, 29.8 E on 4th July, 2017 to measure waves in the MIZ. Deployment coincided with the arrival of a low front accompanied by winds averaging 25 m/s. Long period (16 s) waves of nearly 8 m waveheight were recorded at a distance of over 100 km from the ice edge. We show that a significant amount of energy can be transported well into the sea ice by ocean waves. These results provide rare measurements of waves-in-ice during winter storms in the Antarctic MIZ.
Ocean warming near the Antarctic ice shelves has critical implications for ice sheet mass loss and global sea level rise. Here, we use a global climate model with an eddying ocean to quantify the mechanisms contributing to ocean warming on the Antarctic continental shelf in an idealized 2xCO₂ experiment. We find relatively large warm anomalies both in the upper 100 m and at depths above the shelf floor, which are controlled by different mechanisms. The near-surface ocean warming is primarily a response to enhanced onshore advective heat transport across the shelf break. The deep shelf warming is initiated by onshore intrusions of relatively warm Circumpolar Deep Water (CDW), in density classes that access the shelf, as well as the reduction of the vertical mixing of heat. CO₂-induced shelf freshening influences both warming mechanisms. The shelf freshening slows vertical mixing by limiting gravitational instabilities and the upward diffusion of heat associated with CDW, resulting in the build-up of heat at depth. Meanwhile, freshening near the shelf break enhances the lateral density gradient of the Antarctic Slope Front (ASF) and disconnect isopycnals between the shelf and CDW, making cross-ASF heat exchange more difficult. However, at several locations along the ASF, the cross-ASF heat transport is less inhibited and heat can move onshore. Once onshore, lateral and vertical heat advection work to disperse the heat anomalies across the shelf region.
Variability of Circumpolar Deep Water (CDW) intrusion onto the Prydz Bay continental shelf was studied based on CTDs, Moorings, and some other observations. CDW intrusion in Prydz Bay shows significantly temporal and spacial variability. Water exchange occurs all through the year, but the temperature recorder and current meters shows different characteristics in the Prydz Channel. The key reason which causes the different seasonal responses of temperature and current around CDW intrusion region is documented. CDW intrusion process and character reveal that eddy form is the dominant mode during the CDW intrusion events. Heat and salt budgets along the Prydz channel are also studied, which help to estimate the contribution of Prydz Bay to Southern Ocean in heat, salt and water exchange.
Deep Bottom Mixed Layer Instability Drives Variability of Antarctic Slope Front

Wilma Huneke\(^1\) (wilma.huneke@utas.edu.au), Andreas Klocker\(^1\), Ben Galton-Fenzi\(^2\)

\(^1\)University of Tasmania/Institute for Marine and Antarctic Studies, Hobart, Australia, \(^2\)Australian Antarctic Division, Hobart, Australia

Ocean-driven melting plays a fundamental role in the mass loss of the Antarctic ice sheet. The ocean temperature on the continental shelf is modulated by heat exchange across the Antarctic slope where the so-called Antarctic Slope Front separates the cooler continental shelf seas from the relatively warm Southern Ocean. Nevertheless, little is known about the dynamics of the Antarctic Slope Front in modulating this heat exchange. Here we use a process model to show how downslope bottom Ekman transport of shelf water leads to enhanced bottom mixing on the offshore side of the Antarctic Slope Front. Every few years, this enhanced bottom mixing triggers instabilities of the Antarctic Slope Front which allows Circumpolar Deep Water to propagate closer to the continental shelf and enhances near-bottom water mass transformation. The mechanism exists in the model for both constant and seasonal forcing. The identified mechanism needs to be confirmed in realistic models and in the real ocean. It could impact variability of the cross-shelf heat exchange and basal melt rates as well as of the overturning circulation on interannual time scales.
Sea ice remains one of the least explored climate components. Sea ice drift is forced by winds and ocean currents and is an essential element in the dynamics of the polar oceans. Sea ice extent, concentration, and thickness are heavily influenced by ice dynamics. For the accurate representation of sea ice in climate models, realistic parameterization of the sea ice motion and deformation rates are crucial. Here we present high resolution sea ice deformation fields of the Western Ross Sea as a basis to explore ice-atmosphere interactions. The Ross Sea region including three main polynyas; McMurdo Sound, Terra Nova Bay and the Ross Ice Shelf Polynya has experienced a significant increase in sea ice extent in recent decades. For this study, we used sequential high resolution Advanced Synthetic Aperture Radar (ASAR) images from the Envisat satellite. We downsampled the Wide Swath (WS) mode images from 75 m pixel resolution to 150m, which has a swath width of 400km. For this case study, we focused on the month of maximum sea ice extent, October 2011. The images are acquired roughly 24 hours apart and drift velocity is calculated in kilometres per day. We carried out the correlation using feature tracking and pattern matching techniques. The calculated displacement vector field has been compared with the low resolution available sea ice motion vector standard product. Uncertainty has also been calculated as the coarse resolution product is unable to show short term variation.
Precise knowledge of ocean dynamics and interactions with the grounded ice at high latitudes is very crucial for predicting the sea-level rise and further development of adaptation strategies in a global warming climate. The physics of these ocean-ice interactions particularly related to small scale processes, is poorly understood which, along with limited observation constraints, leads to uncertainties in the predictions of future melt rate. We perform direct numerical simulations to investigate dissolving of ice into cold and salty seawater in the presence of turbulent convection. The main focus will be on the dissolving of ice as characterizes many sites around Antarctica. Under these conditions, the diffusion of salt to the ice-water interface depresses the freezing point and further enhances heat diffusion to the ice. Our simulation also shows boundary layer next to the ice face turbulent motions dominant which further amplifies the basal melt rate. It is also important to quantify the difference between the melting of a vertical ice wall and the melting of a sloping ice shelf. The basal slope is observed to vary significantly, due to the formation of crevasses, channels, and terraces. Our high-resolution simulations are designed for direct comparison with laboratory measurements and theory. The temperature and density structures found under Pine Island Glacier show several layers having a vertical scale that can also be explained by this study.
Atlantic Water and Sea Ice Variability in the 20th Century Arctic Ocean

Morven Muilwijk1,2 (morven@uib.no), Lars Henrik Smedsrud1,2, Mehmet Ilicak2,3, Helge Drange1,2
1University of Bergen, Bergen, Norway, 2Bjerknes Centre for Climate Research, Bergen, Norway, 3Uni Research, Bergen, Norway

Both historical observations and outcome from a fully coupled earth system model show a warming trend in core temperature of Atlantic Water entering the Arctic Ocean over the last few decades (1977-2015). The Atlantic Water is also observed to rise systematically in the water column since the 1990's. This suggest an “Atlantification” of the Arctic Ocean, i.e. an ongoing expansion of the Atlantic domain. A portion of this “Atlantification” and recent warming has been attributed to the current global warming and possibly anthropogenic activity. However, past periods of warm Atlantic Water (1930-1940) have been documented. We believe that the Atlantic Water warming trend in the Arctic Ocean may be part of long-term multidecadal variability, which is influenced and reinforced by strong anthropogenic forcing.

We have therefore investigated the interannual, decadal and multidecadal variability of Atlantic Water and sea ice in the Arctic Ocean using a global ocean model. Here we present results from a simulation for the period 1871-2009 with the ocean-sea ice component of the Norwegian Earth System Model (NorESM-O) forced by a Twentieth Century Reanalysis data set, which are compared with available hydrographic measurements of Atlantic Water in the Fram Strait and north of Svalbard, and observations of sea ice.
Variation of Summer Surface Water and Circumpolar Deep Water in the Prydz Bay

Bingrui Li1 (libingrui@pric.org.cn), Chengxiang Wu1, Fei Zuo1, Jia Wang2
1Polar Research Institute of China, Shanghai, China, 2NOAA Great Lakes Environmental Research Lab, Ann Arbor, MI, United States

Based on hydrographic data obtained during four CHINARE (Chinese National Antarctic Research Expedition) cruises (i.e., the 27th, 28th, 29th, and 31st) in the Prydz Bay (Antarctica), we analyzed the distribution of water masses, interannual variation of Summer Surface Water (SSW), reasons for the interannual change, and interannual variation of the characteristics of upwelling Circumpolar Deep Water (CDW). It was found that SSW had wide ranges of temperature and salinity, especially during the 27th and 29th cruises, with temperatures up to 1.22°C higher during the 27th cruise. There appeared to be less sea ice during the 29th cruise. The SSW was distributed within the upper 50 m of the ocean in the sections of 73°E, 75.5°E, and 67.25°S, whereas it was distributed within the upper 100m during the 31st cruise. The upwelling of CDW was particularly evident in the section of 73°E during the 28th and 29th cruises. It was observed during the 28th cruise that CDW upwelled to 90m and it was found to extend southward to 67.67°S during the 29th cruise. Cyclonic circulation has considerable effect on the transportation of the upwelling of CDW in the Prydz Bay.
The retreat of the Arctic sea ice provides an opportunity for increased economic and scientific exploration. Those require predictions of sea ice conditions up to a few years in advance, which so far has proven challenging. One potential cause is that the role of the ocean is still not fully understood. Using multi-ensemble simulations of the global coupled model EC-Earth, initiated at different states of decadal variability and totalling 2000 years, we here investigate the potential for predictability of the oceanic heat transport through Fram Strait and the Barents Sea Opening. We first determine the atmospheric and oceanic drivers of enhanced heat transport, notably focusing on the dynamic relationship between oceanic heat transport into the Arctic and deep water formation in the Nordic Seas, but also in the North Atlantic where it is easier to observe. We then quantify the impact of enhanced oceanic heat transport through either Fram Strait or the Barents Sea Opening onto the Arctic sea ice.
The role of Antarctic Bottom Water (AABW) in changing the ocean circulation and controlling climate variability is widely known. However, a comprehensive understanding of the relative contribution and variability of Antarctic regional deep water mass varieties that form AABW is still lacking. Using a high-quality dataset comprising three decades of observational shipboard surveys in the Weddell Sea (1984-2014), we updated the structure, composition and hydrographic properties variability of the Weddell Sea deep-layer, and quantified the contribution of the source waters composing Weddell Sea Bottom Water (WSBW) in its main formation zone. Shifts in WSBW hydrographic properties towards less dense varieties likely equate to less WSBW being produced over time. WSBW is primarily composed of 71±4% of modified-Warm Deep Water (mWDW) and 29±4% of Dense Shelf Waters, with the latter composed by ~two-thirds (19±2%) of High Salinity Shelf Water and ~one-third (10±6%) of Ice Shelf Water. Further, we show evidence that WSBW variability in the eastern Weddell Sea is driven by changes in the inflow of Dense Shelf Waters and bottom water from the Indian Sector of the Southern Ocean. This was observed through the rise of the WSBW contribution to the total mixture after 2005, following a twenty-year period (1984-2004) of decreasing contribution.
Observations of Ice Tongue-ocean Interaction at Shirase Glacier

Daisuke Hirano¹ (hirano@lowtem.hokudai.ac.jp), Takeshi Tamura², Shuki Ushio², Kay I. Ohshima¹, Daisuke Simizu², Kazuya Ono¹, Tomohide Noguchi³, Shigeru Aoki¹

¹Institute of Low Temperature Science, Hokkaido University, Sapporo, Japan, ²National Institute of Polar Research, Tachikawa, Japan, ³Marine Works Japan, Yokosuka, Japan

Shirase Glacier Tongue (SGT) is a thick floating slab of ice that forms where the glacier flows down onto the ocean surface at the southern closed-section of Lutzow-Holm Bay (LHB) off Enderby Land, East Antarctica. Compared with other major ice shelves/tongues around Antarctica, SGT is smaller in area but its basal melt rate was estimated to be relatively high at a rate of ~7 m per year (Rignot et al., 2013) based on presence of warm deep water. Detailed analysis of the winter hydrographic observations in 1990/92 suggests a 3-dimensional circulation, associated with the SGT-ocean interaction, that comprises: (1) warm mCDW (modified Circumpolar Deep Water) flows southward at the deep layer of submarine canyon that leads into the region beneath SGT, (2) mCDW meets to melt the base of SGT, and (3) mixture of mCDW and basal melt water exports northward at subsurface layer.

To explore in detail the SGT-ocean interaction, summer comprehensive hydrographic observations in LHB were conducted in 2016/17 under the project called ROBOTICA. The latest observation data show clear evidences that support the suggested SGT-ocean interaction mentioned above. Basal melt signals with elevated melt water fractions are clearly found in the temperature, salinity, and dissolved oxygen profiles, especially at subsurface layer (Winter Water) near the northern edge of the SGT. In this talk, preliminary results from the next hydrographic observations in 2017/18 are also presented.
Cold and dense water masses formed over the Ross Sea continental shelf provide a not negligible contribution to the Antarctic Bottom Water and then, to the global thermohaline circulation. Volume and properties are constrained by cross-slope exchange and mixing along the whole Ross Sea shelf break.

In the past, different international expeditions, focused on the Cape Adare trough and Glomar Challenger trough exchanges, have significantly advanced our understanding of the involved processes.

In this work we describe, mainly from the oceanographic point of view, some observations performed during the 2017 Antarctic expedition, carried out on the r/v OGS-Explora, along selected transects in the eastern part of the Ross Sea. This area, core of the PNRA WHISPERS Project, was poorly explored in the past because often covered by the sea ice.

Data reveals that the energetic variability at small scales and strong mixing induced by overflow/down-slope flow have a significant role on the ways the eastern shelf break of the Ross Sea impacts the deeper circulation and abyssal water renewal.
Variability of the Thermocline Depth on the Amundsen Sea Continental Shelf

Karen M. Assmann¹ (karen.assmann@marine.gu.se), Anna K. Wåhlin¹, Karen J. Heywood², Stanley S. Jacobs³, Tae Wan Kim⁴, Sang Hoon Lee⁴, Louise C. Biddle¹

¹University of Gothenburg, Department of Marine Sciences, Gothenburg, Sweden, ²University of East Anglia, Norwich, United Kingdom, ³Lamont-Doherty Earth Observatory of Columbia University, Palisades, United States, ⁴Korea Polar Research Institute (KOPRI), Incheon, Korea, Republic of

The West Antarctic Ice Sheet has been losing mass at an increasing rate over recent decades. The presence of warm ocean water at the ice-ocean interface has been identified as an important contributor to this mass loss. Access of the warm water to the ice base and grounding lines in the ice shelf cavities surrounding the Amundsen Sea is strongly determined by the depth of the thermocline that separates the bottom layer of warm, salty Circumpolar Deep Water from the overlying layer of colder, fresher Winter Water. Ekman pumping has been invoked as a process controlling thermocline depth near the western shelf break and deep mixing as a result of local surface buoyancy forcing has been shown to affect thermocline depth near Pine Island Glacier. Hydrographic observations since 1994 indicate coherent large-scale inter-annual to decadal variability of the thermocline across the shelf. In addition to the ship-based hydrographic observation a series of hydrographic moorings have been deployed across the Amundsen Sea continental shelf since 2009. We make use of these to identify common patterns and differences in the seasonal to inter-annual variability of the thermocline and to discuss the forcing mechanisms responsible.
Density profiles in the upper 1000 m were recorded using Expendable CTD probes operated from a cargo ship chartered for Indian Antarctic Expedition from Cape Town (38°S, 16°E) to Antarctica (70°S, 9°E) during austral summer of 2013-2017. The vertical density structure showed deep mixed layers (~100 m) in the Agulhas Retroflection Region (ARF) due to the presence of downwelling warm-core eddies. The ARF dynamics was monitored using 1/3° x 1/3° Maps of Absolute Dynamic Topography derived from merged altimetry data, which showed that at least 10 warm core eddies get detached from the ARF and they enter the Atlantic during the austral summer period. The geostrophic transport computed relative to 1000 m indicated that large westward transport into the Atlantic ocean is associated with North Subtropical Front during 2013-2015. The hydrological fronts meander southward in 2016 and 2017 due to enhanced and positive nature of Southern Annular Mode. The Southern boundary of Antarctic Circumpolar Front shifted northward from 2013-2017 possibly due to expanding sea ice extent. We discuss the role of role of air sea interaction in genesis of water masses and evolution of mixed layer.
We review the oceanographic data collected during the 2017 Antarctic cruise (r/v OGS-Explora). The underway measurements provided flow velocity in the upper 700 m, and sub-surface temperature (T) and salinity (S). While crossing the Southern Ocean, 7 autonomous floats, 10 drifters and 29 XBTs (eXpendable BathyThermograph) were deployed. In the Ross Sea (RS), 146 XBTs were launched. The most complete oceanographic assessment was achieved over the slope of the Hillary Canyon (HC; ANTSSS and ODYSSEA projects) where eight closely spaced CTD (Conductivity-Temperature-Depth) casts were done. Two additional casts were performed west of the HC where a new sediment drift was explored by geological and geophysical surveys. The CTD system provided pressure, T, S, fluorescence and turbidity. Lowered Acoustic Doppler Current Profiler registered the flow velocity during the CTD casts. We aimed to explore some dynamical aspects of the down-slope flow near the shelf-break where RS bottom water descends and contributes to the Antarctic Bottom Water formation. East of the HC, where the slope area was explored by seismic surveys (WHISPERS project) another XBT transect was performed. Finally, XBTs provided temperature distribution along 550 km transect near the Ross Ice Shelf front. The acquired data provide a unique opportunity to describe the present water properties and concomitant flow patterns to be associated with the geological evidence of the past circulation.
Fast-ice isolates the ocean from kinetic energy input by the wind, a fundamental driver of the surface ocean. We report on new, coincident vertical mixing (microstructure), ocean energy and nutrient concentration observations made at the same Antarctic shelf site during both summer ice-free and winter fast-ice conditions. To our knowledge these are the first combined measurements of their kind. In late summer, the water column above Circumpolar Deep Water (the source of oceanic heat and nutrients) is temperature stratified in the upper 75 m and turbulent mixing is elevated, then falling by an order of magnitude between 80 m and 100 m, remaining at that lower level down to the maximum measurement depth (300 m). By way of contrast, in mid-winter, and in the presence of continuous fast-ice, turbulence is at near-detection limit down to the maximum measurement depth. Thus, isolating the shelf waters from wind during times of fast-ice cover fundamentally alters the turbulent state of the upper water column. Concurrent wind speed and current profile measurements are used to scale the dependence of mixing, in these contrasting regimes, on atmospheric and oceanic energy levels. Nutrient profiles are used in conjunction with mixing profiles to quantify changes in vertical nutrient supply to the euphotic zone during the spring break-up of fast-ice. Shelf-wide upscaling using remotely sensed data is investigated.
The freshwater cycle of the Southern Ocean is pivotal for Earth's climate, but it is still poorly observed and understood. Indeed, the large freshwater fluxes between the ocean and sea ice, as well as between the ocean and the polar ice caps, directly control ocean circulation, the geography of sea-ice, the melt of the ice-caps, with global and major consequences for global climate and sea-level rise. In particular, the relatively warm circumpolar deep water entering in contact with ice-shelves, and the dense water formed as a result through ocean-ice interactions is essential for establishing global ocean circulation, for the carbon cycle, and for the thermal regulation of the planet. In this study, we aim at shedding light in the freshwater cycle of the circulation in the Southeastern Weddell Sea, on the continental shelf, in front of the Filchner ice-shelf. As part of the WAPITI project cruise, we acquired in Jan-Mar 2017 a new set of oxygen and deuterium isotope from in-situ water-column sampling. Measurements have been acquired on the entire continental shelf, from the shelf break to the ice-shelf front, and over the entire Filchner Depression (from East-to-West). We will present preliminary results from this exciting set of observations and present longer-term plans for freshwater cycle, ocean-ice interaction, and ocean circulation analysis of the region.
Realistic high-resolution model simulations of the southwestern Weddell Gyre are prepared using a state-of-the-art z-coordinate ocean plus sea ice model (NEMO, LIM version 3). One of the novelties of the proposed setup consists in the explicit resolution of the sub-iceshelf seas adjacent to the Weddell shelves, including the cavity between the Filchner-Ronne iceshelf (FRIS), modelling the melt at the iceshelf bases, the oceanic processes accounting for it, as well as its impact on the ocean circulation in the cavities and beyond. The configuration is designed to explore the mechanisms of communication between the open Weddell Gyre and the sub-iceshelf seas, and notably, the role played therein by the circulation, stratification and water mass (trans-)formations on the Weddell shelves. Simulations are spun up from a 1/4° Nemo simulation, and carried out at an isotropic horizontal resolution of 1/12° longitude, which ranges from about 4.5 km at the northern boundary of the gyres, varies between 4 to 2 km over the gyre’s shelves, and reaches less than 2 km in the FRIS cavity.
Seasonal and Interannual Variability of the Mixed Layer in Baffin Bay

Christophe Herbaut\textsuperscript{1} (ch@locean-ipsl.upmc.fr), Marie-Noëlle Houssais\textsuperscript{1}, Anne-Cécile Blaizot\textsuperscript{1}, Rémi Lambert\textsuperscript{1}

\textsuperscript{1}Université Pierre et Marie Curie, LOCEAN, Paris, France

A better description of the seasonal and interannual variability of the mixed layer and the underpinning mechanisms is necessary for a clearer understanding of the primary production evolution in Baffin Bay. Spring and summer in-situ measurements are used to estimate the winter maximum of the mixed layer depth and to establish its spatial variability. This observational study is complemented by the analysis of numerical simulations with a $\frac{1}{4}^\circ$ ice-ocean model, which extends over the Arctic and Atlantic Ocean. The timing of the mixed layer deepening, its maximum and its retreat is established and its variability over the period 1979-2016 is analyzed. Fresh water and heat budget are computed to evaluate the role of the surface forcing (brine rejection by ice growth, fresh water flux due to ice melt, heat fluxes) and the advection of polar water from the Arctic and Atlantic water from the Labrador Sea on the evolution of the mixed layer.
Antarctic sea ice concentration has been observed to increase over the last 30 years, in contrast with the decrease that most climate models show. Here, we aim to understand this disagreement by investigating the respective roles of natural variability and anthropogenic forcing in shaping Antarctic sea ice trend. To do so, we use a suite of three climate models of varying resolutions in the ocean that displays a range of behaviours in natural variability with the representation of Weddell Sea polynyas, and different intensities in the decrease of sea ice trend. We find that the disagreement between models and observations is partly due to a desynchronized or too weak natural variability in models compared to observations. In particular, in one model, the sea ice trend between two polynyas is found to be of similar sign and magnitude to that observed over the satellite record. At high latitudes, all models show a surface cooling on a short time scale, followed by a warming on a longer time scale, consistent with the delayed warming mechanism of Ferreira et al. (2015). Of all models, the higher resolution model shows the strongest surface warming and decrease in sea ice, suggesting an important role for eddies in the response of Antarctic sea ice to climate change.
Seasonal Thermocline Evolution at the Weddell Sea Shelf Break-data and Dynamics

Tore Hattermann\textsuperscript{1,2} (tore.hattermann@akvaplan.niva.no)
\textsuperscript{1}Akvaplan-niva AS, Tromsø, Norway, \textsuperscript{2}Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

Observations and models suggest that access of Warm Deep Water to the Weddell Sea ice shelf cavities links closely to variations of the Antarctic Slope Front thermocline along continental shelf break. A new monthly climatology of the slope front hydrography based on CTD profiles from ships and instrumented seals between 1977 and 2016 shows an elevated thermocline (by about 100 m) depth during the austral summer at Kapp Norvegia (17W). The correspondence of this signal with a seasonal warming at the Filchner Trough further downstream (40 W), indicates a coherent evolution of the slope front structure along a larger portion of the shelf break. The climatological cross sections also show a distinct seasonality of the slope current and upper ocean hydrography, where downwelling of fresh Antarctic Surface Water forms a secondary front above the Warm Deep Water interface in summer. Enhanced baroclinic growth rates at this front suggest that the momentum input from wind, which suppresses the thermocline along the shelf break, is partially dissipated by a shallower eddy-overturning cell when surface water is present. A simple overturning model of the southern limb of the Weddell Sea Gyre confirms the sensitivity of the thermocline depth to the upper ocean density changes and reproduces the observed seasonal evolution of the thermocline as a response to wind and buoyancy forcing.
Motivated by observations we explore a negative feedback loop between ice-mediated Ekman pumping and surface geostrophic currents in the Beaufort Gyre (BG). We show that anomalous anticyclonic surface stress due to sea-ice drift leads to increased Ekman downwelling which strengthens the surface geostrophic currents. Accelerating the geostrophic current reduces the ice-ocean relative velocity and hence the effective surface stress. This provides a strong damping of the downwelling processes in the BG and must be a central part of any theory of BG dynamics.
Seasonal Quasi-circumpolar Acceleration of the Antarctic Slope Current System

Alberto Naveira Garabato¹ (acng@soton.ac.uk), Jack Hooley², Tiago Dotto², Sheldon Bacon³, Michel Tsamados⁴, Andrew Ridout⁴, Tom Armitage⁴

¹University of Southampton, Ocean and Earth Science, Southampton, United Kingdom, ²University of Southampton, Southampton, United Kingdom, ³National Oceanography Centre Southampton, Southampton, United Kingdom, ⁴University College London, London, United Kingdom

The Antarctic slope current system plays a pivotal role in the circulation and climate of the Southern Ocean. By flowing westward around Antarctica, it mediates the flow of water masses and freshwater across the polar Southern Ocean, and regulates the cross-slope exchange of warm deep waters offshore and recently ventilated waters onshore - thereby influencing the melting of Antarctic ice shelves and the production of Antarctic Bottom Water.

Despite its significance, the dynamics of the Antarctic slope current have only begun to be probed. As sea ice often covers the Antarctic slope, in situ measurements are very sparse, and conventional remote sensing approaches are incapable of taking ocean observations. Here, we tackle this issue by developing and analysing a new satellite altimetric data set of the Southern Ocean, based on the SIRAL radar altimeter on board CryoSat-2. Sea level measurements from leads between ice floes are extracted to construct a 5-year time series of the circulation in the seasonally and perennially ice-covered ocean. Analysis of these data reveals that the Antarctic slope current exhibits a seasonal cycle of acceleration and deceleration around much of Antarctica, with maximum transport in April - June and minimum transport in November - February. These altimetric diagnostics are shown to be coherent with observations gathered by a small set of near-coast mooring arrays, and to be indicative of driving by variable winds around the Antarctic continent.
Despite being high-nutrient low-chlorophyll (HNLC) region, the Southern Ocean (SO) plays a key role in global carbon cycle by fixing carbon and exporting it from surface to deep Ocean. The unused nutrients also control primary productivity in the tropical ocean. Phytoplankton growth in SO is hypothesized to be limited by availability of iron and sunlight. Recent study shows that the SO is changing now: it's warming and freshening due to climate perturbations which may have implications to the seasonal evolution of biological properties. The Bio-Argo floats equipped with chlorophyll sensors together with traditional CTD sensors deployed in the frontal zone of the Indian sector of the SO provide critical imformations on phytoplankton and the deep chlorophyll maxima. The high productivity at fronts in the open ocean is commonly attributed to availability of sunlight during the austral summer and supply of large quantities of dissolved iron to the ocean surface through deep mixing/plateau effect. We found that the frontal zone results obtained from the floats show a bloom in the spring in the three frontal regions STF, SAF and PF. Our results also show that the shallowing of MLD over the critical depth and resultant light exposure in the MLD during the spring season play a major role in bloom initiation.
Prydz Bay is a large triangular-shaped embayment in the Indian sector of Southern Ocean (SO) and this region plays a key role in SO thermohaline circulation. Compared to other coastal regions, such as Antarctic Peninsula, Weddell Sea, and Ross Sea, relatively little attention has been paid to understand the complex physical processes occurring in the Prydz Bay. In this study, 3-day continuous in-situ high resolution hydrographic data collected from the Prydz Bay during Indian Southern Ocean Expeditions 2006 and 2017 has been used. During 2017, the sea surface temperature in the Prydz Bay was unusually warm (> 1°C) as compared to 2006 which was also well noticeable in the satellite SST. As compared to 2006, wind speed was less and air temperature was higher in 2017 resulting in a less heat loss (-8 W/m², minus sign indicates heat loss from ocean to atmosphere) from the Prydz Bay region in 2017 as compared (-20 W/m²) to that in 2006. Large variability in the properties of water masses was also noticed in 2017 as compared to 2006. During 2016-17, the warming in the Prydz Bay was started well before the austral summer and continued upto fall. Such an elongated warming period in the upper layer may be enough to melt existing ice and/or prevent new ice forming, resulting in the formation of heat polynyas. Using satellite derived data, model outputs and ARGO data; an attempt has been made to illustrate possible mechanisms of this warming in the Prydz Bay over the last one decade.
Changes in freshwater fluxes can have implications for stratification and deep convection in the Arctic and North Atlantic. It is therefore important to understand the potential for future change in the Arctic freshwater budget. However, on short to intermediate timescales it is challenging to separate changes due to internal variability from those due to external forcing. To explore changes in Arctic freshwater fluxes between the 20th and 21st centuries and quantify the respective role of these two drivers of variability, we have analyzed the output from the CESM Large Ensemble (LE), which is forced by the strong (RCP8.5) CMIP5 forcing. We find that individual freshwater flux terms have varying degrees of internal variability, which influences when we see the forced signal emerge from the natural background variability. This provides information to put the observed changes into a longer-term context, as well as provides projections as to where we are most likely to first see a forced trend emerge. For example, based on the CESM LE, the Davis Strait liquid freshwater export to the North Atlantic is showing full emergence from the natural variability of the background state between 2009 and 2037, indicating that significant changes might be imminent in the near future, despite no clear trend in the short observational record to date.
Frontal System Changes at the High Latitudes of the Southeastern Atlantic Ocean

Martim Mas e Braga¹, Ilana Wainer¹ (wainer@usp.br), Mauricio Magalhaes Mata²
¹Universidade de São Paulo, Oceanography Institute, Sao Paulo, Brazil, ²Universidade de Federal do Rio Grande, Oceanography Institute, Rio Grande, Brazil

The transition between the South Atlantic and the Southern Ocean is marked by a frontal system that includes both the South Atlantic Current and the Antarctic Circumpolar Current (ACC). In the eastern part of the basin the latitudinal position of these fronts is thought to control the input of warm waters into the Atlantic basin through the Agulhas Leakage. Changes in the Subtropical and Polar regimes associated with the frontal system that composes the boundary between the Subtropical Gyre and the ACC are investigated using the simulation results of the ocean component of the National Center for Atmospheric Research (NCAR) Community Earth System Model (CESM), POP2. Sea surface height gradients and specific contours are used to identify and track the ocean fronts position. We compare the Subtropical Front position at the eastern edge of the South Atlantic to changes in temperature and salinity as well as Agulhas Current trans-ports and the overlying wind field in order to determine what could be driving frontal variability at this region and its consequences to mass transport from the Indian into the Atlantic. Results suggest that the Subtropical Front is not the southern boundary of the subtropical gyre, but it responds to changes in the “Supergyre”, especially the Indian Ocean Subtropical Gyre expansion.
Future Changes of the Antarctic Coastal Current: A Downscaling Experiment

Marina Noro dos Santos¹ (marina_noro@hotmail.com), Ilana Wainer¹, Jose Edson Pereira¹
¹Universidade de São Paulo, Oceanography Institute, Sao Paulo, Brazil

The Antarctic Coastal Current (ACoC) plays an important role in the hydrographic properties of Antarctic continental shelf. This current helps to maintain the Antarctic Slope Front, and therefore the exchange between the cold and, relatively fresh waters from continental shelf and warmer, saltier waters offshore. However, the impact of the strengthening and shifting poleward of the southern hemisphere westerly winds observed in the last decades in the interplay between coastal winds, coastal current and heat distribution remains poorly understood. In order to understand this relationship, we investigated the ACoC variability and its influence in coastal oceanography dynamics using a high-resolution regional simulation with Regional Ocean Model System (ROMS) for the period of 1975 to 1999. The preliminary results shows that the model is capable to reproduce the ACoC and its seasonal variability. The maximum ACoC mean transport is approximately 6 Sv in 10°W, where this current becomes part of Weddell Gyre. For the same region, the ACoC transport reaches its maximum during austral winter (~8 Sv) and it is weaker during summer, decreasing by up to 2 Sv compared to winter. Results for temperature-salinity diagrams show that the model reproduces satisfactory the water masses structure in Weddell Sea, identifying predominant water masses for this region.
The aim of the MOMA project is to describe the Antarctic Circumpolar Current (ACC) and its variability, in space and time, south of Africa on the basis of an up-to-date high-resolution observational dataset complemented with model simulations performed for this project.

To do this,
(i) a high-resolution observational database describing the ACC and its variability in the Southern Ocean sector south of Africa will be obtained through dedicated activities during SANAP oceanographic cruises;
(ii) a modelling activity based on sigma-coordinate ocean general circulation model (MACC) and an analysis of a dataset produced by a NEMO ocean/sea-ice global model provided by the LGGE-CNRS partner will be carried out;
(iii) experimental and modelling data will be combined to achieve a deep knowledge and understanding of the hydrographic and dynamical features of the region of interest and of the physical mechanisms that govern locally the variability of the ACC fronts and their predictability.

The MOMA project is part of the international efforts solicited and sustained by the Southern Ocean Observing System (SOOS) and in the First Antarctic and Southern Ocean Science Horizon Scan concerning the study of the Meridional Overturning Circulation, the ACC variability and their impact on global climate.

MOMA is funded by the Italian “Programma Nazionale di Ricerche in Antartide” (PNRA) grant nr. PNRA_16_00196.
Storm Impact on Ocean Mixing and Internal Waves under Arctic Sea Ice

Amelie Meyer¹, Arild Sundfjord¹ (arild.sundfjord@npolar.no), Shane Elipot², Algot Kristoffer Peterson³, Ilker Fer⁴
¹Norwegian Polar Institute, Tromsø, Norway, ²University of Miami, Miami, United States, ³Geophysical Institute, University of Bergen, Bergen, Norway, ⁴University of Bergen & Bjerknes Centre, Bergen, Norway

The internal wavefield under the Arctic sea ice is considered mild compared to open-water areas elsewhere. Sea ice insulates the ocean from the atmosphere, lessening energy transfers between those systems. Yet, with the transition in the Arctic to a first year ice regime that has a thinner and more dynamic ice cover, it is important to understand how energy is transferred, in particular from the atmosphere to the ocean. Here we present mixing and internal wavefield observations from the upper ocean north of Svalbard using a six months’ time series of microstructure and ADCP current data. Collected between January and June 2015 from ice camps during the Norwegian Young sea Ice (N-ICE2015) expedition, these data cover the Nansen Basin in pack ice, over the Yermak Plateau, through the marginal ice zone, and to the ice edge. Our observations show that atmospheric storms strongly impact the ocean even under packed sea ice. Storms enhance mixing in the upper ocean with dissipation rates at the ice-ocean interface 10 times larger during storms than average unforced background values. Near-inertial signals with downward energy propagation follow strong storms. These storms also increase the velocity power spectra in the upper water column. The potential increase of storm frequency in the Arctic currently under debate would affect mixing intensity and distribution, with large implications for nutrient fluxes in the water column and heat fluxes at the ocean-ice interface.

Water Masses Circulation and Transformation in the Southern Weddell Sea

Lucie Vignes¹ (lucie.vignes@locean-ipsl.upmc.fr), Jean-Baptiste Sallée¹, Elin Darelius², Nadine Steiger³, Svenja Ryan⁴, Joel Sommeria⁴, Samuel Viboud⁴

¹LOCEAN, UPMC, Paris, France, ²University of Bergen, Bergen, Norway, ³Alfred Wegener Institute, Bremerhaven, Germany, ⁴LEGI, Grenoble, France

The Weddell Sea is largely fuelling the global thermohaline circulation by transforming large amount of water masses and producing the densest waters of the world’s oceans. Water-mass transformation occurs over the entire area covered by the subpolar gyre, but the most intense and probably the least understood fluxes are concentrated near its southernmost fringe: at the Antarctica continental slope, on the continental shelf, and under the floating ice shelves. In this study, we explore the impact of a continental shelf break in restraining the flow across it, and investigate how water masses circulate and are transformed on the continental shelf, when it is reached. We use a unique combination of in-situ observations (e.g. moorings, profiling floats, instrumented seals and CTD casts) to investigate circulation patterns and water-mass characteristics and transformation on the continental shelf in the Southeastern Weddell Sea, as well as novel experiments done in a 13m diameter rotating platform to examine the dynamical constraints of the flow.
The Southern Ocean in Global Climate: The ORCHESTRA Programme

The Southern Ocean accounts for around half of all oceanic uptake of carbon, and more than three-quarters of the heat uptake. Despite its profound importance, the Southern Ocean is also the least measured and arguably the least understood of the world's oceans: its remoteness and inhospitable nature have led to a dearth of sustained, strategic measurement programmes, and the small-scale and complexity of many of the key processes have precluded the desired advances in simulation. To address these issues, a new £10M programme funded by the United Kingdom NERC has now commenced - 'Ocean Regulation of Climate by Heat and Carbon Sequestration and Transports (ORCHESTRA)'. ORCHESTRA will span five years and use a combination of data collection, analyses, and computer simulations to radically improve our ability to measure, understand and predict the circulation of the Southern Ocean and its role in the global climate. It will make unique and important new measurements in the Southern Ocean using a range of techniques, including basin-wide ocean/carbon/tracer sections, as well as deployments of autonomous vehicles, meteorological aircraft, seal tagging and other innovative techniques for collecting data. It will also involve the development and use of advanced ocean and climate simulations, to improve our ability to predict climatic change in coming decades. This poster will outline the rationale, plans and key results from the ORCHESTRA programme.
Finding Mooring Datasets for Southern Ocean Scientists

David Pasquale¹, Melissa Zweng², Pip Bricher¹ (data@soos.aq), Florence Fetterer⁴
¹University of Colorado at Boulder, Boulder, United States, ²National Centers for Environmental Information, Baltimore, United States, ³Southern Ocean Observing System, Battery Point, Australia, ⁴National Snow and Ice Data Center, Boulder, United States

Mooring data are critical for understanding dynamics in oceans because they provide long time-series of observations from a single location. They are particularly valuable in the Southern Ocean where observations of all kinds are spatially and temporally sparse. Many hundreds of moorings have been deployed in the Southern Ocean in recent decades, but to date it has been difficult to find the resulting data, which are scattered across numerous data repositories around the globe.

Now, however, the Southern Ocean Observing System and our colleagues have compiled a central list of historic and current mooring deployments with links to the data centres that host the data. This is a low-tech, community-driven solution to the lack of centralised data management and will improve data discovery for a neglected data type.

As part of this project, we have also worked to rescue unpublished datasets from scientists' hard drives and filing cabinets. This data rescue operation has involved working with individual scientists to convert their data to an international standard and to write comprehensive discovery metadata records before curating the data itself in international data repositories. In this presentation, we will share our progress in data rescue and invite input on future needs for managing and sharing these valuable datasets.
SOOSmap: Finding and Accessing Circumpolar Southern Ocean Data

Antonio Novellino¹, Marco Alba¹, Patrick Gorringe², Pip Bricher³ (data@soos.aq), Wu Lizong⁴, Taco de Bruin⁵
¹European Marine Observation and Data Network, Genova, Italy, ²EuroGOOS, Stockholm, Sweden, ³Southern Ocean Observing System, Battery Point, Australia, ⁴Polar Research Institute of China, Hangzhou, China, ⁵Netherlands Institute for Sea Research, Texel, Netherlands

For many scientists, finding comparison data to complement their fieldwork is a persistent problem. SOOSmap is a new way to find data from many disciplines in one convenient place. Through SOOSmap, you can find data from many of the world’s data centres and explore thematic, spatial, and temporal gaps in the existing set of observations.

The Southern Ocean Observing System (SOOS) is tasked with finding ways to better aggregate and share observing data from around the Southern Ocean. We are developing SOOSmap with our colleagues at the EMODnet Physics group, who have developed data sharing infrastructure for European marine observing data and are now expanding their horizons to support marine observation systems in other parts of the globe.

In this presentation, we will share our progress in developing SOOSmap as a tool for discovering biological, physical, cryospheric, and other environmental data and for exploring gaps in the existing networks of observations. Through SOOSmap, you can filter data layers and time periods to narrow your search to only the most relevant datasets for your purpose.
The Arctic Ocean is a quiescent ocean due to its sea ice cover and a strong halocline, which decouple the subsurface ocean from atmospheric processes. For a better understanding of the Arctic ocean, sea ice, and ecosystem it is important to understand processes that drive the vertical energy and matter fluxes in the water column. Nevertheless, direct flux measurements are difficult to obtain and therefore sparse. We present under-ice turbulent microstructure observations from the Eurasian and Makarov Basin of the Arctic Ocean from two expeditions in 2015. These cover periods of melt during late spring north of Svalbard and freeze-up during anomalously cold late summer conditions across the Eurasian and Makarov basins. Long-term (4-24 h) sampling generally showed elevated dissipation rates at the base of the mixed layer with strongest dissipation near the Eurasian continental slope. In the Makarov Basin, the presence of Bering Sea Summer Water led to stratification and enhanced dissipation within the upper halocline in the Makarov Basin. We discuss these findings in the light of the anomalous conditions in the upper ocean, sea ice and atmosphere during 2015 and present estimates of vertical fluxes of heat, salt and other dissolved substances across the Arctic Ocean.
Subtropical Frontal Mixing and Turbulence in the Indian Sector of Southern Ocean

Anilkumar Narayana Pillai\(^1\) (anilncaor@gmail.com), George V Jenson\(^2\), M. Nuncio\(^1\), Melena Soares\(^1\), Ravi Naik\(^1\), S. C Tripathy\(^1\)

\(^1\)National Center for Antarctic and Ocean Research, Ministry of Earth Sciences, Vasco da Gama, India, \(^2\)Indian Institute of Sciences, Bangalore, India

Abstract

In the subtropical frontal region the upper layer diapycnal mixing studies were carried out using the microstructure shear profiles measured during one of the expeditions to Indian sector of Southern Ocean. In the dynamic and extremely turbulent subtropical region nitrate flux was calculated with the nutrient and turbulence measurement. The low nitrate flux indicates weak turbulence and weak vertical gradient of nutrient. The eddy diffusivity (\(K_p = 10^{-5} \, \text{m}^2/\text{s}\)) has been computed and its application to nutrient gradient appears that the nutrient supply in the study period may not be due to vertical diffusion and a very low quantity of nutrients is supplied through this process. Hence it can be suggested that the vertical supply of nutrients perhaps may be due to advection.
Experimental Highlights of the Eddy Saturation Regime in the Southern Ocean

Milena Menna, Yuri Cotroneo, Pierpaolo Falco, Pierre Marie Poulain, Giorgio Budillon

OGS, Trieste, Italy, Parthenope University, Science and Technology Department, Napoli, Italy

Drifter, satellite, XBT and Argo float data are used to define the response of the Pacific Sector of the Southern Ocean (PSSO) to the large scale climatic patterns as depicted by the Southern Annular Mode Index - SAMI - and the Multivariate ENSO Index - MEI in the period 1995-2017.

During this period, the SAM index is predominately positive, strengthening the westerlies, but ENSO might have played an important role producing an increase/decrease of the EKE during La Niña/El Niño events. In fact, The interplay between SAM and ENSO generates peculiar scenarios with different ocean responses where positive values of SAMI are positive/negative correlated with the EKE when MEI is negative/positive.

In particular, the effects of the SAMI trend are consistent with an increase of the eddy kinetic energy (EKE) field and the ACC transport relatively constant up to the 2007.

Results confirmed that the ocean state were close to the eddy saturation regime up to 2007 underlining the important role of eddies in modulating the ocean circulation response to the main atmospheric forcing. After 2007, the ACC transport shows a different pattern with three well defined maximums. Two of them are in agreement with the SAMI and MEI phases whereas there is the maximum on 2012 that is still difficult to explain.
Along the Western Antarctic Peninsula, ecological hotspots are spatially coherent with submarine canyons and have persisted for millennia. Palmer Deep Canyon, a representative hotspot, is known to have higher phytoplankton biomass than the surrounding non-canyon regions. The physical mechanisms that maintain and deliver phytoplankton and Antarctic krill biomass, potentially increasing prey availability to predators, are not well known. To better understand these important mechanisms, we deployed a purpose built integrated polar observatory consisting of high frequency radar, coordinated gliders, and moorings. The gliders identified a depth dependent influence of the underlying canyon bathymetry on physical and biological variability. A series of simulated particle release experiments in the HF radar current maps were used to estimate surface residence time and connectivity across the canyon. With an average residence time of 2 days, our analysis indicates that the elevated phytoplankton biomass over the central canyon is transported into and out of the hotspot on time scales much shorter than the observed phytoplankton growth rate, suggesting that the canyon may not act as an incubator of phytoplankton productivity as previously suggested. It may instead serve more as a conveyor belt of phytoplankton biomass produced elsewhere, continually replenishing the phytoplankton biomass for the local krill community, which in turn supports numerous top predators.
Italian Mooring Observations in the Western Ross Sea from 1995 to 2016

Pasquale Castagno1, Pierpaolo Falco2 (pierpaolo.falco@uniparthenope.it), Arturo De Alteris1, Massimo De Stefano1, Giovanni Zambardino1, Giancarlo Spezie1, Giorgio Budillon1

1University of Naples Parthenope, Dipartimento di Scienze e Tecnologie, Naples, Italy

Antarctic Bottom Water (AABW) plays an important role in the deep ocean stratification and in the transport of heat, carbon and nutrients throughout the global ocean. In the Pacific Sector of the Southern Ocean, the Ross Sea is responsible for shaping the properties of approximately 25% of the world’s AABW.

The Italian Marine Observatory in the Ross Sea (MORSea) project, funded by the Italian National Program of Research in Antarctica (PNRA), has a network of four active moorings in the western Ross Sea: two located in the Terra Nova Bay polynya, where the AABW precursor (High Salinity Shelf Water) is formed, and two close to the shelf break in the Drygalski and Joides troughs where the AABW is formed from the interaction of the shelf waters and the warm circumpolar deep water and subsequently exits from the continental shelf.

This network together with 3 moorings deployed from 1998 to 2007 in the central Ross Sea have an important role to assess the cross-shelf exchanges processes and changes in the AABW formation in the Ross Sea and how rapidly these changes occur.

Here, we present temperature and salinity time series and the flows variability measured at the four moorings from 1995 to 2016 to describe trends and variability of the water properties inside the Ross Sea. In particular, the flow and water properties variability associated with the tides and mesoscale instabilities are considered to establish their role in the cross-shelf exchange processes.
Deep convection (DC) in the Greenland, the Labrador and the Irminger Seas form the main source of waters of the Atlantic Meridional Thermohaline Circulation (AMOC), and presents an important component of the global climate system. The DC is formed in highly localized mesoscale regions and is accompanied by formation of submesoscale convective cells, instability vortices, narrow jet streams, which makes it difficult to observe in-situ and reproduce in ocean models. In this study we analyze the DC variability using 3 complementing datasets: in-situ data from EN4 Hadley Centre dataset, SODA ocean reanalysis model and ARMOR3D dataset, combining satellite and in-situ observations, data covers period from 1993 to 2015. The Mixed Layer Depth (MLD) was calculated using Montegut (2004), Kara (2003) and Dukhovskoy (2017) methods. Interannual variability of DC, based on analysis of all available in-situ profiles, show significantly shallower DC, as compared to ARMOR3D and SODA data. The latter results also show the similar tendencies with various DC indices (integral potential energy, volume of the water mass formed, etc.)

The research was supported by RSF (project No. 17-17-01151)
On the Response of the LEC for the Southern Ocean to Intensified Westerlies

Yang Wu¹ (yang.wu@hhu.edu.cn), Zhaomin Wang¹, Chengyan Liu²
¹Hohai University, College of Oceanography, Nanjing, China, ²Nanjing University of Information Science & Technology, School of Marine Sciences, Nanjing, China

The potential impact of intensified westerlies on the Lorenz Energy Cycle for the Southern Ocean is examined by employing a global eddy-permitting ocean-sea ice model. Two idealized sensitivity experiments are designed for this purpose: one is driven by 1992 forcing with weaker westerlies and the other driven by 1998 forcing with stronger westerlies. The intensified westerlies lead to the most significant increase of about 30% in the EKE, followed by the mean kinetic energy (MKE) increase (17.9%), eddy available potential energy (EAPE) increase (8.6%), and mean available potential energy (MAPE) increase (6.5%). In contrast, the increases in the generations of kinetic energy and available potential energy are quite similar, ranging from 21% for EAPE generation to 26% for MKE generation. There are considerably increased energy transfers from MKE to MAPE (about 75%) and from MAPE to EAPE (about 78%), reflecting greatly enhanced baroclinic instability pathway. The conversion rates are strongly influenced by large topography; in particular, a relatively large energy conversion from EKE to MKE exists in the regions associated with large topography, in contrast to the energy flow from MKE to EKE over the broad Southern Ocean. Under stronger wind forcing, all energy conversions are enhanced, and the increases in the conversion rates from EAPE to EKE and from EKE to MKE are more prominent than the increases from MKE to MAPE and from MAPE to EAPE near large topography.
Benefits of high resolution modeling of the ocean and sea ice in Adelie Land

A set of regional simulations is performed in the d’Urville sea, Eastern Antarctica. This coastal area boarded by the Antarctic Slope Front, is one of the windiest place in the world and a major spot for dense water formation. Our goal is to assess the importance of spatial resolution and the explicit representation of small scale processes in the ability of the model to reproduce sea ice state and ocean circulation. For this purpose, two resolutions - respectively 1/4° (~10km) and 1/24° (~2km) - will be tested in the NEMO-LIM3 model during years 2010-2013. To also evaluate the effect of interactions with the atmosphere, both configurations will be forced by DFS (0.75° ~30km) and by outputs of the MAR atmospheric model at 8km resolution. The simulations will be analyzed with several foci : at a regional and seasonal scale (~500 km) to evaluate the effect of resolution on heat, momentum and freshwater fluxes. Then, at a smaller scale (~50km), we will give a closer look at the circulation on the continental shelf and the way it is linked to sea ice, ice shelf melting and katabatics. Finally, a focus will be given to the air-sea interface in the presence of sea ice, to investigate in which way small scale processes could influence fluxes between the component of the polar climate.
The NASA-funded RISE UP program (Ross Ice Shelf & Europa Underwater Probe) is a three-season project to monitor basal ice conditions, ice-ocean interactions, and environmental conditions from the ice to the sea floor beneath the McMurdo sound sea ice, the McMurdo Ice Shelf, and the Ross Ice Shelf. The main feature of the program is the novel and scientifically capable Icefin hybrid AUV/ROV vehicle that will conduct surveys from the ice to the seafloor to provide an integrated picture of the conditions below the ice. Nominally, the project will conduct its work in the 17/18, 18/19, and 19/20 austral summers. In cooperation with the Antarctica New Zealand Ross Ice Shelf Programme, PI Christina Hulbe, RISE UP will also deploy Icefin through a borehole at two positions on the Ross Ice Shelf to access previously unmapped regions of the sub-shelf water column.

I will highlight the first results of RISE UP’s first field season from October 2017 to early January 2018. This season includes data collection at three sea ice locations, two that allow us to swim Icefin underneath the ice shelf, and one at the Erebus Glacier Tongue. Onboard Icefin, we collect data from two sonars, two cameras, a DVL/ADCP, and sensors for conductivity & temperature, depth, pH/ORP, DO, CDOM/FDOM and turbidity. I will describe Icefin, and provide preliminary observations of the basal ice conditions, oceanographic properties below the sea ice and ice shelves, and seafloor conditions we observed.
Variability of Ocean Properties along the West Antarctic Peninsula Shelf

Carlos Moffat¹ (cmoffat@udel.edu), Mike Dinniman², John Klinck², Borja Aguiar-Gonzalez¹, David Sutherland³, Jennifer Graham⁴
¹University of Delaware, Newark, United States, ²Old Dominion University, Norfolk, United States, ³University of Oregon, Eugene, United States, ⁴Met Office Hadley Centre, Exeter, United Kingdom

The west Antarctic Peninsula shelf has been one of the most rapidly-warming systems in the southern hemisphere, and glaciers terminating in this coast have undergone dramatic retreat, although with a distinct along-shore pattern: on average, those in contact with the colder waters in northern Bransfield Strait have retreated slower than those terminating in the warmer, southern central coast. The supply of warm Circumpolar Deep Water to this southern region is modulated by deep troughs cutting across the shelf which steer the circulation, and provide a pathway for relatively small, warm ocean eddies to carry heat shoreward. Here, we use the output of the highest-resolution, shelf-wide numerical model available for the wAP as well as available hydrographic data to characterize the spatial and temporal scales of variability of the ocean properties forcing glacier retreat along the coast. The model (ROMS) configuration is eddy-resolving at 1.5 km horizontal resolution, includes 24 vertical levels, and was forced with realistic meteorological fields and observed sea-ice (at the model boundaries) for two years. Results show that the deep northern shelf water variability is dominated by seasonal inflow from the Weddell Sea and bottom-intensified synoptic variability while in the southern wAP shelf seasonal variability in deep water properties is mostly absent. The dynamics of exchange between these two regions and the implications for glacier retreat along the wAP are discussed.
Observational data of the under-ice circulation characteristics were collected in June 2017 during a twelve-day ice drift over the northern Yermak Plateau (approx. 82°N/10°E), as part of the R/V Polarstern expedition PS106. A top anchored mooring line equipped with three upward looking RDI Acoustic Doppler Current Profilers (ADCP) and three SBE microCATs (CTD) was deployed through the ice with the main purpose to measure under-ice water velocities and temperature/salinity characteristics in the upper 180 m of the water column. Additional measurements of under-ice particle size distribution and concentration were undertaken with a Laser In-Situ Scattering and Transmissometry (LISST) particle size analyser, both in profiling and constant-depth mode. Supplemental data of the water properties were collected with the standard shipboard instrumentation. Here, we present results in terms of the vertical and horizontal under-ice water motion and the consequences for the distribution of mass and heat within and below the mixed layer. The ADCP data are additionally interpreted as sound scattering layers used to identify vertical migration patterns of small mesozooplankton (a few mm in size). Our study provides yet some pieces of information about the under-ice dynamics and the vertical positioning of organisms in the spring-to-summer transition of the Arctic Ocean.
Interannual Variability of Modern Fram Strait Outflow Revisited

Georgi Laukert¹ (glaukert@geomar.de), Martin Frank¹, Jan Dreyer¹, Benjamin Rabe², Dorothea Bauch¹, Wilken-Jon von Appen²
¹GEOMAR Helmholtz Centre for Ocean Research Kiel, Kiel, Germany, ²AWI – Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany

Several studies have shown strong variability in the composition of shallow waters leaving the Arctic Ocean through the western Fram Strait. In particular, the fraction of Pacific-derived waters has been suggested to vary annually from dominating to absent. However, this fraction has been determined by calculations involving dissolved nutrient relationships, which can be altered by biogeochemical processes (occurring, for example, on the Greenland Shelf) and, hence, not always reflect water mass advection and mixing alone. An alternative approach uses dissolved radiogenic neodymium (Nd) isotopes (expressed as $\varepsilon_{Nd}$) to identify and quantify the different Arctic water mass components present in the outflowing Arctic waters. This method is applied here to review the interannual variability of the outflow composition. New dissolved $\varepsilon_{Nd}$ data obtained for the years 2014, 2015 and 2016 for the western Fram Strait are complemented by Nd isotope data previously reported for 1999, 2002 and 2012. Constant $\varepsilon_{Nd}$ signatures near -9 and Nd concentrations of $\sim$30 pmol/kg in the core of the outflow are observed for all investigated years and reflect nearly steady contributions of Pacific- and Atlantic-derived waters at a ratio of $\sim$2:3, and minor slightly varying riverine inputs. The remarkably constant Nd characteristics argue for a stable composition of the outflowing Arctic waters, which allows us to hypothesize that the annual outflow was more uniform in the past than previously assumed.
Southern Ocean Stratification Delayed by Submesoscale Wind-front Interactions

Marcel du Plessis\(^1\) (marceldp10@gmail.com), Sebastiaan Swart\(^2\), Isabelle Jane Ansorge\(^1\), Amala Mahadevan\(^3\)

\(^3\)Massachusetts Institute of Technology, Boston, United States

Ocean stratification and the upper mixed layer influence the rate and magnitude the ocean absorbs and stores atmospheric heat and carbon. One way in which these air-sea fluxes are moderated is through the interaction between surface winds and ocean flow fields, such as fronts and eddies. The energetics of the ocean are particularly amplified at submesoscales (1-10 km) which manifest in regions of large horizontal density gradients. Both strong atmospheric forcing and submesoscale features are ubiquitous in the Southern Ocean. We use four high-resolution glider experiments to investigate the impacts of these wind-front interactions on upper ocean processes in the Subantarctic Zone. The mixed layer is found to have a strong seasonal signal superimposed with large submesoscale fluctuations. These periods consist primarily of MLD deepening phases which drive an offset in the onset of summer restratification by up to 35 days. Summer restratification is arrested when the winds orientated along the flow of fronts (down-front) induce a destabilising flux via a horizontal Ekman buoyancy flux (EBF) towards the less dense domain of the front. By incorporating an EBF equivalent heat flux into a 1D model, the upper ocean stratification improves significantly compared to when the model is run using 1D forcing. This study shows the need to incorporate submesoscale processes, such as EBF, into global climate models to correctly account for upper ocean processes that impact climate.

Modification of Atlantic Inflow along its Northern Passage into the Arctic Ocean

Agnieszka Beszczynska-Moeller¹ (abesz@iopan.gda.pl), Waldemar Walczowski², Agata Grynczel³, Malgorzata Merchel¹

¹Institute of Oceanology PAS, Sopot, Poland

Understanding variable oceanic fluxes of volume and heat, carried by Atlantic water (AW) into the Arctic Ocean, and their impact on ocean-atmosphere-ice interactions, ocean heat content, sea ice cover and propagation of anomalies are key challenges to understand the new, warmer regime of the Arctic Ocean. As the AW progress northwards, its properties are modified by ocean-atmosphere interactions, mixing and lateral exchange. AW temperature drops from 7-10°C at the entrance to the Nordic Seas to 3-3.5°C when it leaves Fram Strait. Warm anomalies reaching the Arctic Ocean can result from smaller heat loss during AW northern passage towards and through Fram Strait, and/or from an increased oceanic advection. During the last two decades the extraordinary warm Atlantic water inflow has been reported to progress into the Arctic Ocean, however with strong interannual variations. Here we present results from 20 years of annual hydrographic surveys, covering the Atlantic water inflow in the eastern Norwegian and Greenland seas, Fram Strait up to the southern Nansen Basin. Observations from year-round moorings west and north of Svalbard and regularly deployed Argo floats are also used to elucidate processes contributing to AW modifications during its passage into the Arctic Ocean. Long-term observations reveal new details on spatial structure and temporal evolution of warm anomalies carried into the Arctic Ocean, and their links to heat fluxes and sea ice variability north of Svalbard.
Antarctic outlet glaciers are undergoing rapid transitions. Induced changes in freshwater release to the Southern Ocean have been suggested to contribute to ongoing trends water mass properties and sea ice regimes. However, ocean/sea-ice models disagree as to the quantitative response of the Southern Ocean to changes in glacial freshwater forcing.

In this study, a series of ocean/sea-ice modeling experiments is undertaken with NEMO global 1/4° model configuration in order to study the physical processes involved in the changes of Southern Ocean sea ice over recent decades. Perturbation experiments are carried out with respect to atmospheric and freshwater forcing over recent decades. The freshwater forcing scenario explicitly takes into account the observed changes in the volume of Antarctic ice shelves, which is found to be a key component of changes in freshwater release.

Our results show that changing freshwater release overall increases Antarctic sea ice extent, but with distinctive regional patterns and with large changes in sea-ice thickness. The processes involved in the response differ substantially from region to region depending on the local conditions. Our results suggest that up to one half of the observed total changes in sea ice extent over recent decades might be due to changes in freshwater release, the other half being induced by atmospheric changes. This study emphasizes the need for improving the representation of freshwater sources in climate models.
Existence of the Mendeleev Gyre and its Role in Arctic Circulation

Jinping Zhao¹ (jpzhao@ouc.edu.cn)
²Ocean University of China, College of Oceanic and Atmospheric Sciences, Qingdao, China

On the basis of conductivity, temperature, and depth (CTD) and nutrient data obtained during the Korean R/V Araon 2012 summer Arctic cruise, a gyre-like local circulation in the Chukchi Abyssal Plain is identified as the Mendeleev Gyre (MG). Evidence supporting the existence of the MG includes uniform temperature, salinity, and density in the central plain; a cold core surrounding the plain; a bowl-like surface steric height embedded in the background field; and a lens structure appearing in the vertical section. The nitrate-phosphate (N-P) relationship in the Chukchi Abyssal Plain suggests gyre-like mixing. In an ice-ocean coupled model used to simulate the MG and its multiyear variation, a gyre-like flow pattern is shown to appear only during 2011-2014 corresponding to the sea ice retreat, particularly in 2011 and 2012. Therefore, the MG might be an accompaniment of sea ice retreat. Lateral entrainment is suggested as the driving factor of the MG. The eastward boundary current and the northwestward Pacific inflow provide momentum and relative vorticity by lateral turbulent friction, which facilitates the current leaving from the isobaths to generate a gyre. The inclined isopycnal interfaces from west to east are verified to facilitate an eastward slope flow along inclined isosteric height interfaces. The MG plays the role of a watershed in preventing the outflow of the shelf water and benefiting the colder and fresher shelf water transported directly to the Canada Basin.
Multi-disciplinary observations have been conducted by the Chinese Arctic Research Expeditions (CHINARE) at several sections in Chukchi Sea since 1999. With CTD data from 6 CHINARE cruises during 1999-2014 and outputs from a coupled sea ice - ocean numerical model, Pacific inflows in the Chukchi Sea and their inter-annual variations are analyzed. These sections are limited in the eastern Chukchi Sea, consist of one meridional section along 169°W and several nearly zonal sections between the meridional section and the Alaskan coast. The Alaskan coast water (ACW) occurred in the east end of the zonal section to the Point Hope, as a northward coastal current. The ACW observed in 2012 and 2014 were obviously warmer than that in 2010, approaching to 10°C. At section 169°W, relative warm and fresh waters concentrated at surface layer in the Central Channel to the south of the Herald Shoal, with two separate cores observed in some cruises (e.g. 1999, 2003 and 2010). These waters are identified as ACW with the additional supports from numerical model outputs. The simulated circulation shows that a branch (or two branches) of ACW flows to northwest from Point Hope, across 169°W and reaches Herald Canyon, while most ACW still flows toward northeast along Alaskan coast and enters Barrow Canyon. The thermohaline structure around Herald Shoal showed large inter-annual variability, which implies the complicated interactions between different water masses, including Pacific waters.
Circulation of the Weddell Gyre Inferred from Long-term Observations

Krissy Anne Reeve1 (kreeve@awi.de), Torsten Kanzow1,2, Gerd Rohardt1, Olaf Boebel1, Volker Strass1, Rüdiger Gerdes1
1Alfred-Wegener-Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, 2Bremen University, Physics and Electrical Engineering, Bremen, Germany

The Weddell Gyre plays a fundamental role in the climate system by advecting heat poleward to the Antarctic ice shelves and by regulating the density of water masses that feed the lowest limb of the global overturning circulation. Profile and trajectory data between 2002 and 2015 from a fleet of Argo floats between 50 and 2000 m are exploited in order to produce a full gyre scale view of the Weddell Gyre’s circulation. The data exhibit a gradual cooling of the Warm Deep Water (WDW) as it circulates cyclonically around the gyre. A double-cell structure of the Weddell Gyre is revealed, with a stronger eastern core that intensifies with depth, and a weaker western core that remains invariant with depth. The deep outflow of Weddell Sea Deep and Bottom Water (WSDW, WSBW) at the western boundary of the gyre, formed from WDW by complex modification processes involving sea ice formation, and basal ice shelf melting, is not covered by the float observations. Using mooring array-based observations near the tip of the Antarctic Peninsula between 1989 and 1998, and between 2005 and 2014, a cooling of the WSBW plume is revealed over the observational period. This is in striking contrast to the WSDW in the interior Weddell Sea which has been undergoing a decadal warming. While the cause of the cooling of the WSBW plume is currently unclear, the mooring-based velocity observations indicate that the volume transport of the WSBW plume of 2.5 Sv has been stable over time.
Decadal Covariability of Arctic and Subarctic North Atlantic Freshwater Content

Myriel Horn$^1$ (myriel.horn@awi.de), Ursula Schauer$^1$, Benjamin Rabe$^1$, Claudia Wekerle$^1$
$^1$Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany

Significant freshwater changes have recently been observed both in the Arctic Ocean and the subpolar North Atlantic. To investigate possible links, we compared the liquid freshwater content of the subarctic North Atlantic with the sum of liquid and solid freshwater content of the Arctic Ocean from observations. We found a distinct decadal anti-correlation of the freshwater anomalies in these two regions with anomalies of almost the same magnitude. An analysis of freshwater fluxes from the global Finite Element Sea ice Ocean Model (FESOM) and the CORE2 atmospheric forcing data set revealed that the observed freshwater variations resulted from changing freshwater transports. Furthermore these changes are correlated with the Arctic and North Atlantic Oscillation indices. We suggest that changing freshwater export from the Arctic Ocean to the subarctic North Atlantic responds to multidecadal alternations of the dominant large-scale atmospheric variability. According to the present phase of this large-scale atmospheric variability, the freshwater accumulated during the previous decades in the Arctic Ocean might be released into the sub-Arctic Seas in the coming years. This has the potential to impact the North Atlantic meridional overturning circulation. To further investigate the involved processes, find the driver of freshwater transport changes and proof our hypotheses we show further results from the FESOM simulation and an analysis of the atmospheric forcing.
Marginal ice zone (MIZ) is an area of active interaction between atmosphere, ocean and sea ice. The change of roughness and temperature over the underlying surface (ice/open water) impacts the wind speed and direction. Accurate wind estimates are the core not only for more exact heat fluxes assessments in rapidly changing environment, but also can help to predict the wind drift on the short time-scales. The estimates of wind drift in MIZ can help to reconstruct the ocean surface currents speed finally.

With the lack of in situ measurements in MIZ, one of the best tools covering large areas in polar regions is satellite data. We studied the transformation of wind flows using high resolution Sentinel-1/SAR-C data. The wind fields were calculated from EW Sentinel-1 images with CMOD-5 geophysical model function at 500 m horizontal grid and then compared to ECMWF ERA-INTERIM reanalysis wind data. The possible role of the fetch when calculating wind speed with CMOD-5 is discussed. Several configuration of wind flows position according to the sea edge were studied: on-ice/off-ice, for weak and moderate wind speeds. The estimates of wind-driven ice drift and ocean surface currents are provided for the case studies in 2014-2017 in the Arctic.
Variability and Drivers of the Ice-covered Ross Gyre Circulation

Tiago S. Dotto1, Michel Tsamados2 (m.tsamados@ucl.ac.uk), Alberto G. Garabato1, Sheldon Bacon1, Andy Ridout2, Paul Holland3
1National Oceanography Centre Southampton, Southampton, United Kingdom, 2University College London, London, United Kingdom, 3British Antarctic Survey, Cambridge, United Kingdom

The Ross Gyre (RG) is one of the main current systems of the polar Southern Ocean, and conveys the warm waters from the Antarctic Circumpolar Current toward the cold continental shelves of the Antarctic Pacific sector - regulating the stability of the Ross Ice Shelf. Due to the seasonal sea ice cover, little is known on the variability of the RG circulation and its driving forces. Here, novel altimetry data from Cryosat-2 is used to document the variability and drivers of the RG circulation in the period 2011-2015. The variability of altimetric sea surface height (SSH) is highly coherent with that of ocean bottom pressure inferred from the GRACE mission, suggesting that RG variability on time scales up to interannual has a dominant barotropic component. The ocean surface stress curl was identified as the main driver of the observed variability in the surface circulation. Statistical analyses indicate that variations in the area and strength of the RG are regulated by ice-mediated wind forcing via two distinct dynamical modes of SSH variability:

1) one involving barotropic modes that either follow the continental shelf break around the entire Antarctic continent or are trapped within the Southeastern Pacific basin;
2) and another implicating coherent variability across all ice-covered regions of West Antarctica. This work illustrates the potential of this new altimetric technique in uncovering the nature and dynamics of the circulation in the ice-covered Southern Ocean.
Remote Sensing of Eddies in the Arctic Ocean

Igor Kozlov1,2,3 (igor.eko@gmail.com), Larisa Petrenko2, Anastasya Artamonova4, Oksana Atadzhanova6,5, Alexei Zimin5

1Russian State Hydrometeorological University, Satellite Oceanography Laboratory, St. Petersburg, Russian Federation, 2Marine Hydrophysical Institute of RAS, Remote Sensing Department, Sevastopol, Russian Federation, 3Woods Hole Oceanographic Institute, Physical Oceanography Department, Woods Hole, United States, 4Russian State Hydrometeorological University, St. Petersburg, Russian Federation, 5Shirshov Institute of Oceanology of RAS, St. Petersburg, Russian Federation

Here we present the results of high-resolution satellite observations of oceanic eddies over the selected Arctic regions, including the Eurasian Arctic sector, and Chukchi and Beaufort Seas. The study is based on analysis of a large dataset of ENVISAT Advanced Synthetic Aperture Radar (SAR) images acquired in summer-autumn 2007-2011. Detailed maps of eddies' locations, their diameters and vorticity sign are presented and discussed. This work is supported by RFBR grant 16-29-02106 mol_a_dk, RSF grant No. 17-77-30019, and FASO Russia project No. 0827-2014-0011. ENVISAT ASAR data used in this study were provided by the European Space Agency (ESA) through Cat-1 Project C1F-29721.
The research discusses the cultural identity of the sealer-whalers who were in the Livingston Island (South Shetland Islands, Antarctica) in the nineteenth century through the practices of footwear. The studies were developed from the shoes archaeological collection rescued by the LEACH/UFMG-Brazil. Three groups of related materiality were investigated: the footwear; the bodily practices; and the Antarctica as a place of experience. The study of the format indicates the permanence of models and traditional construction techniques of their shoes. However, they also incorporated the industrial production of the early nineteenth century and, often, articulated to the supply of ships and the whaling crew. All identified units or parts come from simple shoe models similar to “slippers”. There are no adornments or use of other aesthetic features among the shoes of ordinary whalers. The shoes have heavy usage and repairing marks and evidence of material removal. These data tell us about the unavailability of resources and how footwear functioned as an interface between physical performance and the work space in Antarctica.
The Conservation Practices of Sealer-Whalers' Remains in Livingston Island

Gerusa Radicchi\(^1\) (gerusaradicchi@hotmail.com)
\(^1\)Universitat Politècnica de València, Valencia, Spain

The proposal aims to present questions about the methods of the conservation after the archaeological excavation of the sealer-whalers sites in the Livingston Island (South Shetland Islands, Antarctica). These objects are characterized mainly by the presence of very fragile wet organic materials; only preserved by the specific conditions provided by the Antarctic context. The hunters were taken to the islands by whaler shipping companies during the first half of the eighteenth century. They performed their hunting activities in the summer months, living on the beaches in shelters built from rocks found in the region and other resources. Since the first excavation expedition made by the (Leach/UFMG-Brazil), in 2010, an axis of research that articulates the methodology of excavation to conservation has been developed.
Remoteness, Environmental Protection, Mobility and Antarctic Material Remains

Lize-Marié van der Watt¹ (lizemarie.vanderwatt@abe.kth.se)
¹KTH Royal Institute of Technology, Division of History of Science, Technology and Environment, Stockholm, Sweden

This presentation explores the relationship between heritage and environmental protection in Antarctica through focusing on the potential mobility of Antarctic material remains. Using research infrastructures as an example, I ask to what extent heritage designation can be not only geopolitically motivated but also a more pragmatic strategy - for example, to avoid the cost of removal. This also leads to the question of whether or not particular historical remains' heritage status can be enhanced through removal to a more accessible site - and what value impact that has. Could the *de facto* exemption of pre-1958 structures from environmental regulations be seen as a testament to different environmental regimes in the past, and of the remains' importance to particular national narratives? Have the values of environmental protection that underlie removal and eradication programs influenced Antarctic cultural heritage and if so, how does this reflect on our understanding of the relationship between cultural heritage and the Antarctic environment?
Trust in the System of the Formation of Social Capacity in the Arctic Region

Lidia Belonozhko¹ (lnbelonozhko@gmail.com), Oleg Barbakov², Anatoly Silin¹
¹Industrial University of Tyumen, Department of Marketing and Public Administration, Tyumen, Russian Federation, ²Industrial University of Tyumen, Department of Business Informatics and Mathematics, Tyumen, Russian Federation

One of the foundations of social harmony, largely determining the dynamics of the development of the social situation is trust which is acting as confidence in the integrity and sincerity of others or the state and public institutions.

Sociological studies conducted by the authors in recent years in the Yamalo-Nenets Autonomous District recorded a decrease in the level of trust among representatives of different social groups of the population. Thus, mass surveys on representative samples in cities, shift camps and national villages showed that indigenous people representing one northern ethnos less trust the others, and, especially, alien visitors who live in the North constantly, are increasingly negative to shift workers from other regions.

It was found, that the greatest level of social dissatisfaction, pessimism and distrust to the authorities was expressed by the representatives of indigenous ethnic groups (Nenets, Khanty and Selkups), who believe that "they are all deceived". They are often afraid to answer frankly (about half of the respondents chose "difficult to answer" option).

Meanwhile, the social situation in the Arctic and subarctic regions, the resources of which have provided the economic stability for many years, remains largely outside the field of attention of the authorities and the expert community. At the same time, there are still latent processes of social frustration, which can lead to unpredictable forms of protest.
Cultural Heritage and Commercial Fishing in the Southern Ocean

Ricardo Roura1 (ricardo.roura@worldonline.nl)
1Independent Scholar, Amsterdam, Netherlands

The cultural heritage of Antarctica reflects over two hundred years of human presence in the region, primarily early exploration, site occupation and scientific research. The exploitation of Antarctic marine ecosystems began early on with sealing and then whaling. In the past several decades commercial fishing for finfish and krill has been one of the dominant forms of human presence in the Antarctic region. Although now regulated by different instruments and bodies, sealing, whaling and some of the earlier commercial fishing resulted in over-exploitation of target species and a lasting ecosystem legacy. Paradoxically, the material cultural record of commercial fishing is almost entirely absent or invisible in Antarctica, including a lack of associated Historic Sites and Monuments. Since the establishment of the Commission for the Conservation of Marine Living Resources (CCAMR) the legacy of fishing includes a body of databases and scientific knowledge, legal instruments, and “lines on the map” reflecting spatial management measures. Southern Ocean fishing is also associated with some places outside Antarctica. This presentation discusses some concepts of cultural heritage as they apply to Southern Ocean fishing. It suggests that the history and heritage of fishing requires more public visibility. This would contribute to maintain the memory of past over-exploitation and to increase the transparency of CCAMLR’s management of Antarctic marine life.
Managing Antarctic Heritage: The Sealer Sites in the South Shetland Islands

Maria Jimena Cruz¹ (jimenacrz@gmail.com), Andrés Zarankin¹, Michael Pearson²
¹Universidade Federal de Minas Gerais, Anthropology, Belo Horizonte, Brazil, ²Independent Scholar, Fischer, Australia

The concern about the protection and conservation of historical patrimony in Antarctica has been developing during the last decades. These efforts are evidenced by the creation of guidelines and resolutions that aim to avoid the destruction and damage of the sites caused specially by human activities. Sealer sites of the nineteenth century identified in the South Shetland Islands are in an ambiguous position considered part of this patrimony. Differently to other “relevant” historical sites, these places are not directly linked to one particular nation (for example the Heroic Era huts), resulting in a lack of interest in developing conservation strategies. As a consequence of this, several factors that impacted negatively on the conservation of these places have been identified, the main ones being: natural causes (presence of animals and rising sea levels), the increasing tourism activity in the area and the presence of other researcher’s parties in the location. Taking this situation as a starting point, in this presentation we seek to discuss the initial actions that have been carried out by the Antarctic Historical Archaeology Project in order to secure the preservation of these sites. At the same time, we aim to encourage a broad and interdisciplinary discussion between researchers from different disciplines that can help to generate new ways of cooperation and dialogue concerning the conservation of the historic patrimony in Antarctica.
In 1927 the Argentine José Manuel Moneta, head of the Meteorological Station at Laurie Island, shot there the documentary Among Orkney Islands ice (Entre los hielos de las islas Orcadas). Through a sociohistorical analysis of its representations, this paper considers this film as a cinematic document of a new Antarctic social institution, which includes a series of practices internalized by scientists overwintering on permanent stations. Since 1904 these practices were institutionalized through logistical and scientific crews that are yearly relief and today this is one of the most characteristic features of the Antarctic science. The film shows a new form of human activity in Antarctica in a way that differentiates from the heroic age and its most characteristic elements. There, a scientific station becomes the space where scientific activity develops over twelve months, repeating itself each year with a set of elements and social practices that defines it to the present. Moneta shot the documentary during his third winter in Antarctica. He overwintered four times, so he knew very well the details of regular overwintering scientific experience and filmed those practices in the Antarctic environment to show them to the society. Here we will also use his book Four Years in the South Orkney Islands (Cuatro años en las Orcadas del Sur) to complement the analyses with other media and understand how this Antarctic social institution was perceived at that time.
Antarctic Wintering Art of Living: AWAL

Daphné Buiron¹, Elisa Dupuis², Ann-Isabell Guyomard³, Emmanuelle Sultan⁴ (emmanuelle.sultan@mnhn.fr)
¹Collectif CryoSalide, Paris, France, ²Sorbonne Universités (Université 4), Paris, France, ³Oijha - Art and Ethics from Antarctica, Paris, France, ⁴MNHN, DGD REVE, Dinard, France

The Antarctic Observatory CryoSalide project looks at the human presence organization in southern environments. In this intention, the AWAL project is dedicated to the collection and the highlighting of craft and art developed on Antarctic stations during wintering periods. In order to compensate some lack of equipment, craft has naturally being developed, using the limited local means. These creations are unique witnesses of the art of living in Antarctica, and it represents a precious culture heritage, which should be known, collected, archived and valued. Focusing on both Dumont d'Urville (Adélie Land) and Dome C Concordia (East-Antarctic plateau) stations, we offer to conduct a preliminary inventory of art and craft realisations locally performed. Thanks to the voluntary participation of people who have wintered, the AWAL team will provide a catalogue describing, explaining and referencing the different kind of arts (fine arts, culinary art, etc.) developed during wintering times. This data base will be available from the Antarctic Observatory CryoSalide under creative common license (or other to be defined). The purpose is to make this Antarctic art alive, and systematically included in our cultural heritage. So the art of living in Antarctica will become one day a history of the southern art.

First results of the Antarctic art and craft catalogue will be shown with the intention of demonstrating the interest and the potential of such an effort.
Building an Arctic Urban Sustainability Index

Robert Orttung1 (rortung@gmail.com)
1The George Washington University, Sustainability Collaborative, Washington, United States

This presentation will discuss the progress of a multi-disciplinary, international project designed to build an Arctic Urban Sustainability Index. The project looks at 50 cities across the circumpolar area. The index focuses on five areas: economic, environmental, social, governance, and planning. The purpose of the Index is to help policy makers and ordinary citizens promote sustainability and resilience by providing tools to measure progress, identify areas of most urgent need, select verifiable best practices, examine opportunity costs, and determine where external actors can have the greatest impact.

The presentation will examine issues related to defining “urban” and “sustainability” in Arctic conditions. It will discuss the issues related to identifying appropriate indicators for the five areas that make up the index. It will also discuss the issues related to gathering data to measure sustainability and the indicators involved.

In the concluding section, the presentation will present preliminary finding of the project and examine what the next steps will be. Most important is work to define specific indicators that can be used to measure sustainable outcomes in Arctic urban settings. This discussion will focus on the use of indicators that measure such things as greenhouse gas emissions and the appropriateness of different types of education systems for promoting sustainability in Arctic cities.

Antarctic’s Values and Perception of Responsibility in its Protection and Care

Claudia Estrada Goic¹ (claudia.estrada@umag.cl), Mariana Cabanas¹, Constanza Lopez¹, Camila Jalli¹, Kimberly Hechenleitner¹, Ana Latorre¹
¹University of Magellan, Psychology, Punta Arenas, Chile

Social identity is the part of the self that is built from the recognition of our belonging to social groups (Tajfel, 1984). Its link to different social categories which comprise the belonging to a cultural or geographical region has been extensively studied.

The Regional Ecological Identity (IRE) tries to represent an aspect of who we are that depends on our connection with natural environments (the environment we interact with, either in a real or a symbolic way). We present the results of a study on this topic whose subject are inhabitants of the extreme south of Patagonia, who are linked to the Antarctic from a scientific and logistic perspective. A set of instruments measured IRE, the attribution of values to the Antarctic and the perception of personal responsibility in its protection and care; some other socials and ecological variables were also applied. The results show that the participants attribute a high general value to the Antarctic territory, particularly aesthetically and scientifically. Their identification with this territory is strong despite little knowledge and no direct contact. Finally, the social variables are more useful than the ecological ones in explaining the link with this territory. These results are discussed in the background of their significance for the evolution from an anthropocentric concept of the Antarctic to a biocentric / conservationist view.
Thawing Arctic permafrost poses a threat to Arctic cities that are reliant on fossil fuel development by altering the landscape on which critical energy infrastructure is built. Permafrost thaw can not only destabilize oil and gas pipelines by shifting the underlying earth, but resulting exploding methane bubbles can create large craters that have the capacity to damage oil and gas infrastructure. Arctic cities face potential economic, security, and environmental risks from such damage. Many cities in the Arctic rely on oil and gas revenue to meet the needs of their people. Disruptions in oil and gas delivery from pipeline damage may have larger energy security implications that can impact regional and international supplies. Lastly, such damage can cause leaks which can have negative environmental consequences for the surrounding environment. As an extension of the National Science Foundation grant, Arctic PIRE: Promoting Urban Sustainability in the Arctic, this paper will examine the nature of the threat of permafrost thaw on oil and gas infrastructure for a sampling of Arctic cities and discuss if and how these cities are planning to build greater resilience into the energy infrastructure on which they depend.
Participatory Processes in the Arctic: The Case of Urban Development

Dorothea Wehrmann¹ (dorothea.wehrmann@die-gdi.de), Arne Riedel²
¹German Development Institute, Bonn, Germany, ²Ecologic Institut, Berlin, Germany

The Arctic is subject to complex and in many regards interrelated environmental, social-cultural and economic changes and in this context, the proposed presentation discusses specifically the case of urban development in the Arctic, which is encouraged by climate change impacts and the growing development of mineral resources. The presentation first illustrates the various interests and different say that stakeholders have in policy-making processes that concern urban development in the Arctic. Second and under consideration of approaches from political science and legal studies, it discusses how more inclusive policy-making can be encouraged in the governance of Arctic regions. Thereby, the proposed presentation relates to a central criticism often formulated by “people from the North” on the one hand (their perception of being dominated by policies adopted in distant capital cities), and to the often stated need to include local knowledge in policy-making to address the complex challenges in a sustainable manner, on the other. Overall, the proposed presentation outlines different strategies how local stakeholders from remote regions in the Arctic can be better and more effectively included in policy-making processes that affect their livelihoods. By embedding the proposed options also in the wider debate on the governance of the Polar Regions, the proposed presentation concludes by relating these options to local, national, regional and global levels.
The Arctic is warming at a rate twice as fast as the global average; sea ice-free summers are possible by 2050. Arctic exploration and exploitation is expected to increase due to the presence of significant oil and gas resources. Although this provides an opportunity for socio-economic development of the region, environmental risks would also be associated with such activities. Increase in air pollution and related health and ecosystem issues would likely result from growth in industrial, transport, tourism and domestic activities. Given this possible future scenario, it is important to close knowledge gaps of Arctic air pollution sources, their societal and ecosystem impacts, and conceivable future development. A transdisciplinary study design is being developed to define the mitigation options for local Arctic scenarios to advice on sustainable development. This design requires a focus on:
(a) physico-chemical analysis of air pollution, its atmospheric processing and transport,
(b) human exposure assessment,
(c) community-based monitoring,
(d) environmental system analysis,
(e) development of mitigation scenarios together with citizens, policy-makers and other stakeholders, and
(f) meta-analysis in order to transfer the obtained knowledge and mitigation strategies to other Arctic locations.
This is a cross-cutting effort by the international initiative ‘Air Pollution in the Arctic: Climate Environment and Societies’ (PACES) and the International Arctic Science Committee.
Urban sustainability is an important research topic on the global scale. Organizations including the World Bank and UN are leading efforts to measure sustainability in many global cities. Arctic cities, which are characterized by accelerated climate-change, boom-bust economic cycles, diverse societies, and complex governmental structures, have been overlooked within these initiatives. This presentation describes the results of an ongoing project focused on assessing Arctic urban sustainability.

The Arctic Partnership for International Research and Education (PIRE) project has two major components. The first is focused on the development of research tools to measure past, present and future levels of urban sustainability. These data-driven tools are intended to help policymakers define and implement strategies, compare cities, and describe the interactions between pillars of sustainability. The second component focuses on increasing student engagement with Arctic themes. Initiatives include classroom-based digital storytelling exchanges and university-level international field courses. Such pedagogic tools promote knowledge sharing between students of various age groups, within the circumpolar region and outside it.

These components work together to enhance the quality, accessibility, and reach of knowledge about Arctic cities, with applications for diverse Arctic stakeholders.
The continental shelf of the Eastern Bering Sea is home to some of the most productive fisheries in the world. Over the last few decades, winter ice cover in the Bering Sea has retreated earlier and returned later each year, changing the landscape of this diverse region. Species that rely on sea ice for critical life stages such as marine mammals have already begun to experience the negative effects of habitat loss associated with a warming climate. As sea ice projections over the coming decades become even more dire, subsistence communities must face the possibility of the loss of the species they rely so heavily on for survival. As of yet, little is known about how the Bering Sea's marine mammal-dependent communities will be impacted by the loss of biodiversity that is expected in this region. This study uses two vulnerability analysis frameworks to
(1) identify the vulnerability of marine mammals in the Bering Sea to climate change,
(2) determine how these changes will affect indigenous populations dependent on subsistence harvesting in the region, and
(3) assess the management institutions in place and their capacity to provide an adequate response in order to adapt to and mitigate the impacts of climate change.
We demonstrate how this interdisciplinary type of analysis can be used by Native Arctic communities and resource managers to plan ahead for the impacts of climate change and develop management solutions aimed at reducing ecological and social vulnerability.
Economic Valuation of Changes in Ecosystem Services of the Arctic

Hyosun Kim¹ (hyosun@kopri.re.kr)
¹Korea Polar Research Institute (KOPRI), Polar Policy, Incheon, Korea, Republic of

According to the recent observation by NOAA (US National Oceanic and Atmospheric Administration), 2015 was the warmest year based on global average temperature since 1880. The air temperatures in the Arctic have been rising at almost twice the global average and the extent and thickness of sea ice in the Arctic have declined. The warming process in the Arctic is accelerating rapidly. These impacts of drastic change in sea ice caused by climate change in the Arctic threaten the eco-system service and biodiversity in the Arctic.

This study intends to estimate the economic value on changes in eco-system services and biodiversity of the Arctic caused by climate change. The result of the valuation indicates that the total benefit from improvement of ecosystem in the Arctic ranges from 318.6 billion won to 715.9 billion won per annum. Replication scenarios can be explored into two broad categories: scenarios in consideration of conflicts of different stakeholders and scenarios based on wider or narrower definition of biodiversity in the Arctic.

Finally, based on those analysis, this study puts forward some feasible policy suggestions for strengthening the extent of sustainability in the Arctic region.
This research tries to assess if the antarctic bases studied respond or not to the needs of the users. Architecture can be read as the expression of a way of communicating between human collectives and the environment. Design of spaces, distribution in the land, esthetics, the functionality and the historical context can explain the set of relationships that were looking to develop those who carried out the buildings more than 50 years ago. Actually, those who inhabit and use these stations condense different needs from those who have built them, that’s why it is necessary to find the incompatibilities to take them into account in order to undertake reforms. The methodology is based on the complex systemic approach, which consists of the theoretical construction of systems, searching for their observable features as empirical anchorage and the analysis of the relationships that structure them. The processes are differentiated by levels, so as to integrate them through the concrete manifestations of their mutual determinations. Institutional histories, political contexts, regulations and ecological determinants are analyzed. Data were collected in two scientific stations by interviews and participant observation. The human relationship with nature makes antarctic bases emerge as technical sets of artifacts and organizations, which, when studied, reveal systemic contradictions that were developed over time, and are difficult to identify from daily management.
"More Swans Lately": Indigenous Perspectives of Biodiversity Change in Yakutia

Stanislav Ksenofontov1 (stanislav.ksenofontov@geo.uzh.ch), Norman Backhaus1, Gabriela Schaepman-Strub2

1University of Zurich, Geography, Zurich, Switzerland, 2University of Zurich, Environmental Biology, Zurich, Switzerland

Global change drivers have altered biodiversity in the Arctic. As a result, many terrestrial, freshwater and marine species have shifted their distribution, abundance and seasonal activities. Biodiversity change has implications for local indigenous peoples since they depend on biodiversity for their traditional activities. There is a lack of scientific records of biodiversity change in remote Arctic areas and thereby it is vital to incorporate indigenous perspectives to scientific research. Therefore, this paper assesses indigenous perspectives of biodiversity change caused by global change drivers in the Arctic region of the Republic of Sakha (Yakutia) in North-Eastern Siberia, Russia.

The results of the study demonstrate that global change drivers have significantly affected Arctic Yakutian biodiversity. Climate change has altered species distribution. Land use change has impacted plant and animal species. New species are competing with the native ones, thereby some species have shifted their habitats. Global change in Arctic Yakutia has either natural or anthropogenic reasons. Interviewees attribute changes in biodiversity to technological development (abundance of vehicles as well as shipping), and natural processes (e.g., increasing precipitation). The narrative of the predatory but sacred swan symbolizes the quandary indigenous people of Arctic Yakutia find themselves in, when trying to deal with global change.
Aquamess is a science art exhibit and study of marine debris found in the Arctic and Antarctic. The project explores garbage samples from Svalbard (currently exhibited in the Canada Science and Technology Museum) and includes multimedia materials, and scientific information about how marine debris circulates in oceans. It also highlight polar and global initiatives to research, avoid, intercept and redesign the plastic economy for marine ecosystem and human health.

Polar oceans store anthropogenic heat and carbon dioxide and help regulate global atmospheric temperatures. Yet oceans are the trash bins of the planet with an estimated 8 million tonnes of plastics circulating today. What are humans doing, what can and must we do better? This presentation is a blend of visuals, scientific facts and questions to encourage dialogue.

I helped with a cleanup in Svalbard in 2015, collecting and exhibiting a survey of the marine debris and documented in an exhibit Aquamess with portraits of the trash and landscapes. In 2016 in Antarctica I collected a survey of garbage found there, which has not yet been exhibited.

We’re still learning about the volume, location and impact of marine debris in polar regions and in between. But we know it’s harmful to wildlife and to organisms and us too when it breaks down and enters the food chain.

Aquamess is presented in the context of international frameworks and initiatives to protect marine environments significant for planetary health.
The Dry Valley Ecosystem Resilience Programme: Overview and implementation

Stephen Craig Cary1 (caryc@waikato.ac.nz), Charles Lee1, Kurt Joy1, Ian Hawes1, Marwan Katurji2, Jayne Belnap3
1University of Waikato, International Centre for Terrestrial Antarctic Research, Hamilton, New Zealand, 2University of Canterbury, Christchurch, New Zealand, 3U.S. Geological Survey, Moab, United States

Although a consensus exists internationally that Antarctica is vulnerable to invasive species, climate change, and increasing human presence and activity, there is a notable lack of objective measures that facilitate evidence-based environmental management and clearly articulated conservation goals. The aims of the DryVER programme are to deliver objective, evidence-based planning and management tools for the McMurdo Dry Valleys (MDV). This interdisciplinary project’s primary output will be a comprehensive understanding of the resilience and sensitivity of MDV habitats to human impacts and invasive species. This understanding has been gained through fieldwork, laboratory analyses and experimentation, remote-sensing and instrument-based data collection, and climate and ecological modelling. The information is spatially explicit for direct integration into an interactive GIS framework that will map and predict biodiversity, productivity, and sensitivities to impact and invasion across the entire MDV region. Specific information has been obtained on the legacy of previous human impacts and the efficacy of remediation. Importantly, a predictive, physics-based climate model of the MDV will underpin our GIS framework, allowing us to project outcomes under climate change scenarios. The research direction has been informed and enhanced by direct engagement with our primary end users ensure clear pathways for implementation of the research outputs.

Findings from a National Survey on Gender Equity in Australian Antarctic Science

Meredith Nash1 (meredith.nash@utas.edu.au), Mary-Anne Lea², Justine Shaw³, Matt King⁴, Narissa Bax², Hanne Nielsen²
1University of Tasmania, Sociology, Hobart, Australia, ²University of Tasmania / Institute for Marine and Antarctic Studies, Hobart, Australia, ³University of Queensland, Biological Sciences, Brisbane, Australia, ⁴University of Tasmania, School of Land and Food, Hobart, Australia

Although 60% of polar early career researchers are women, there is little available data on gender equity in polar science (Strugnell et al 2016). Existing research primarily tracks publications to measure women’s STEMM participation. This approach risks ignoring disproportionate rates of gender bias and sexual harassment experienced by women. For instance, women in polar research are 3.5 times more likely to experience harassment than men (Clancy et al 2014).

This paper reports findings from an online survey designed to 1) identify socio-demographic characteristics of women working in Australian Antarctic science and 2) detail and contextualize their experiences of scientific research cultures/field-based research. Survey results indicate that 64% of respondents had been sexually harassed during their career, and that most women did not report sexual harassment at the time. Other experiences of reported gender bias included lack of appropriately fitted Antarctic clothing; fewer leadership opportunities; lack of career mobility; and penalties associated with caring responsibilities. Such findings indicate a pressing need to address significant structural barriers to women’s career advancement and leadership opportunities in polar research. They also highlight the problematic contextual and relational conditions that put women at high risk of sexual harassment in the field. These findings can be used to inform long-term responses to gendered inequality in the field.
Leadership in Extreme and Isolated Environments: Perceptions from Antarctica

Daleen Koch1 (daleen.koch@gmail.com)
1University of Stellenbosch, Business School, Economic and Management Sciences, Belville, South Africa

The extreme, isolated and confined environment encountered at Antarctic stations provide unique challenges to management and leadership. The study investigated effective leadership at Antarctic stations, as well as the difference in perceptions based on gender, expedition experience, and the occurrence of emergencies or interpersonal conflict.

The findings were gathered from 180 returned expeditions who participated in the South African National Antarctic Programme from 1961 to 2015. The research collected primary data, using a standardised questionnaire as a survey instrument. The results were analysed using descriptive statistics.

The analysis showed that an effective station leader maintains a personal bond with individuals, maintains a balance between active and passive regulation of the emotional well-being of team members, makes an effort to create and sustain a positive team climate, and maintains a moderate involvement in professional duties of the team. Gender, experience and events at the station influenced perceptions of the station leader’s role in maintaining a personal bond, individual well-being, the team climate and intervention in professional duties. This research report is of value to National Antarctic Programs, space exploration missions, as well as to organisations in distress, who find themselves in environments that are harsh and unforgiving, similar to the isolated and extreme environments at an Antarctic station.
In this paper I will present my dissertation project within the framework of REXSAC - Resource Extraction and Sustainable Arctic Communities. The objective of my research is to explore how stakeholders in different parts of the Arctic have dealt with mining legacies - both material and immaterial - during different time periods and in different places. I will compare former mining areas in three regions; Northern Sweden, Svalbard and northern Canada. Stakeholders in all of these regions have had to deal with a multitude of legacies from mining, from both recently closed mines as well as legacies from older mines. The operations are gone, but their legacies still linger in the collective memories of the local communities and in the landscape. My approach will be multidisciplinary, combining theory and method from critical heritage studies, history of technology, economy, human geography and social/cultural anthropology. I will primarily work with methods such as archival research and interviews, as well as archaeological field work at industrial and post-industrial sites in the Arctic.
Autonomous Thermal Sonde for Subglacial Lakes Exploration

Pavel Talalay¹ (ptalalay@yahoo.com), Youhong Sun¹, Yuansheng Li², Guoping Li³, Jingbiao Liu⁴, Qifeng Cui⁵, Pinlu Cao⁶, Alexey Markov¹, Jixin Wang¹, Jianhua Wang⁴, Rusheng Wang⁵, Dongliang Wang⁶, Xiaopeng Fan¹, Nan Zhang¹, Haibin Yu⁴, Shilin Peng⁴, Sheng Wu⁶, Yang Yang¹, Bing Li¹, Ting Wang¹, Yongwen Liu¹, Yanji Chen¹, Yunchen Liu¹

¹Jilin University, Changchun, China, ²Polar Research Institute of China, Shanghai, China, ³Nanjing Institute of Astronomical Optics & Technology, National Astronomical Observatories, CAS, Nanjing, China, ⁴Hangzhou Dianzi University, Hangzhou, China, ⁵Research Institute of System Engineering, Shanghai Aerospace Bureau, Shanghai, China, ⁶National Ocean Technology Center, Tianjin, China

To date, more than 400 relatively small subglacial reservoirs and several large lakes were discovered in Antarctica. Certainly subglacial lakes exist in Greenland. In recent years, different approaches were taken to access and directly sample subglacial water environments. RECoverable Autonomous Sonde (RECAS) allows to access subglacial lake when water remains isolated from the modern ice sheet surface during sampling. The thermal drill can melt a hole to ice sheet bottom and is able to move upwards. It includes two electrically powered thermal drill bits located at the upper and lower ends of the sonde, heated body, control system, sampling chamber and coiling system. All down-hole RECAS components will be sterilized prior to deployment. The melted water is not recovered from the hole and it refreezes behind the sonde. The power and signal line is released from the coil inside the sonde. When sampling and monitoring are complete, the coil motor is activated and the top drill bit is powered. It is proposed that the research personnel leave the site after RECAS deployment and the sonde operates as a fully autonomous system. The power is provided by no-live-operator diesel engine generators. The first laboratory tests of sonde prototype are scheduled for early 2018, field tests are planned in season 2018-2019, in the area of Chinese Antarctic station Zhongshan.
Comparing Data Derived from Animal-borne and Argo Observations

Anne M. Treasure¹,² (anne.m.treasure@gmail.com), Isabelle J Ansorge², Marcel du Plessis², Marthán N. Bester¹, P.J. Nico de Bruyn¹
¹University of Pretoria, Mammal Research Institute, Department of Zoology & Entomology, Pretoria, South Africa, ²University of Cape Town, Department of Oceanography and Marine Research Institute (Ma-Re), Cape Town, South Africa

The physical structure of the Southern Ocean (SO) plays a crucial role in the global ocean and climate system. Nevertheless, many areas of the SO have remained relatively poorly sampled. Oceanographers often rely on ship-based measurements to track water masses; however, these data are scarce in the SO and seasonally biased. A significant enhancement is Argo, which is a global array of temperature/salinity profiling floats. However, Argo does have limitations in Antarctica - for example, there are few Argo profilers south of 60S due to sea ice. An important addition to data collection methods is conductivity-temperature-depth satellite relay data loggers (CTD-SRDLs) deployed as animal-borne platforms to sample vertical temperature and salinity profiles. While studies have used Argo and CTD-SRDL data, little is known about how well the two data sources complement each other both spatially and temporally, and how comparable they are in data quality. Therefore, this study examines data from CTD-SRDLs and Argo to assess the comparative value of the data sources to increasing our understanding of the ocean dynamics in the South African sector of the SO. This will help to improve our confidence that seals can be used to comprehensively sample regions previously restricted to ship-based observations.
UAS for Evaluating Retrievals and Model Performance at High Latitudes

Gijs de Boer¹ (gijs.deboer@colorado.edu), Dale Lawrence¹, Amy Solomon¹, Janet Intrieri², Dave Turner², Steven Borenstein¹, Douglas Weibel¹

¹University of Colorado, Boulder, United States, ²NOAA Earth System Research Laboratory, Boulder, United States

Over the past several years, scientists have deployed to Oliktok Point, Alaska to make atmospheric measurements as part of the Evaluation of Routine Atmospheric Sounding measurements using Unmanned Systems (ERASMUS) and Inaugural Campaigns for ARM Research using Unmanned Systems (ICARUS) campaigns. These deployments included operations using the University of Colorado DataHawk UAS. The DataHawk was configured to make measurements of atmospheric thermodynamics, wind and surface temperature.

Over these deployments, hundreds of profiles of lower atmospheric temperature have been derived between the surface and cloud base. These profiles are being used to help evaluate the performance of retrievals conducted using measurements from ground-based remote sensors. As a part of this presentation, we will show results from this evaluation and provide insight into the strength of using these sorts of platforms for this purpose.

Additionally, during a recent October deployment, the team witnessed the development of near shore sea ice. In this presentation, we will give an overview of measurements obtained during this time and how they were used to better understand freeze up processes in this coastal environment. Additionally, we will provide insight into how these platforms are being used for evaluation of a fully-coupled sea ice forecast model. Finally, we will provide details on planned 2017 Arctic unmanned aircraft operations by the US DOE, NOAA and others.
The unmanned aerial system ALADINA (Application of Light-Weight Aircraft for Detecting In-situ Aerosol), based on a funded project of the German Research Foundation, is operated for atmospheric research at the Institute of Flight Guidance since 2013. The total amount of more than 200 measurement flights at different locations, prove the high usability of the aircraft. In order to obtain the high quality of atmospheric boundary layer research in harsh Arctic conditions, ALADINA was re-engineered and newly designed for the planned campaign in Ny-Ålesund for spring 2018. The system was insulated to avoid cooling of batteries and to guarantee a flight endurance of about 30-40 min. In addition, the modular payload is heated constantly to temperatures of approximately 30°C, so that all instrumentation can run properly. Further, the system was equipped with a new autopilot system as well as new telemetry to adapt the frequency limitation of less than 2 GHz, due to a sensitive radio telescope on site. Besides, a modular package for batteries was implemented in order to change the batteries by minimal outlay and in a short time period so that flight missions can be performed continuously. With the presentation of the new set-up, we fulfil the expertise to show a reliable system that is optimal prepared for studies in polar region.
Remote Assessment of Albedo by Photographic Equipment Based on UAV

Nikita Kuprikov¹ (nkuprikov@gmail.com), Boris Ivanov², Danila Zhuravskiy³, Mikhail Kuprikov¹, Sergey Kashin⁴
¹Polar Initiative, Moscow, Russian Federation, ²Arctic and Antarctic Research Institute, St. Petersburg, Russian Federation, ³Moscow Aviation Institute (National Research University), Moscow, Russian Federation, ⁴Arctic & Antarctic Scientific-Research Institute, St. Petersburg, Russian Federation

A method for determining of albedo was developed and tested with the combined use of radiation and a photo device. The proposed original method is based on the use of available measuring techniques and is intended primarily to reduce the time required to obtain albedo values on large areas. The theoretical possibility of using the proposed technical solution and its testing in the field using UAV are considered. Based on the results obtained, conclusions are drawn about the possibility of using the proposed schematic diagram, the potential for its improvement and application for the data collection. Mean vile that simple method for determining the albedo of the underlying surface give the opportunity to collect data in situ non-stop, what led us to big data of underlying surface, what is a good basis for future researchers and projects. Method for determining the albedo of the underlying surface gives the chance to work with photos for getting results. The obtained results of the research allow to draw a conclusion about the high potential of the proposed technical solution, not only for carrying out data collection and observing albedo, but also for designing new devices based on the proposed principles. The change in dimensions and the possibility of installation on UAV made it possible to develop a new method of surveying. The developed method provides the ability to quickly and qualitatively collect data on large areas with the help of advanced aircraft technology.

Unmanned Aerial Systems over Sea Ice during the SeaState and PIPERS Expeditions

Guy Williams¹,² (guy.darvall.williams@gmail.com), Darren Turner³, Ted Maksym⁴, Hanumant Singh⁵, Stephen Ackley⁶

¹University of Tasmania, Institute of Marine and Antarctic Studies, Hobart, Australia, ²Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia, ³University of Tasmania, TerraLuma UAV Facility, Hobart, Australia, ⁴Woods Hole Oceanographic Institution (WHOI), Woods Hole, United States, ⁵Northeastern University, Electrical and Computing Engineering, Boston, United States, ⁶University of Texas at San Antonio, San Antonio, United States

In recent years we have deployed multi-rotor and fixed wing Unmanned Aerial Systems (UAS) in support of Autonomous Underwater Vehicles (AUV) missions beneath sea ice in both the Arctic (ONR DRI SeaState - Beaufort Sea, Oct 2015) and Antarctic (NBP1704 PIPERS - Ross Sea, Apr-Jun 2017). Despite significant logistic and meteorological challenges in the polar environment, our UAS project has developed into a cost-effective and integral component of the modern sea ice research expedition. Using ‘off-the-shelf’ multi-rotors and a delta-wing photogrammetry UAS developed by the TerraLuma facility at the University of Tasmania, we achieved icebreaker-based and ice station launch and recoveries with over ten hours of missions. These missions collected visual imagery for ice reconnaissance, floe-size distribution over marginal ice zones and 3D surface topography of larger floes in concert with AUV ice draft mapping below. New fieldwork is planned for the Antarctic marginal ice zone that will incorporate additional thermal IR and hyperspectral capabilities, together with an evolution towards longer missions beyond visual line of sight, once again in tandem with long-range AUV missions.
Intricacies of Making Measurements in Supercooled Water

Natalie Robinson1 (natalie.robinson@niwa.co.nz), Craig Stevens1,2, Brett Grant1, Matt Walkington1, Mike Williams1

1National Institute for Water and Atmospheric Research, Marine Physics, Wellington, New Zealand, 2University of Auckland, Physics, Auckland, New Zealand

For the past 15 years, New Zealand researchers have been investigating interactions between the ice and ocean, principally in McMurdo Sound, Ross Sea. During this time, the range and technical capability of oceanographic instruments has increased dramatically. However none of the standard oceanographic equipment has been designed to incorporate process near the phase-change limit. Here we document our experience teasing data from ocean that is near, and often below, in-situ freezing temperature, as a set of principles of operation. We discuss the difficulties routinely experienced, and suggest mitigation strategies for these. We also highlight some of the curiosities of working in crystal-laden water, and the surprising results that flow from detailed examination of these data. Finally we introduce the ‘Supercool-ometer’ - a modified SeaBird CTD that incorporates a heating chamber and second set of sensors designed to characterise the effects of ice formation (and/or melt) inside the instrument. We will outline the development to date of the supercool-o-meter and highlight results from three recent deployments in significantly supercooled water.
Non-coring electro-thermal drills, often called as Hotpoint drills (HPD), allowed fast penetration rate (up to 25 m/h) at relatively low power. As lab and field experiments show penetration rate of the HPD is proportional to snow-firn-ice density. Continuous registration of the HPD penetration rate allows one to obtain continuous density profile up to a few dozen meters of depth. Density resolution of the HPD is close to 5 kg m⁻³ while depth resolution is about 10 mm. Snow-firn density profiling system includes: 1) HPD, 2) instrumented rig, 3) data acquisition and power source. The system is called Speedograph - penetration rate/speed recorder. Robotic version of the Speedograph can operate as addition to glacier surface moving autonomous platform. The robotic Speedograph can be programmed to perform density profiling as calibration option to snow-firn radar. Required power for the robotic version of the Speedograph is 300-800 W. Estimated weight of Speedograph is about 6 kg while total volume is about 0.02 m⁻³.
Wind and Turbulence Measurements with RPA during the ISOBAR Campaign

Alexander Rautenberg¹ (alexander.rautenberg@uni-tuebingen.de), Stephan Kral², Joachim Reuder², Jens Bange¹

¹Universität Tübingen, Environmental Physics, Tübingen, Germany, ²University of Bergen, Geophysical Institute, Bergen, Norway

The remotely-piloted fixed-wing aircraft MASC (Multi-purpouse Airborne Sensor Carrier) from the environmental physics working group of the University of Tübingen was used to investigate physical processes in the ABL during the ISOBAR (Innovative Strategies for Observations in the Arctic Atmospheric Boundary Layer) campaign over the frozen Baltic Sea in northern Finland in February 2017. MASC is equipped with a high resolution thermodynamic sensor package including a five-hole probe and IMU for wind vector measurements. During the three week long field period also ground based weather stations, remote sensing systems (Lidar and Sodar) and a small fixed-wing system (SUMO) for atmospheric profiles up to 1800 m were applied. Intensive observational periods including nocturnal flights with MASC were performed. This talk will focus on results for the wind, turbulence and flux measurements from some flights with MASC. The strategy of the measurements as well as the quality of the data and comparisons will be addressed. Furthermore future adaptions and developments of the measurement system and the remotely-piloted aircraft for polar use will be presented.
Advances in Sub-ice Navigation: AUV Tests in Overhead Environments

Kristof Richmond¹ (kristof.richmond@stoneaerospace.com), William Stone¹, Christopher Flesher¹, Laura Lindzey¹, Neal Tanner¹, Victoria Siegel¹
¹Stone Aerospace, Del Valle, United States

Beyond the obstacles to navigation presented by underwater operations (e.g. the lack of continuous, precise external aiding from GPS), sub-ice navigation presents unique challenges to an autonomous vehicle. The overhead environment prevents essentially all external navigation aiding, and severely limits ingress and egress locations for deployment, recovery, or data transfer. In such environments (e.g. under sea ice, ice shelves, or in sub-glacial lakes), existing methods of exploration autonomy eventually break down as highly-limited sensor range and unbounded navigation drift lead to the inability of the vehicle to return to the point of origin for recovery, or to return to a site of interest following an initial broad survey. Groundbreaking work on overcoming these limitations using the local environment as a navigation reference was conducted as part of the NASA DEPTHX project (2003-2007). A distant, miniaturized successor to DEPTHX, known as SUNFISH, has been tested by Stone Aerospace in the overhead environment of underwater caves in northern Florida, acting as a surrogate for complex sub-glacial lakes. We present field test results of SUNFISH on new autonomous behaviors and methods to navigate such overhead environments with sufficient precision to allow the AUV to approach or contact objects of interest; provide a 3D map updated in real time; and to plan paths for egress and exploration despite map inconsistency—all in the absence of any external navigational aiding.
Marine Mammals Exploring the Oceans Pole to Pole: Review of the MEOP Consortium

Anne M. Treasure1,2 (anne.m.treasure@gmail.com), Fabien Roquet1, Isabelle J. Ansorge2, P.J. Nico de Bruyn1

1University of Pretoria, Mammal Research Institute, Department of Zoology & Entomology, Pretoria, South Africa, 2University of Cape Town, Department of Oceanography and Marine Research Institute (Ma-Re), Cape Town, South Africa, 3Stockholm University, Department of Meteorology (MISU), Stockholm, Sweden

Polar oceans are poorly monitored despite the important role they play in regulating Earth’s climate system. Marine mammals equipped with biologging devices are now being used to fill the data gaps in these logistically difficult to sample regions. Since 2002, instrumented animals have been generating exceptionally large data sets of oceanographic CTD casts (>500,000 profiles), which are now freely available to the scientific community through the MEOP data portal (http://meop.net). MEOP (Marine Mammals Exploring the Oceans Pole to Pole) is a consortium of international researchers dedicated to sharing animal-derived data and knowledge about the polar oceans. Collectively, MEOP demonstrates the power and cost-effectiveness of using marine mammals as data-collection platforms that can dramatically improve the ocean observing system for biological and physical oceanographers. Here, we review the MEOP program and database to bring it to the attention of the international community.
The West Antarctic Peninsula (WAP) has undergone rapid atmospheric warming occurring between the 1950s and the late 1990s, with significant reductions in the duration and thickness of sea ice and rapid thinning of ice shelves and glaciers. Many of these changes are driven by a warming Circumpolar Deep Water (CDW) layer, the deep water mass that originates in the open Southern Ocean and supplies heat to the WAP shelf. Consequently, much attention has focused recently on the delivery of heat to the shelf through mechanisms including eddies, and flow inertia, particularly at deep glacially-carved troughs such as Marguerite Trough (MT). However, less attention has been focused on the export of colder shelf waters that compensates the inflow of CDW. Here, we use ocean glider data from 2015 to examine the hydrographic structure of a quasi-permanent meander found close to the mouth of MT, from which cold-core cyclonic eddies detach and export dense water into the Southern Ocean. Rossby numbers of these features (0.05-0.1) are consistent with geostrophic dynamics. The circulation structure observed is consistent with an onshore transport of CDW (by small 5-10 km eddies) towards the northeastern parts of the trough, and an offshore transport of colder, fresher waters towards the southwestern edge. Potential vorticity fields from the gliders and an ocean model are used to determine the instability mechanisms that drive the production and separation of eddies from the boundary current.
Measurements of Snow Properties on Ice Sheets with a Polar Robot

Joshua Elliott¹, Austin Lines¹, Mary Albert² (mary.r.albert@dartmouth.edu), Laura Ray¹
¹Dartmouth College, Hanover, NH 03755, USA, Thayer School of Engineering, Hanover, United States,
²Dartmouth College, Thayer School of Engineering, Hanover, United States

Snow specific surface area and optical grain size of snow on the polar ice sheets are key parameters for measuring the atmospheric interactions of snow, monitoring metamorphosis in response to environmental change, and facilitating interpretation of remotely sensed data. Making the measurement by a ground-based robot can save time over human deployment, and eliminates the amount of fuel that would be needed if the instrument were towed by snowmobile. We describe robotic deployment of an instrument that uses a shortwave infrared camera with changeable optical band pass filters (centered at 1300 nm and 1550 nm) that can be used to quickly measure the average SSA. The device and method are compared with calculations made from measurements taken with a field spectral radiometer, and performance of the robot is documented.
Mapping Penguins and Blue-eyed Shags at Remote Islets by Fixed Wing UAV

Christian Pfeifer¹ (christian.pfeifer@think-jena.de), Hans-Ulrich Peter², Marie-Charlott Rümmler², Osama Mustafa¹

¹ThINK - Thuringian Institute of Sustainability and Climate Protection, Jena, Germany, ²Friedrich Schiller University, Institute of Ecology, Jena, Germany

The rocky northwestern coast of Nelson Island and the southwestern coast of King George Island (South Shetland Islands) is known as a breeding area for chinstrap penguins. However, due to its difficult accessibility the last published population counts date back to the 1980s. To obtain current, accurate and complete data, several flights with a UAV have been carried out during December 2016 and January 2017. The 30 km long investigation area ranges from Smilets Point at Nelson Island to Sygit Point at King George Island. In that area all larger islets have been mapped by a micro fixed wing UAV equipped with an optical camera. The images have been processed to orthophotomosaics with a ground resolution of about 2 cm. In these mosaics more than 200 rocks, islets or rock outcrops have been surveyed for penguin colonies or other breeding birds. We found 26 sites with breeding chinstrap penguins (Pygoscelis antarctica) and four sites with breeding blue-eyed shags (Phalacrocorax atriceps), some of them recorded for the first time. For all sites breeding pair numbers of the penguin colonies were derived by counting the individuals manually from orthophotomosaics and using a correction factor. For blue-eyed shags the breeding pair numbers were derived by counting the nests directly. As a result the most complete and accurate dataset on the distribution and numbers of breeding chinstrap penguins and blue-eyed shags in the investigated area was created and will be presented.
The unmanned research aircraft ALADINA (Application of Light-Weight Aircraft for Detecting In-situ Aerosol) was extensively used during field studies in Melpitz (Germany) and Savè (West Africa) since 2013. The performance of more than 200 measurement flights and several publications support the reliability of the system. The main focus of the project is on the variability of aerosol particles depending on different atmospheric boundary layer conditions. For future perspectives, a new aircraft campaign is planned for spring 2018 at the local airfield in Ny-Ålesund (Spitsbergen), in association with project partners of Leibniz Institute of Tropospheric Research and Eberhard Karls University Tübingen, as well further international collaborators. The goal of the campaign is to study the horizontal and vertical distribution of aerosol particles in the particle diameter from around 5 nm to 5 µm between ice surfaces up to the height of around 1000 m. In addition, one aethalometer is installed, in order to investigate black carbon mass concentrations in a generally clean environment that is, however, temporarily affected by ship emissions. Due to harsh Arctic conditions by low temperatures and possible icing, the sensitive aerosol instrumentation had to be adapted properly and the new paylaod will be presented. Further, the performed campaign will be introduced and first results of the pending application with the main focus on polar new particle formation will be shown.
Melting tidewater glaciers and ice shelves from the Greenland and Antarctica Ice Sheets are now substantially contributing to global sea level rise. The most significant submarine melt acceleration has taken place deep within ice shelf cavities near the grounding zones where glaciers begin to float beneath more than 500 m of ice and 10-100 km or more from the open ocean. There is a need for long-range, long-duration, in situ under ice exploration and data collection in these environments to determine how warming ocean waters are affecting ice shelf stability. Scientists and engineers at JPL are developing new technologies to enable autonomous exploration and data collection in these unexplored ice shelf cavities with the objective of improving our fundamental understanding of their physical, chemical, and biological characteristics.
Mapping of Antarctic Wildlife by Drones

Jakob Maercker¹, Max Haucke¹, Stefan Knetsch¹, Hans-Ulrich Peter², Christian Pfeifer¹, Osama Mustafa¹
(osama.mustafa@think-jena.de)
¹ThINK - Thuringian Institute of Sustainability and Climate Protection, Jena, Germany, ²Friedrich Schiller University Jena, Institute of Ecology, Jena, Germany

Changes in size and distribution of Antarctic wildlife populations are difficult to monitor. Breeding sites of seabirds are often located at remote and difficult to access locations while seals can be found at almost all parts of the Antarctic coast. Therefore, by classical methods a high effort is necessary to conduct detailed surveys of larger areas with often incomplete results. Besides, mapping or counting these populations directly implies a significant disturbance of the animals. Thus, the use of drones provides an option to map colonies and aggregations of seabirds and seals.

We studied the feasibility of mapping Southern Giant Petrels (Macronectes giganteus), Cape Petrels (Daption capense) and Kelp Gulls (Larus dominicanus) as well as different Antarctic seal species by use of an electric powered quadrocopter micro drone. While Giant Petrels often breed at remote islets and are known to be very sensitive to disturbance, many breeding sites of Cape Petrels and Kelp Gulls are located at steep inaccessible rocks. Seal aggregations can be found at many sites almost everywhere along the Antarctic coast. The study was performed at different sites of Fildes Peninsula (King George Island, South Shetland Islands).

We present the results of this survey regarding quality, effort and disturbance. Advantages and disadvantages of different methodological settings will be discussed.
The Dry Valley Summertime Atmospheric Boundary Layer Evolution

Marwan Katurji1 (marwan.katurji@canterbury.ac.nz), John Cassano2,3, Dion O’Neale4, Peyman Zawar-Reza1
1University of Canterbury, Geography, Christchurch, New Zealand, 2University of Colorado, Department of Atmospheric and Oceanic Science, Boulder, United States, 3University of Colorado, Cooperative Institute for Research in Environmental Sciences, Boulder, United States, 4University of Auckland, Department of Physics and Te Pūnaha Matatini, Auckland, New Zealand

The Dry Valleys are snow-free polar deserts surrounded by patches of frozen lakes and glaciers. The arid environment limits life to microbial subsurface communities, and the complex terrain allows the development of localized meteorology modulated by surface-atmospheric energy fluxes that are largely controlled by the insolation diurnal profile and topographic shading.

Two custom built fixed-wing small UAVs were used to sample the atmospheric boundary layer near Lake Vanda of the Wright Valley. The objectives of the January 2017 field campaign was to understand the diurnal variability of the mean velocity, temperature, and turbulence from the surface up to 1000m, which influence the microclimate spatial variability of the Dry Valleys. The meteorological payloads consisted of air temperature, pressure, relative humidity sensors, GPS and a 5-hole probe for mean wind and turbulence measurements at 50Hz. We conducted a total of 19 vertical profiling flights over a period of 6 days covering a wide range of stable, unstable and transitioning boundary-layers. This data provides a unique opportunity to understand the time scales of the thermodynamic evolution of the near-surface atmosphere in a region where mountain meteorology directly influences available melt-water for biodiversity.
During the last years polar oceans showed the effects of global climate change, with important variations of physical, chemical and biological characteristics. Global warming causes a significant reduction in sea-ice thickness and in tidewater glaciers extension during late summer and autumn intensifying the input of freshwater and sediments, causing a reduction of water transparency as a consequence of increasing water turbidity. These processes have an impact on phytoplankton biomass life cycle, especially in the Kongsfjorden area, Svalbard Archipelago, that is relatively warmer than other Arctic areas. An oceanographic experimental survey was performed during June 2017 to study the ice melting of the tidewater glaciers in the Kongsfjord making use of traditional and innovative instrumentations. Two 'state of the art' probes, Idronaut 305 plus and Cyclops-7F™ Turner Design, and a new low-cost probe were installed onboard an innovative unmanned marine vehicle, PROTEUS (Portable RObotic TEchnology for Unmanned Surveys). The survey was carried out along Kronesbreen and Blomstrandbreen glaciers, where a series of transects extending from a support boat up to the direct front of the glaciers allowed the acquisition of surface water temperature, conductivity, dissolved oxygen, chlorophyll a, fluorescence and turbidity. This work shows the preliminary results of data acquired by the different probes, with a particular focus on the comparison between traditional and innovative ones.
ALICE - A Remotely Piloted air Sampling System for Methane Isotopic Analysis

Falk Pätzold¹ (f.paetzold@tu-braunschweig.de), Thomas Krüger¹, Konrad Bärfuss¹, Barbara Altstädter¹, Stefan Nowak¹, Ellen Damm², Josefa Verdugo², Astrid Lampert¹
¹Technische Universität Braunschweig, Institute of Flight Guidance, Braunschweig, Germany, ²Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, Marine Geochemistry, Bremerhaven, Germany

Methane is a very effective greenhouse gas, but the role of the Polar Regions in the methane budget and its sources there is subject to discussion. The sparse surface network data and satellite data indicate significant source regions above the polar oceans. The remotely piloted system (RPAS) of quadrocopter type ALICE was developed at the Technische Universität Braunschweig for taking air samples to study methane isotopic composition related to different polar atmospheric boundary layer conditions above sea ice and open water. The quadrocopter ALICE has a maximum take-off weight of 25 kg and a large payload capacity of 18 kg. The thrust to weight ratio is high compared to other RPAS to operate in wind speeds up to 70 km h⁻¹. The scientific subsystem consists of different meteorological sensors and twelve 100 ml glass bottles for air sampling. Profiles with high resolution meteorological data and air samples at operator selected altitudes up to 1000 m can be obtained. The initially tested prototype was field operated for the first time during Polarstern cruise PS109 (ARK-XXXI/4), so-called GRISO (Greenland ice sheet/ocean interaction) from 12 September until 14 October, 2017. During this proof of concept expedition the safe shipborne operation and system functionality in harsh polar environment was demonstrated successfully. In this presentation, the design of the RPAS and the scientific payload will be introduced and functionality discussed based on flight test results.
Robotic vehicles have proven valuable scientific assets in subsea polar environments; yet the ability of fully autonomous vehicles (AUVs) to physically interact with the seafloor or ice remains limited or non-existent. Remotely operated vehicles (ROVs) routinely execute these activities in ice-free waters. Real-time data access, via the ROV’s tether, enables pilots to execute complex interaction tasks and to react immediately to the unknown or unanticipated, a capability that could prove especially important in the relatively unexplored polar environment. However, conventional tethering systems require the host vessel to hold station above the vehicle, a constraint that makes operating conventional ROVs in ice difficult. Micro-tethers, small diameter unarmored fiber-optic cables, alleviate this constraint. Micro-tethers transmit only communication signals and not electrical power, thus vehicles that use them must carry their own batteries and are referred to as AUV/ROV hybrids. We have adapted a 250 µm diameter micro-tether system, 20 km in length, to a purpose-built under-ice hybrid ROV called NUI. In 2016 we demonstrated the ability to operate NUI on the Arctic sea floor at 87 N, over a km away from the host vessel, on a dive that obtained high-definition (HD) video imagery of the seafloor and acquired targeted samples using NUI’s dexterous manipulator arm. We discuss the micro-tethering system, NUI, and potential future polar applications of each.
Monitoring the Arctic regions allows understanding the impact of global warming on Earth's climate but some processes affecting the climate change cannot be fully discerned because data are sparse and even missing due to difficulties in collecting them in hazardous area. This is particularly true in the proximity of the arctic calving glaciers that induce changes in the physicochemical and biological properties of the seawater. Unmanned marine and aerial vehicles allow the in-situ observing of such processes. In June 2017 CNR-ISSIA, in collaboration with other institutes of the CNR (IAMC, ISMAR, ISAC, IBIMET) and UNITUS, has conducted a measurement campaign in the Kongsfjord, a small fiord in Svalbard. A customised octocopter (OTTO) capable of carrying various types of heavy payloads was used. A set of low cost and high-resolution sensors were used to analyse the column of air in order to monitor atmospheric parameters and gases (humidity, temperature, CO, CO2, O3, NO2). A thermal camera was also installed on the drone to reconstruct a thermal map of the sea/ice in the area surveyed by the Unmanned Marine Vehicle PROTEUS equipped with underwater sensor. The measurements performed allowed to fully characterise the state of air-sea interface near marine glacier fronts. A preliminary data analysis to correlate the different measured quantities shows interesting results but further experiment need to be done to achieve a complete understanding of the processes.
The goal of the UVASS (Unmanned Vehicles for Autonomous Sensing and Sampling) project is the use of unmanned vehicles to perform air, water and ice data sensing and sampling in dangerous places (e.g. close to fronts of tidewater glaciers), difficult to access for human beings. The purpose of the Arctic expedition carried out in Summer 2017 by ISSIA-CNR, in cooperation with other institutions, was the use of a little swarm of unmanned vehicles performing simultaneous data acquisition in order to improve the understanding of phenomena related to the global climate changes, especially ice melting. The marine autonomous vehicle PROTEUS was equipped with sensors and samplers, i.e. multi-parametric probe and turbidimeter and towed a small trimaran vessel hosting heavy or voluminous sensors i.e. an automatic water multisampler, a plankton multisampler and a SeaBird CTD probe. Besides PROTEUS, two drones were also used: the OTTO drone recorded pictures and videos of the area and was equipped with additional payload (thermal camera, humidity, temperature and air quality sensors) to collect environmental parameters. The Splash drone was used to record videos and images of the coordinated operations performed by PROTEUS and OTTO for documentary and dissemination purposes. The atmospheric data coming from OTTO, together with the marine data acquired by PROTEUS, will allow scientists to obtain a good characterisation of the whole marine-air column in the proximity of tidewater glaciers.

Long-term Automatic Ice Buoy System for ArcticAtmosphere-ice-Ocean Observation

Zhuoli Yuan¹ (yuanzhuoli@pric.org.cn)
²Polar Research Institute of China, Ocean Department, Shanghai, China

The interaction process of atmosphere, sea ice and ocean is a major topic of CHINARE Arctic researches. Various types of ice buoys were utilized to observe Arctic, but few of them shall provide long-term, effective or highly integrated observation, which limits the development of the interaction process researches. This article offers one long-term automatic ice buoy system for Arctic atmosphere-ice-ocean observation. System consists of main buoy, attached buoy and atmosphere tower. Main buoy is equipped with ice/snow thickness sonar, ice temperature chain sonar and ice radiation flux sensors. Atmospheric pressure, temperature and humidity sensors are installed on top of the main buoy body, which shall provides one-layer atmosphere observation. Fixed profile observation module is equipped beneath the bottom of the attached buoy, profile observation module consists CT, chlorophyll sensors and dissolved oxygen sensors, which shall provide six-layer multiple ocean physical data observation. Atmosphere tower consists anemometers, atmospheric pressure sensors and temperature and humidity sensors and shall provide 2-layer atmosphere physical data observation. The material of buoy body is high-strength aluminum alloy, covered with cathodic protection. Buoys are equipped with buoyant material, which shall keep the system alive after the ice melts and continue the observation work. Battery of the systems shall provide system with more than 1 year long-term observation duration.
Arctic Observing Using Integrated Systems of Autonomous Instruments

Luc Rainville¹ (rainville@apl.uw.edu), Craig Lee¹, Jim Thomson¹
¹University of Washington, Applied Physics Laboratory, Seattle, WA, United States

Systems of autonomous platforms offer the ability to collect sustained, collocated measurements of the ocean-ice-atmosphere system, accessing spatial and temporal scales that have previously been difficult or impractical to sample. The recent Office of Naval Research Marginal Ice Zone and Arctic Sea State Programs provide examples of these systems applied to investigations of the processes that govern evolution of the rapidly-changing seasonal ice zone in the Beaufort Sea. Autonomous platforms operating from the ice and within the water column collected measurements across the atmosphere-ice-ocean system and provided the persistence to sample continuously through the springtime retreat and autumn advance of sea ice. Autonomous platforms also allowed operational modalities that reduced the field programs' logistical requirements. These programs demonstrate effective use of light-weight logistics and integrated systems of autonomous platforms for persistent, multi-scale Arctic observing. Networks of autonomous systems are well-suited to capturing the vast scales of variability inherent in the Arctic system.
Expanding Argo Float Measurements into the Arctic

Katrin Latarius¹ (katrin.latarius@bsh.de), Birgit Klein¹, Kjell Arne Mork², Jari Haapala³, Waldemar Walczowski⁴, Romain Cancouet⁵

¹Federal Maritime and Hydrographic Agency, Hamburg, Germany, ²Institute of Marine Research, Bergen, Norway, ³Finnish Meteorological Institute, Helsinki, Finland, ⁴Institute of Oceanology of Polish Academy of Sciences, Sopot, Poland, ⁵Institut Polaire Francais, Plouzane, France

Ice-tethered profilers have already successfully been used as part of the integrated Arctic observing system and provide platforms for multidisciplinary ice-atmosphere-ocean observatories under stable ice conditions. But several observations and predictions suggest that an ice-free Arctic summer is likely to occur within the next decades and the ongoing decrease of sea ice coverage in the Arctic Ocean is already leading to extended periods of open water in parts of Arctic. This development facilitates measurements with profiling Argo floats in the Arctic.

The Euro-Argo ERIC, the European contribution to the international Argo program, has therefore started to investigate the use of profiling floats in the Arctic. First deployments are intended for summer 2018 in the Barents Sea and north of Svalbard within the national Argo programs of Finland, Norway and Poland. In order to avoid damage to the floats by surfacing under ice-conditions it is necessary to hold them in ice-free areas and/or to equip them with ice-sensing algorithms. Within the context of the EU funded MOCCA project (Monitoring the Oceans and Climate Change with Argo) the Euro-Argo ERIC has started to develop such algorithms for the hydrographic conditions in the Arctic and is coordinating the European deployments in the area.

The talk is meant as a summary of the present state of activities within the project and a possibility to discuss ideas and collaborations for the future.
Aerosols and clouds have a large impact on the radiative balance of the earth’s surface. The aerosol-cloud interactions are still not well understood and have significant uncertainties. Especially in turbulent environment of the boundary layer with low aerosol burden such as the sub-Arctic region of Northern Europe. The 7th Pallas Cloud Experiment (PaCE2017) took place at the Pallas Atmosphere-Ecosystem Supersite - Sammaltunturi Global Atmospheric Watch (GAW) station (67°58' N, 24°07' E). Unmanned Aerial Vehicles (UAVs) of three teams - the Cyprus Institute, Airclip Service GmbH & Palas GmbH, and Finnish Meteorological Institute (FMI) - were employed to perform airborne in-situ measurements of aerosol and cloud physical properties together with meteorological parameters. The airborne measurements took place within the FMI’s reserved airspace EFD431 - PALLAS that is centered around the Sammaltunturi GAW station with boundaries of 7 km and ceiling limit FL80 (1994 m MSL). The acquired vertical profiles cover five consecutive days from Sept 24th to Sept 28th 2017, and characterize situations under-, in- and above-clouds. The collected data were also combined with balloon soundings, concurrent continuous ground-based observations and remote-sensing instrumentation.
Geological investigations in the Arctic confront many difficulties due to its remoteness and extreme environmental conditions. Greenland has unique potential for discoveries of mineral ore deposits of world-class scale. Mineral exploration activities in Greenland have been only focused on certain targets or areas with variable intensity and density of data collection, leaving most of the parts of Greenland largely underexplored compared to other areas with similar geology elsewhere in the Arctic. The northern Greenlandic Archean terranes are often remote and not well-known. In north Greenland the Palaeozoic Franklinian Basin is recognized to host several Zn-mineralization, of which the Citronen Fjord Zn-Pb deposits is the best known. In this investigation, the application of Landsat-8 satellite remote sensing data was evaluated for lithological discrimination and mineral prospecting in the northern Greenland. Developed image processing approach such as specialized band rationing, image transformation techniques and directional filtering were implemented for mapping lithological units, gossans and structural features. Geological units, the facies-border and structures that most likely have a guiding on mineralizing systems within the Franklinian Basin in north Greenland were mapped using Landsat-8 spectral bands. This satellite-based remote sensing approach is comprehensively applicable for ore minerals prospecting in other inaccessible regions in Greenland.
Changing Arctic Snow Cover: Rain-on-Snow and Ice Layer Detection

Alexandre Langlois¹ (a.langlois2@usherbrooke.ca), Caroline Dolant¹, Ludovic Brucker², Alain Royer¹, Benoit Montpetit⁴, Alexandre Roy⁴
¹Université de Sherbrooke, Sherbrooke, Canada, ²NASA Goddard Space Flight Center, Greenbelt, United States, ³Landscape Science & Technology, ECCC, Ottawa, Canada

The first and strongest signs of global climate variability and change have been observed in the Arctic over the past three decades. Patterns in the spatial extent and mass balance of snow show a statistically significant trend towards negative anomalies. More specifically, the currently observed warming in the Arctic leads to winter rain-on-snow (ROS) events, which are now more frequent. Those events often lead to the creation of ice layers that prevents ungulates from accessing their food.

We present here results from ROS detection algorithms, validated with 625 ROS observations across the Canadian Arctic Archipelago. Three periods were studied separately and results show that despite no significant trends in the cumulated yearly occurrence, an increase is seen in the occurrence of fall and winter ROS events. Furthermore, an anomaly analysis suggest positive anomalies in event occurrence starting in the late 80’s. In addition to monitoring ROS, presence of ice layers is detected from satellite observations using variability in the polarization ratio at 11, 19 and 37 GHz. Observed trends in ice layer presence and ROS occurrences are similar. It is shown, however, that ice layers are less frequent, given that not all ice layers are of sufficient thickness to be detected by our algorithm. Finally, a spatio-temporal analysis identified specific areas such as Cornwallis Island, Somerset Island and Northern Baffin Island to be more prone to ROS and ice occurrence.
Retrieving Ice Parameters with a UAV-mounted RADAR

Daniel Kramer¹ (daniel.kramer@usherbrooke.ca), Alexandre Langlois¹, Alain Royer¹, Donald McLennan²
¹University of Sherbrooke, Sherbrooke, Canada, ²Polar Knowledge Canada, Ottawa, Canada

To estimate the thickness of lake ice and detecting ice layers within the snowpack, a frequency-modulated continuous-wave (FMCW) RADAR has been mounted on a small UAV. The RADAR is working at 24 GHz (Ka band) and has an approximate retrieval accuracy of 2cm. The system will be flown in several locations in Canada, including Cambridge Bay (Nunavut) during a winter expedition in April 2018. Additionally, the system will be tested over sea ice to estimate the influence of brine on ice thickness retrieval accuracy.

Combined with other techniques (e.g. Snow Depth-retrieval), this platform offers the perspective to greatly improve measurements for estimating the amount of snow and ice presence in the ecosystem. Initial results are promising, but the potential for (arctic) applications is unclear as an underestimation was measured in wet snow conditions and the required low flight level of less than 5m limits the area of operation. This presentation will highlight retrieval accuracy and ice layer detection potential for Arctic areas while discussing pros and cons of UAV operations at high latitudes.
The aim of this work is to produce a simplified vegetation map of ice-free areas of the Fildes Peninsula (FP) and Ardley Island (AI) through object-oriented classification using a Quickbird satellite image and to evaluate the influence of the global solar radiation (GSR) over the vegetation distribution. The vegetation data was generated from multi-resolution segmentation, and for the classification we calculated the normalized vegetative difference index and the green normalized vegetative difference index. Two classes were created: Lichen and Moss Cushion Sub-Formation and Moss Sub-formation with 48 vegetation samples collected in 2008 and 2009. The GSR was estimated in order to evaluate the effect of meteorological phenomena and cloud cover, and we measured the GSR using a net radiometer model CNR4 installed in FP between 2014 and 2016. The estimate of GSR was done for seasons of 2015, in order to estimate the light compensation point and the saturation point for the plant communities in FP and AI. The kappa index was 0.73 and the global accuracy was 0.78, showing consistency between the classification and ground truth. The area was covered by vegetation in FP was 16.7% and in AI is 59.1%. The vegetation cover is distributed differently at FP and AI and our results suggest GSR plays an important role in vegetation distribution and these tendencies could be related to greater GSR demand by mosses when compared to lichens.
A Parametric Method for Snow Density Estimation Based on Ultrasonic Waves

Krzysztof Herman¹ (kherman@ubiobio.cl), Tadeusz Gudra², Dariusz Banasiak², Krzysztof Opielinski², Tomasz Budzik³

¹University of the Bio Bio, Department of Electrical and Electronics Engineering, Concepcion, Chile, ²Wroclaw University of Technology, Department of Electronics, Wroclaw, Poland, ³University of Silesia, Department of Earth Sciences, Sosnowiec, Poland

In this paper a method for snow density estimation based on non contact ultrasound examination is described. This ground based method involves a constant frequency, air coupled ultrasound waves and incorporates a parametric method for reflected energy estimation. The paper issues theoretical considerations as well as the technological details of the addressed problem. Due to the fact that the amount of the reflected sound energy is related to the snow density the acoustic data processing scheme is presented. The theoretical model was applied to the data collected during field experiments in the vicinity of the Polish Antarctic Station Arctowski, South Shetlands, Antarctic. The results obtained permit to develop a new autonomous sensor for measurements of the snow ablation and density.
Sea Ice Concentration in the Chukchi Sea in Summer

Hyangsun Han¹, Hyun-Cheol Kim¹ (kimhc@kopri.re.kr)
¹KOPRI, Unit of Sea Ice Prediction, Incheon, Korea, Republic of

Sea Ice Concentration (SIC) has been used as a primary data source for climate change prediction and ship navigation. However, Passive Microwave (PM) SIC have an uncertainty in accuracy during summer. In this research, we evaluated the SIC derived from PM measurements using four representative sea ice algorithms: NASA Team (NT), Bootstrap (BT), Ocean and Sea Ice Satellite Application Facility (OSISAF) hybrid, and Arctic Radiation and Turbulence Interaction Study (ARTIST) Sea Ice (ASI). Korean Multi-Purpose Satellite-5 (KOMPSAT-5) Enhanced Wide-swath synthetic aperture radar (SAR) images was used for the evaluation in the Chukchi Sea in summer. SIC estimated from the NT and BT algorithms were largely underestimated and overestimated, respectively, compared to KOMPSAT-5 SIC, while the OSISAF and ASI algorithms slightly overestimated the SIC. Meanwhile, SIC estimated from the algorithms showed different error trends according to the KOMPSAT-5 SIC range. All algorithms overestimated SIC in open drift ice zones, in marginal ice zones and in consolidated pack ice zones SIC. The differences in SIC estimated from each algorithm were due to different sensitivities to surface effects, atmospheric effects, and the presence of melt ponds.
High Resolution Sea Ice Motion and Deformation Measurements

Chang-Uk Hyun¹, Hyun-Cheol Kim¹ (kimhc@kopri.re.kr)
¹KOPRI, Unit of Sea Ice Prediction, Incheon, Korea, Republic of

Sea ice motion and deformation have generally been measured using low-resolution passive microwave remote sensing technique to monitor wide polar regions, e.g., entire arctic ocean or polynya. This study presents an application of multi-sensor optical satellite images for high-resolution sea ice motion and deformation measurements. The sea ice motion was measured by using a maximum cross-correlation technique with hierarchical approach to decrease outliers and multi-temporal images acquired from multiple optical sensors of Korea Multi-Purpose Satellites (KOMPSATs). The sea ice motion extracted from image pairs of short acquisition time intervals were compared with time-interpolated in-situ buoy location records. The root mean square errors and biases of the image-derived ice motion indicate more accurate measurements than from the sea ice motion datasets from conventional low-resolution passive microwave satellite data. In the dense sea ice deformation grids, free drift patterns of ice floes that appear in summer were delineated. The results demonstrate that using high-resolution multi-sensor optical images from operational satellites enabled accurate sea ice motion and deformation measurements, thus this approach could be used for validation of wide-range sea ice motion studies as a supplementary dataset to buoy based reference datasets.
Regional Chlorophyll Algorithms in Coastal Waters of Svalbard, Arctic

Young-Sun Son¹, Hyun-Cheol Kim¹ (kimhc@kopri.re.kr)
¹KOPRI, Unit of Sea Ice Prediction, Incheon, Korea, Republic of

AOP (Apparent Optical Properties) and IOP (Inherent Optical Properties) data from 2007 to 2013 were analyzed to evaluate the performance of the ocean color algorithms to retrieve chlorophyll concentration in polar coastal waters. Field data were collected from the Svalbard coast, Arctic, in late spring and early summer between May and June. For the measurement of chlorophyll concentration using satellite data, we statistically evaluated and analyzed current algorithms. Current algorithms tend to overestimate chlorophyll at low chlorophyll concentrations, while underestimating chlorophyll at high concentrations. Bio-optical analysis of the coastal waters in this region showed that high chlorophyll-specific absorption coefficients and suspended sediment concentration were the main causes of chlorophyll overestimation and large size phytoplankton such as diatoms caused chlorophyll underestimation. We proposed regionally tuned algorithms, which led to better results in the Svalbard coastal waters.
Ice Thickness and Frontal Ablation of Nine Outlet Glaciers on Novaya Zemlya

Andrey Glazovsky¹ (glazovsky@igras.ru), Ivan Lavrentiev¹, Evgeny Vasilenko²
¹Institute of Geography RAS, Department of Glaciology, Moscow, Russian Federation, ²Institute of Industrial Research 'Akadempribor', Uzbekistan Academy of Sciences, Tashkent, Uzbekistan

Knowledge of the volume and proportion of ice mass loss due to frontal ablation (the sum of ice loss through calving and submarine melt) from tidewater glaciers on Russian Arctic archipelagoes is very limited. Meanwhile the frontal ablation there is an important factor of current change of glaciers, as well as this knowledge is required for iceberg hazard assessments. We present our estimations of frontal ablation for nine Novaya Zemlya tidewater glaciers, calculated from satellite-derived ice velocities, airborne 20 MHz GPR RES measurements of glacier ice thickness in 2014-2016, and mass change due to changes in terminus position (MCTP). These glaciers are located in northern part on Novaya Zemlya (5 on its western side, and 4 on eastern side). The average ice thickness at glacier fronts varies from 70 to 250 m, and average ice velocity at fluxgates varies from 40 to 840 m a⁻¹.

The total mean rate of frontal ablation for these nine glaciers in 2015-2016 is 2.47 km³ a⁻¹ of ice with dominance of western side glaciers (2.08 km³ a⁻¹). The average ratio of MCTP to frontal ablation is 2/5 on western side and 1/5 on eastern side. The most active frontal ablation is found on Inostrantsev Glacier, where it comprises 0.72 km³ a⁻¹ (with gate ice flux 0.58 km³ a⁻¹ and MCTP 0.14 km³ a⁻¹). On Kara Sea side, the especially active frontal ablation 0.24 km³ a⁻¹ is on Vershinsky Glacier. RES data allows also to identify those frontal parts of studied glaciers that are close to the flotation.
Satellite images are an essential source of information for sea ice products such as the sea ice concentration maps issued by the national ice charting agencies. In this regard, Synthetic Aperture Radar (SAR) is especially valuable given its all-weather capabilities. Within this study we investigate the usefulness of fully polarimetric SAR by utilizing an automatic sea ice classification algorithm, developed for Near Real Time (NRT) services, on two sets of spatially and temporally near coincident fully polarimetric acquisitions from the ALOS-2, Radarsat-2 and TerraSAR-X satellites acquired during the N-ICE2015 sea ice drift study. Overlapping coincident sea ice freeboard measurements from Airborne Laser Scanner (ALS) data are used to validate the classification results. We analyzed the usefulness of 18 different polarimetric parameters for sea ice characterization. In order to deliver sea ice products in NRT savings in computational time are very important and by reducing redundant parameters we can speed up the delivery time. Validation with the coincident ALS data shows that 100% of the open water is separated from the surrounding sea ice and that the sea ice classes have at least 96.9% accuracy. A notable difference between the C/X-band and the L-band images was the high importance of entropy for the L-band sea ice classifications.
Thermodynamic Evolution of Arctic Sea Ice Using L-band SAR

Mallik Mahmud¹ (msmahmud@ucalgary.ca), Stephen Howell², Torsten Geldsetzer¹, Vishnu Nandan¹, John Yackel¹
¹University of Calgary, Geography, Calgary, Canada, ²Environment and Climate Change Canada, Toronto, Canada

Selection of C-band SAR (synthetic aperture radar) as the preferred frequency for sea ice monitoring was made in the 1980s when the Arctic sea ice regime was different (i.e. Multi-year ice [MYI]) from what it is today (i.e. predominantly first-year ice [FYI]). Moreover, during the melt season, it has been demonstrated that C-band fails to exhibit necessary backscatter contrast among various ice-types that make classification difficult compared to L-band. Thus, L-band SAR is considered as an optimal choice for sea ice monitoring in the new Arctic sea ice regime. Considering limited L-band sea ice application, this study aims to investigate the thermodynamic evolution of snow-covered Arctic sea ice over the Canadian Arctic Archipelago using L-band ScanSAR imagery from ALOS PALSAR. Time-series microwave backscatter signatures for both FYI and MYI are explored using L-band SAR imagery in 2010. Seasonal evolution of L-band microwave backscatter over FYI shows similarity with C-band, with lower intensity. However, this study reveals that seasonal evolution of L-band MYI signature during winter to melt transition is opposite to C-band, which certainly exhibit different scattering mechanism. The unique characteristic of L-band SAR during thermodynamic evolution of Arctic sea ice that will be invaluable with imminent launch of future L-band missions (e.g. SAOCOM, NISAR). This study recommend further investigation of L-band SAR interactions with sea ice compared to higher frequencies.
L-band Brightness Temperature and Snow Surface Properties at Dome C, Antarctica

Marion Leduc-Leballeur¹ (m.leduc@ifac.cnr.it), Ghislain Picard², Giovanni Macelloni¹, Laurent Arnaud², Marco Brogioni¹, Arnaud Mialon³, Yann H Kerr³

The physical properties of the surface are essential for understanding the surface energy and mass budgets of the Antarctic ice sheet and, in turn, for predicting climate change and a rise in the sea level. Several glaciological properties are relevant, such as snow grain size, density, roughness, etc.

A careful analyse of snow surface properties at Dome C showed that an unusual event happened during the 2014-2015 austral summer. At the same time, an exceptional variation (2 events in 6 years) is observed by L-band radiometers (DOMEX ground radiometer and the ESA's SMOS satellite). Here we present our investigation of this period combing multiple sources of information. From November to March, a slow increase in brightness temperature (Tb) occurred concomitantly with a decrease in surface snow density. During this period, low wind speed made the presence of hoar and the accumulation of light snow possible. Around 20 March 2015, an abrupt decrease in Tb was observed and corresponded with a clear increase in surface snow density. Strong wind was also observed, which could have compacted or removed the light snow presents on the surface. Simulations performed with the WALOMIS snow-emission model indicated that L-band Tb was affected by both the surface snow density and the thickness of the superficial layer. Future work will explore the widespread nature of this kind of event and the interest to use them as climate indicator of change at the continent scale.
Accurate characterization of the Surface Radiative Energy Budget (SRB) of the Arctic is critically important for understanding its key role in climate regulation. This is most cost-effectively done with satellite observations. In particular, we know that accurate estimates of the Cloud Optical Thickness (COT) of Arctic clouds are a prerequisite for successful SRB calculations. Yet we also know that COT retrievals over bright surfaces such as snow or sea ice are very challenging, particularly for legacy instruments such as the Advanced Very High Resolution Radiometer (AVHRR). Yet, utilization of the multi-instrument AVHRR timeseries offers us the single best chance for obtaining a long SRB timeseries if the challenges can be overcome. Thus our research question: How do AVHRR-based COT retrieval methodologies perform over the Arctic, and can we identify specific issues that set limitations for COT retrieval accuracy?

We have spatiotemporally collocated a large multi-year dataset (N=270K+) of individual AVHRR-based COT retrievals from the CM SAF CLARA-A2 and NOAA APP-x datasets with corresponding observations from both CALIPSO/CALIOP and Cloudsat, based on the SNO method. We show a comparative analysis of the different COT retrievals, taking into account the inherent limitations in each (e.g. CALIPSO’s COT saturation over thick clouds, Cloudsat’s insensitivity to very low clouds, etc.). We furthermore present the findings grouped by background surface type and cloud type.
Sea ice coverage is one of the major challenges for ship expeditions in the Antarctic Southern Ocean. Even icebreakers with a high ice class can get into trouble on their journeys through sea ice covered areas. Sea ice information in near-real time independent of weather conditions and daytime are therefore highly desirable. The German radar satellites TerraSAR-X (TSX) and TanDEM-X (TDX) are capable to provide such a near-real time application.

The Earth Observation Center (EOC) of the German Aerospace Center (DLR) covers the entire spectrum of remote sensing from data reception to processing, as well as developing new information products. In combination with the German Antarctic Receiving Station (GARS) O'Higgins, which is equipped with an operational near-real time processor for TSX/TDX data, it is possible to deliver sea ice information just about 60 minutes after the raw data has been acquired. These information products can be used by ship crews for navigation purposes as well as for planning biological, geological or oceanographic sampling sites by scientists aboard the supported research vessels.

Since 2015 this service has been successfully tested during several ship expeditions. Information on the processing chain and examples of delivered products will be presented.
Supraglacial river networks set efficacy and time lags by which surface meltwater is routed to the englacial and proglacial portions of the ice masses and thereby have important implications for surface ice mass balance and ice dynamics. However, these crucial hydrologic features remain poorly studied mainly because they are too narrow to be reliably delineated from conventional moderate-resolution satellite images. This study uses 10 m Sentinel-2 MSI images to map supraglacial rivers on the Northwest Greenland Ice Sheet, Devon Ice Cap, and Barnes Ice Cap. Results show that Sentinel-2 images are preferable to Landsat-8 images for delineating narrow and continuous supraglacial meltwater channels, yielding sufficient detail and higher drainage density than Landsat-8. The Sentinel-derived rivers form different surface meltwater drainage patterns at each study area. In northwest Greenland, supraglacial rivers drain meltwater directly off the ice sheet into proglacial rivers, whereas on the Devon Ice Cap and the Barnes Ice Cap, numerous supraglacial rivers are interrupted by moulins and thereby drain considerable portions of surface meltwater to subglacial systems, potentially coupling surface melt with ice dynamics. Overall, the Sentinel-2 images raise prospects for investigating supraglacial meltwater drainage patterns and improving our understanding of surface hydrology and ice flow of global ice masses.
Ice cliff backwasting on debris-covered glaciers is recognized as an important process, potentially responsible of the so-called “debris-cover anomaly”, i.e. the fact that debris-covered and debris-free glaciers loose mass at a similar rate in Himalaya. In this study, we assess the total contribution of ice cliff backwasting to the ablation of Changri Nup Glacier tongue over one year. We use three very high resolution datasets (terrestrial photogrammetry, UAV photogrammetry, Pléiades tri-sereo) acquired simultaneously in November 2015 and 2016 to survey the glacier tongue topography. Using terrestrial photogrammetry data, we calculated the volume losses of 12 cliffs with various size applying a full 3D method. We used these reference volume loss estimates to assess the applicability of UAV and Pléiades data to calculate volume losses of individual ice cliffs. We found that the total difference between the volume loss measured with the terrestrial photogrammetry and the UAV and Pléiades was less than 3% and 7%, respectively, demonstrating the suitability of these datasets to measure volume loss from ice cliffs. We then applied the same method to the entire glacier tongue, and found that ice cliffs contribute to 23 ± 5 % of the total ablation of Changri Nup Glacier tongue.
In this study, sea ice thickness (SIT) and sea ice extent (SIE) in the Bohai Sea from 2000 to 2016 were investigated. A surface heat balance equation was applied to calculate ice thickness using ice surface temperatures estimated from MODIS data with input from air temperature and wind speed from reanalysis weather data. No trend was found in ice thickness in this period. The mean SIT and SIE during this period were 5.58±0.86 cm and 23×10^3±8×10^3 km^2, respectively. The retrieved ice thickness in the winter of 2009/2010 agreed reasonably well with in situ observations at two offshore oil platforms, with RMSE of 6.42 cm and 2.26 cm. Annual variation in mean ice thickness was rather limited within a range of 3-7 cm. The SIE varied significantly with a rather large standard deviation of approximately 8,000 km^2. The largest ice thickness and ice extent periods were observed during the second half of January and the first half of February, respectively. The Spearman correlation coefficient between mean ice thickness and average air temperature from 21 automatic weather stations around the Bohai Sea was -0.94 (P < 0.005), and the coefficient between median ice extent and negative accumulated temperature was -0.503 (P < 0.001). The rate of increase in air temperature around the Bohai Sea is 0.271°C decade^{-1} in winter for 1979-2016 (P < 0.05), which has not resulted in a decreasing trend in sea ice thickness and extent for the past 16 years in the Bohai Sea.
Remote Sensing of Grounding Lines - Current Methods and Data

Peter Friedl\textsuperscript{1} (peter.friedl@dlr.de), Anke Fluhrer\textsuperscript{1}
\textsuperscript{1}German Aerospace Center (DLR), German Remote Sensing Data Center (DFD), Wessling, Germany

The grounding line is the boundary between the floating and the grounded part of an ice sheet or tidewater glacier. Knowing its position is critical for assessing glacier/ice sheet stability, glacier/ice sheet mass balance calculations and numerical modeling. However, as it is a subglacial feature, mapping of the grounding line is challenging. Although ice sounding surveys may be capable to map grounding line positions directly, they often do not yield satisfying results. Other field measurements try to map grounding lines indirectly e.g. by measuring ice flexure with tiltmeters or kinematic GPS. Nevertheless, such surveys are not suitable for picking grounding lines over large and inaccessible areas. In contrast, the continuous development of new remote sensing sensors and techniques over the last decades enabled grounding line delineation over extensive areas at low costs. Modern remote sensing techniques mainly use space- and airborne SAR, optical, radio echo sounding and altimeter data to map features in the grounding zone which can be taken as grounding line proxies. We present a state-of-the-art review of existing remote sensing techniques and data for mapping grounding lines. We discuss the advantages and disadvantages of the methods and evaluate commonly used sensors and data. We also give an overview of freely available grounding line products. Finally we compare grounding lines inferred from different remote sensing methods and data in example regions.
Sea Ice Leads Detection Based on Multisensory Remote Sensing Data

Meng Qu¹, Xi Zhao¹ (xi.zhao@whu.edu.cn), Mohammed Shokr², Qing Ji¹, Xiaoping Pang¹
¹Wuhan University, Chinese Antarctic Center of Surveying and Mapping, Wuhan, China, ²Environment Canada, Toronto, Canada

Sea ice leads serve as prime window for heat transfer between the Arctic ocean and the atmosphere during winter seasons. They also provide pathways for human to enter the core Arctic area. The objective of this study is to extract sea ice leads utilizing multisensory remote sensing data and explore potential use of high-resolution Radarsat-2 images in lead detection. We found that ice surface temperature derived from MODIS thermal bands has capability of detecting leads prevailed by open water or thin ice, but cannot differentiate refrozen leads from the surrounding thick ice, i.e. multi-year ice (MYI) and first-year ice (FYI). Whereas Radarsat-2 images outperformed in discriminating several sea ice types including new ice (NI), young ice (YI) and refrozen leads (RL). Ice surface temperature and optical reflectance from MODIS were introduced using decision tree to reduce ambiguity in Radarsat-2 classification. We concluded that dual-polarization Radarsat-2 data could provide more details on sea ice condition in lead area compared with moderate resolution MODIS images, especially for refrozen leads. On the other hand, could-free optical images, if available, can add valuable information for discrimination between FYI and NI, thus improve the classification accuracy.
A Spectral Linear Mixing Model (SLMM) is proposed to estimate wet snow fraction images for the Antarctic continent based on calibrated SMMR, SSMI and SSM/IS EASE-Grid data (25 km spatial resolution) with a daily temporal resolution. We compared calibrated brightness temperatures of DMSP SSM/I images (19GHz-H, 19GHz-V, 37GHz-H and 37GHz-V channels) with fraction images of Wet Snow Zone (WSZ), Dry Snow Zone (DSZ) and Rock Outcrops (RO), derived from classified ENVISAT ASAR wide swath images (150 m) acquired at 16 dates. Then, these data were used on a least squares solution to estimate the unknown spectral signatures in brightness temperatures (Kelvin) for these three endmembers, in channels 19H, 19V, 37H and 37V, respectively: WSZ (256.122; 269.679; 239.865; 251.192); DSZ (200.256; 227.464; 204.568; 224.161); RO (261.514; 287.697; 215.217; 227.824). The $r^2$ were higher than 0.98 and p-values lower than 0.00001 for all channels. These spectral signatures and SSM/I images were then used in this SLMM to estimate WSZ fraction images, which were compared with correspondent ASAR fraction ones at 11 dates. The average overall accuracy was 73% for class ranges of 0.2 (i.e., each class represents 20% of one pixel). The RMSE was lower than 0.06 for all dates, excepting for one with 0.29. The analysis of the estimated WSZ fraction images indicated that the most persistent and intensive melt was observed on the Larsen and Wilkins ice shelves during the period 1978-2017.
In order to support studies on landscape changes of elements like snow, ice, water bodies and vegetation, a new and updated mosaic of Greenland is necessary. In this study, we created a 30m mosaic of Greenland from 229 individual Landsat8 scenes acquired during June to August in 2014 and 2015. There are four steps to finish the mosaic. Firstly, planetary reflectance for three single spectral bands (red, green and blue bands) was calculated. Since concentrations of atmospheric water vapor and aerosols are very low over Arctic regions, the planetary reflectance is a good approximation of surface reflectance. The planetary reflectance was used as the surface reflectance in this study. Secondly, to minimize differences of surface reflectance among scenes caused by acquisition date, solar elevation angles and other factors, a solar elevation correction and a non-Lambertian adjustment were applied to the surface reflectance data. Thirdly, non-linear piecewise functions were used to convert surface reflectance values to 8-bit values ranged from 0 to 255 for each visible wave band of Landsat8 scenes. Then three 8-bit values images were combining into a 24-bit multispectral scene in order of red band, green band and blue band. Finally, all multispectral scenes were mosaicked to finish the full image mosaic of Greenland.
Mapping Ice Shelf Surface Melt using Object Based Image Classification

Eleri Evans¹,² (eleri.evans@utas.edu.au), Vanessa Lucieer¹, Sue Cook², Alexander Fraser², Richard Coleman¹,²

¹University of Tasmania, Institute for Marine and Antarctic Studies, Hobart, Australia, ²Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia

Surface melt features, such as supraglacial ponds, influence ice shelf stability through hydrofracture induced iceberg calving, and change other ice shelf properties through the redistribution of mass. Accurately mapping the pattern of surface melt at a high temporal and spatial resolution is key to understanding the surface melt regime. Previous studies have used algorithms to successfully discriminate ice shelf surface facies using multi-temporal Synthetic Aperture Radar (SAR) data to map the spatial-temporal patterns of surface melt, identifying the onset of melt and refreezing. However, these studies were restricted by low resolution images and noisy data quality which reduced classification accuracy. The work presented here investigates the application of Object Based Image Analysis (OBIA) to classify Sentinel-1 SAR images covering the Sørsdal Glacier, a small ice shelf in East Antarctica that experiences significant surface melt. The classification was performed using Trimble’s eCognition software, where user-defined rules are based on a priori knowledge of the relationship between ice surface properties and radar back scatter intensity and how this relationship changes with surface melt. The OBIA based classifications will be evaluated using classified Landsat 8 imagery. Mapping the dynamics of the surface melt regime is key to understanding how it influences other ice shelf processes, especially iceberg calving, and how this influence may change in the future.
Temporally Resolved Ice Velocities of Greenland Glaciers using Sentinel SAR Data

Saurabh Vijay¹ (sabvj@space.dtu.dk), Kristian K. Kjeldsen¹, Shfaqat Abbas Khan¹, Anders Kusk¹, Anne Munck Solgaard³, Anders Anker Bjørk¹,²,⁴,⁵

¹Technical University of Denmark, Copenhagen, Denmark, ²National History Museum of Denmark, Copenhagen, Denmark, ³Geological Survey of Denmark and Greenland, Copenhagen, Denmark, ⁴NASA Jet Propulsion Laboratory, Pasadena, United States, ⁵University of California Irvine, Department of Earth System Science, Irvine, United States

The mass loss due to ice discharge via marine-terminating glaciers in Greenland is largely well known. Previous studies have indicated interannual variabilities of ice velocities of different glacier systems in Greenland. However, in most cases these studies were limited by low temporal resolution of the available data. Here, we present ice velocities of 45 Greenland glaciers, including, 79N Gl., Helheim Gl. and Upernavik Isstrøm, with very high temporal sampling during 2015-2017, derived from SAR offset tracking applied over Sentinel SAR data. Moreover, we combine radar backscatter from Sentinel SAR data and air temperature recorded at various weather stations in Greenland, to mark the onset and extent of the melt season. We also derive the changes in the frontal positions of selected glaciers. Seasonal velocity fluctuation of most of the investigated glaciers (26) appear to be primarily controlled by subglacial hydrology. For instance, a group of glaciers (8) speed up with the onset of surface melt, attain maximum velocity in the middle of the melt season and slowdown afterwards. Other glaciers (18) show comparable velocities during late winters and early melt season with significant slowdown afterwards. Seasonal velocities of 6 glaciers appeared to be sensitive to their ice front positions. Our results with such temporal details are crucial for calibrating models projecting the future ice dynamics of marine-terminating glaciers and their mass loss due to ice discharge.
Wed_362_TE-3_966

Gap Filling of Antarctic Sea-ice Freeboard from ICESat: Comparison of Approaches

Huan Li1 (lihuan2016@tsinghua.edu.cn), Hongjie Xie2, Yang Hong1,3, Wei Wan1, Cunguang Wang1, Siyu Zhu1
1Tsinghua University, State Key Laboratory of Hydroscience and Engineering, Department of Hydraulic Engineering, Beijing, China, 2University of Texas at San Antonio, Laboratory for Remote Sensing and Geoinformatics, Department of Geological Sciences, Texas, United States, 3University of Oklahoma, School of Civil Engineering and Environmental Sciences, Oklahoma, United States

Due to the sparse laser-point observations by ICESat, methods are needed to get a complete Total Freeboard (TF) of sea ice coverage over the Antarctic. Three methods, Gaussian Weight Regression (GWR), Ordinary Kriging Interpolation (OKI), and Random Forest Regression (RFR), have been used for gap filling of TF under 6.25 km grid scale with 17 ICESat observation periods during 2003 and 2009. The TF is derived from ICESat by the improved Lowest Level Elevation method and randomly divided into training set (80% grids) and test set (20% grids). Gap filling grid extents are defined with average AMSR-E sea ice concentration larger than 0 in corresponding time periods. Differing from GWR and OKI that only use TF values for gap filling, the RFR method integrates TF values with sea ice cover, sea surface temperature, air pressure, 10 m U wind component, and 10 m V wind component from atmospheric reanalysis data ERA-Interim. With estimated RMSEs on the test set, our primary results show that GWR and OKI have very similar prediction accuracy. By integrating several climate parameters, the RFR shows the best accuracy during the 17 periods.
Precipitable Water Retrieval over Antarctica from Satellite Microwave Sounders

Atmospheric water vapor is an important constituent of the global hydrological cycle; it transports humidity and heat and it is the most important greenhouse gas. Large-scale observations in polar regions with low water vapor burden are difficult to obtain because of the low water vapor signal and, over sea ice and land ice, the high and highly varying surface emissivity. A procedure has been suggested exploiting the data of the satellite humidity sounders SSM/T2, AMSU-B and MHS aboard the DMSP, Aqua and Metop satellites or satellite series, respectively. The algorithm uses three channels of neighbouring frequencies around the water vapor absorption line near 183 GHz plus the 150 GHz channel. The procedure excludes the surface contribution in the satellite signal by considering the ratio of brightness temperature differences. Moreover, the procedure has been adapted to the microwave humidity sounders AMSU-B and MHS with slightly different channels (Melsheimer and Heygster, 2008). Results for Antarctica will be presented for the years 2006-2007. In coastal Antarctic areas, PW time series are available from Global Positioning System (GPS) and radiosounding (RS) stations. Data from five Antarctic sites (Negusini et al. 2016) will be used to correct the satellite based retrievals and then to extend the PW retrieval over whole Antarctica.
Support of Logistics by Satellite Remote Sensing in East Antarctica

Stefan Knetsch1, Stuart McFadzean2, Christian Pfeifer1, Osama Mustafa1 (osama.mustafa@think-jena.de)
1ThINK - Thuringian Institute of Sustainability and Climate Protection, Jena, Germany, 2White Desert Ltd, London, United Kingdom

For scientific and logistic expeditions in Antarctica, identifying safe traverse routes and safe landing areas on snow or ice is a significant challenge. The ability to perform meaningful assessments of ground conditions during the planning phase of an expedition is invaluable. Here we present satellite based approaches to support traverse planning as well as exploration of a new blue ice runway in Dronning Maud Land, East Antarctica. For traverse planning we used both optical (Landsat 8, 15 m ground sample distance (GSD)) and C-band radar images (Sentinel-1, 10 m GSD and Radarsat-2 1.5 m GSD). Data on ice flow speed helped us to detect shear zones with higher risk of crevasses. For the blue ice runway we used hi-res optical images (World View 2, 0.4 m GSD) and a stereographic derived Digital Surface Model (2m GSD). By combining and analyzing these data sets we could identify dangerous areas (e.g. crevasses, erratica, steep slopes). For the runway exploration additionally hi-res maps on micromorphological parameters (e.g. slope, roughness) and cross sections were created in scales up to 1:12,000. All results were delivered as interactive field maps with offline usability. To deal with highly dynamic glacial areas, near-time support to field teams, using of the most recent satellite images can be provided. Antarctica is a high stakes environment and our studies can identify potential hazards during the planning phase to reduce costs, time and increase the safety of field work.
Identifying Blooming Algae in Antarctic Remote Sensing Observations

James Blake\textsuperscript{1,2}, Matthew Davey\textsuperscript{2}, Andrew Fleming\textsuperscript{1}, Peter Convey\textsuperscript{1}, Lloyd Peck\textsuperscript{1}, Andrew Gray\textsuperscript{3}, Alison Smith\textsuperscript{2}, Peter Fretwell\textsuperscript{1} (ptf@bas.ac.uk)
\textsuperscript{1}British Antarctic Survey, Cambridge, United Kingdom, \textsuperscript{2}University of Cambridge, Department of Plant Sciences, Cambridge, United Kingdom, \textsuperscript{3}University of Edinburgh, NERC Field Spectroscopy Facility (FSF), Edinburgh, United Kingdom

The quantity, distribution and contribution to primary productivity of snow algae in Antarctica are currently unknown. We present the first remote sensing analysis of snow algae distribution in Ryder Bay (Adelaide Island, Antarctic Peninsula, 68°S) using a detection algorithm for World View 3 satellite data. Impurity concentration is one of the primary inherent characteristics that determine the optical properties and albedo of snow and snow algae are a prolific impurity that darken the snow pack and increase snow melt through absorption of solar radiation. This analysis is supported by ground and atmospheric spectral field sampling of the same region obtained during the 2017/18 growing season. We compare the area coverage of snow algae to other photosynthetic organisms such as mosses, lichens and higher order vegetation.
Monitoring of glaciers and glacier changes is important for many purposes. The goal of the Copernicus Glacier Service Norway is to develop a national service for glaciers. The Norwegian Water Resources and Energy Directorate (NVE) and Norwegian Polar Institute (NPI) are responsible for monitoring the ice masses in mainland Norway and Svalbard, respectively. The project will mainly use optical imagery from Sentinel-2, but also other sensors such as Landsat-8 and Sentinel-1. Glacier products that will be produced are:
1) Glacier outline, area and calving front,
2) Glacier surface type and snow line,
3) Ice velocity,
4) Glacier crevasses and surge, and
5) Glacier lake outlines.

Here we report results on geometric performance of Sentinel-2, we present ice velocity maps for Svalbard and selected glaciers in mainland Norway, we demonstrate how combined sensors can be used for glacier snowline mapping and we use Sentinel-2 for mapping evolution of glacier lake outlines at selected sites with potential for glacier lake outburst floods.

The glacier products will be made available from NPI and NVE websites (as Web Map Service’s and download) and through the CryoClim portal. Data will also be submitted to GLIMS.
A New Approach to Ice Concentration Retrieval from MW-retrieved Refractive Index

Sang-Moo Lee, Byung-Ju Sohn, Jong-Min Kim
Seoul National University, School of Earth and Environmental Sciences, Seoul, Korea, Republic of

This study attempts to develop a new algorithm for retrieving sea ice concentration from AMSR (Advanced Microwave Scanning Radiometer)-retrieved refractive index. This algorithm is based on the property that the refractive indices of ice and snows are nearly constants regardless of frequency in microwave domain, on the other hands, refractive index of sea water highly varies with frequency. Therefore, the new algorithm gives possibility to reduce statistical uncertainty by using difference of the retrieved refractive index from dual-channel observations because it can reduce tie points for three different types (i.e., first-year, multiyear, and open water) to one for open water. The tie points for sea water are found from analyzing monthly distributions of the retrieved refractive index of water. In other words, dynamic tie points are selected in this algorithm for considering seasonal variation of refractive index of water due to temperature change itself. The sea ice concentration retrieved in this study is compared with those with three different algorithms (e.g., NASA Team, bootstrap, and ASI (ARTIST Sea Ice) algorithm) and the result shows that accuracy of ice concentration produced using refractive index is comparable to the others. In this presentation, systematic difference over the complete AMSR period between developed algorithm and others will be presented and discussed.
Glacier facies are distinct zones in the surface layer of an ice sheet or glacier, which are related to patterns of accumulation and ablation. This study has attempted to map the surface facies of selected glaciers from the Chandra Basin, in the Great Himalayan Range. The digital mapping of spatial extent of glacier facies was carried out using object-based and pixel-based approaches on very high resolution satellite imagery. Traditional glacier facies mapping methodologies have usually utilized data acquired during the melt season. This study however has attempted to map glacier facies using data acquired during early winter. WorldView-2 (WV-2) imagery was used to develop customized spectral indices using the new spectral bands in its multispectral (MS) range. Error matrices were utilized to assess the classification accuracies of final maps. The object-based approach provided an overall accuracy of 88.33%. Two pixel based classifiers, namely maximum likelihood (MXL) and spectral angle mapper (SAM) were utilized, which yielded overall accuracies of 81.67% and 78.33% respectively. The highest kappa statistics obtained for the object based strategy is 0.86 and the pixel based classifiers delivered Kappa statistics of 0.78 and 0.74 respectively. The results indicate that the object-based classification is superior to the pixel-based classification methods for glacier facies mapping in Himalayan environment.
Environmental changes observed on the northern tip of the Antarctic Peninsula over the last decades have contributed to recession in local glaciers and expansion in ice-free areas of the region, creating more adequate conditions for vegetation grow and colonization of newly exposed ground. However, identifying vegetation cover in areas such as the Antarctic Peninsula can be a challenge to remote monitoring due to the nature of the typical Antarctic cryptogamic vegetation, which often appears in small patches and scattered across ice-free areas. In this study, we use remote sensing techniques and criteria to identify this cover in very high-resolution images, acquired by unmanned aerial vehicles (UAV). Spectral Vegetation Indices (SVI) - based on the high absorption in the visible range and the increased reflection in the NIR by plants - were applied in the ice-free area of Hope Bay, in the Trinity Peninsula. The results enabled an evaluation of the indices according to the targets of the area (especially vegetation and penguins nests), and to the types of cryptogamic vegetation (algae, lichens and mosses), in addition to a quantification of local vegetation. We found 5% of the area imaged with some type of vegetation cover, and the best method for the automatic identification of areas with presence of mosses and algae was the Green Normalized Difference Vegetation Index (GNDVI).
Climate Change and the Expansion of Ice-free Areas on the Trinity Peninsula

Maria Eliza Sotille¹ (sotille@gmail.com), Ulisses Franz Bremer¹, Jefferson Cardia Simões¹

Among one of the most rapidly warming regions on Southern Hemisphere, the northern tip of the Antarctica Peninsula has been reacting to rising air temperatures over the past decades, which have led to greater-than-average summer melting, causing changes in its ice-covered and ice-free areas. In the Trinity Peninsula, areas not covered by ice are sparse and restricted to a few headlands, although it is assumed these could significantly expand as a result of a warmer weather. Mapping these areas create conditions to identify and monitor the changes occurring in these environments, checking for eventual responses to climate change. Here, we performed a survey of variations occurred over the last three decades (1988-2017) in the ice-free areas of the Trinity Peninsula, using Remote Sensing techniques. The study used Landsat satellite imagery to identify ice-free area variations using the VIS, NIR and SWIR bands to differentiate ice and snow from rocks, which can be problematic in the Antarctic environment due to extensive cloud cover and areas with shadow.
On the Retrieval of Ice Sheet Temperature Profile by using SMOS Satellite Data

Giovanni Macelloni¹ (g.macelloni@ifac.cnr.it), Francesco Montomoli¹, Marion Leduc-Leballeur², Marco Brogioni¹, Catherine Ritz²,³, Ghislain Picard²,³
¹IFAC-CNR, Sesto Fiorentino, Italy, ²UGA - CNRS, IGE, Grenoble, France, ³CESBIO (CNES, CNRS, IRD, UPS), Univ. Toulouse, Toulouse, France

The internal ice sheet temperature is a key parameter for the understanding of the ice sheet dynamics which, at present, is available only from glaciological models or in the few boreholes where temperature has been measured. However, the drilling of boreholes is a very expensive activity and the state-of-the-art climate or glaciological models are unable to determine the temperature profile at continental scale with a sufficient accuracy. From the spatial analysis of space-borne L-band data from the ESA’s SMOS, collected over Antarctica, it was proved that they are sensitive to the ice sheet temperature profile. The latter depends on several factors as the ice thickness, the surface temperature, the geothermal heat flux, the mean annual accumulation. The satellite observations suggested that, by using a proper glaciological and microwave emission model it is possible to retrieve the ice sheet temperature profile starting from SMOS data. Starting from these considerations an inversion algorithm, which uses as inputs SMOS data and ancillary information, the ice sheet temperature profile was derived from a large portion of Antarctica. Areas where the retrieval is not applicable (i.e. near to the coast or where the ice sheet velocity is higher than 10m/yr) are masked out and a quality flag with the confidence of the estimation was also provided. Secondary products are the geothermal heat flux and snow accumulation maps at the same spatial resolution of SMOS.
The Antarctic ice sheet is predicted to be the major contributor to sea-level rise during the XXI century. Therefore, monitoring ice dynamics of outlet glaciers in Antarctica is of great importance to assess future sea-level rise predictions. Union Glacier is one of the major outlet glaciers of the Ellsworth Mountains and drains into the Ronne-Filchner Ice Shelf. We acquired high resolution Stripmap HIMAGE SAR images from the COSMO-SkyMed satellite constellation during austral summer of 2011-2012, and applied SAR offset tracking to compute ice velocities. Then, we compared our derived velocities with field data obtained between December 2011 and January 2012. Mean values of ice velocity estimated for the main trunk of the glacier are 15.7 m a\(^{-1}\), with maximum values of 109.9 m a\(^{-1}\) and 14.3 m a\(^{-1}\) SD, and are in agreement with previous studies and field measurements. Higher velocities are associated with changes in elevation between the plateau and the main valley. A model of ice thickness based on lamellar flow theory is proposed, using estimated surface ice velocity in combination with surface slope derived from TanDEM-X as input data. Comparison of our modeled ice thickness with radar data from published studies agree with high accuracy. Finally, we computed principal strain rates and compared with glacier surface features as seen in high resolution COSMO-SkyMed Spotlight-2 SAR images in order to show the relation between surface features and acting strain components.
We performed a spatiotemporal trend analysis of snowmelt in the Antarctic continent for the 1978-2017 period based on wet snow fraction-images, calculated by the Spectral Linear Mixture Model - SLMM. This subpixel analysis was performed using passive microwave brightness temperature data (SMMR, SSM/I and SSMI/S) with daily resolution, and 25 km of spatial one. To measure the snowmelt surface area, we used the total fraction melt area calculated by the sum of the total wet snow fraction-images during 90 days of the Austral summer with the highest snow-melt (December, January and February) in seven regions of Antarctica. Using the Mann-Kendall test, we performed a analysis that shows negative trends in the Antarctic Peninsula, Marie Byrd Land, Amery Ice Shelf and Dronning Maud Land regions. On the other hand, positive trends are observed in the Ross Ice Shelf/Siple Coast and Wilkes Land. Taking in consideration these results, we are able to distinguish two different snow-melting trends according to two groups of regions in the Antarctic continent, which show a negative trend as a whole.
The first systematic observation of the ice drift had been held more than a century ago. Spatial ice drift vector fields can be retrieved from remote sensing data. The sea ice motion is estimated by comparing the points of sea ice patterns in two subsequent snapshots.

We propose a feature tracking algorithm for sea ice drift retrieval from sequential satellite synthetic aperture radar (SAR) images. The method is based on feature tracking comprising of feature detection, description and matching steps. The Scale Invariant Feature Transform (SIFT), its alternative called ORB and A-KAZE features are selected for the intercomparing. The approach exploits the benefits of nonlinear multi-scale image representations using A-KAZE features, which is a method that detects and describes image features in an anisotropic scale space that preserves important object boundaries while adaptively removing noise and small image details.

These techniques were implemented as a part of ice drift retrieval algorithm and tested on dual polarized Sentinel-1A C-SAR extra wide swath mode data over Arctic Seas. To evaluate the developed of sea ice drift retrieval algorithm we performed a series of experiments over the Arctic seas. Data collection and processing is done in real time. Validation of the results performed in parallel and includes comparisons with other statistical and manual methods.
Given current climate trends, it is imperative that we improve our understanding of ice-sheet responses to climate change and consequent sea-level changes. Numerical ice sheet models are central to addressing this challenge, and are tested and refined by comparing model predictions of past ice geometries with field-based reconstructions from geological, geomorphological, and ice core data. However, on the East Antarctic Ice Sheet, Dronning Maud Land (DML) comprises a critical gap in the empirical data required to reconstruct changes in ice sheet geometry. MAGIC-DML is an international collaboration working to delineate the timing and pattern of past ice surface changes on the western DML margin and produce a comprehensive reconstruction of the region’s glacial history. Part of this work involves remote-sensing-based mapping of western DML glacial geomorphology to recognise potential traces of a thicker ice sheet that may have covered some or all of the mapped nunatak ranges during previous glacial maxima. High-resolution WorldView (WV) optical satellite data was used in ArcGIS to map landforms manually across a range of scales. Observations from two field seasons are being used to validate the remote sensing mapping. Here we present the mapping to date, and evaluate the use of the WV datasets for geomorphological mapping and for cosmogenic nuclide site selection.
Wetland Identification Methods Applied for Fildes Peninsula, Antarctica

Carina Petsch¹ (carinapetsch@gmail.com), Kátia Kellem da Rosa¹, Luiz Felipe Velho¹, Rosemary Vieira², Rafaela Mattos Costa¹, Jefferson Cardia Simões¹
¹Universidade Federal do Rio Grande do Sul / INCT da Criosfera, Porto Alegre, Brazil, ²Universidade Federal Fluminense, Niterói, Brazil

The wetlands are flat areas of low altitude that accumulate a thin layer of water and allow the vegetation growth. So, this study compares a supervised classification and a new multicriteria method developed for the delimitation of meltwater wetlands. The study area is an ice-free area in the south of King George Island, Antarctica. We classified seven images of the Landsat series (1986-2017), using the QGIS 2.19.8 software, for delimiting the wetland area. After classification tests, we concluded the vegetation location is the main factor to determine the wetlands limits, we use different weights to develop a new processing chain, with the following variables: vegetation (obtained with the Normalized Difference Vegetation Index - NDVI), slope, altitude and slopes oriented north and northwest (from a Digital Elevation Model). Supervised classification identified only lakes, but does not identify correctly wetlands areas. As most wetlands are located in vegetated areas under 50 m of altitude and slopes less than 16%, respectively, the new method showed good results with accuracy from 78 to 89%. The new method, however, does not work properly in shadowed areas (due to the relief) and images with thick snow cover. In short, relief parameters added to the location of the vegetation allow better results than a simple supervised classification.
Wed_377_TE-3_1897
Impact of Tundra Snow Layer Thickness on Measured and Modelled Radar Backscatter

Nick Rutter¹ (nick.rutter@northumbria.ac.uk), Mel Sandells², Chris Derksen³, Josh King³, Peter Toose³, Leanne Wake⁴, Tom Watts⁴, Matthew Sturm⁵
¹Northumbria University, Geography and Environmental Sciences, Newcastle upon Tyne, United Kingdom, ²CORES Science and Engineering Limited, Burnopfield, United Kingdom, ³Environment and Climate Change Canada, Toronto, Canada, ⁴Northumbria University, Newcastle upon Tyne, United Kingdom, ⁵University of Alaska - Fairbanks, Fairbanks, United States

Microwave radar backscatter within an Arctic tundra snowpack is strongly influenced by spatial variability of the thickness of internal layering; often comprising two dominant snow layers (basal depth hoar overlain by wind slab). Determining the relative proportions of depth hoar and wind slab from a snowpack of a known depth may help our future capacity to invert forward models of electromagnetic backscatter to improve simulations of snow water equivalent.

Extensive snow measurements were made within Trail Valley Creek, NWT, Canada in April 2013 at 18 pit and 9 trench locations (trench extents ranged between 5m to 50m). Ground microstructure measurements included traditional stratigraphy, near infrared stratigraphy, Specific Surface Area (SSA), and density. Coincident airborne Lidar measurements were made of snow depth across the catchment, in addition to airborne radar snow backscatter (X- and Ku-band Synthetic Aperture Radar).

Ground measurements showed the mean proportion of depth hoar was just under 30% of total snow depth and the mean proportion of wind slab was consistently greater than 50%, which showed an increasing trend with increasing total snow depth. Consequently, we run forward simulations of the SMRT microwave scattering model using Lidar derived snow depths. The influence of microstructural variability on relationships between airborne radar and simulated backscatter, with spatial aggregation between scales of 10m to 250m, was then explored.
Remote sensing is increasingly being used in the Chinese National Antarctic/Arctic Research Expedition (CHINARE). In the 33th Chinese Antarctic Research Expedition and the 8th Chinese Arctic Research Expedition, multi-source remote sensing data were utilized for providing support to ship ice navigation, discharge and investigation on sea ice. The remote sensing data that used including AMSR2, Terra/Aqua MODIS, Landsat-8, SPOT-5, Radarsat-2, Sentinel-1A, COSMO-SkyMed, etc. With the aid of the analysis results from the multi-source and multi-temporal remote sensing data, the 33th Chinese Antarctic Expedition planned ship route reasonably, explored land-fast sea ice and laid down a plan of discharge; and the 8th Chinese Arctic Expedition crossed the Trans-Polar Passage successfully, chose appropriate sea ice stations. Applications of remote sensing data saved time for scientific investigation and logistics services, ensured the safety of people, ship and equipments.
Influence of Gap Filling on the Accuracy of Snow Mapping Using MODIS and VIIRS

Dorothy Hall¹ (dorothy.k.hall@nasa.gov), George Riggs², Nicolo DiGirolamo², Miguel Roman³
¹University of Maryland, Earth System Science Interdisciplinary Center, College Park, United States, ²SSAI, Lanham, United States, ³NASA Goddard Space Flight Center, Greenbelt, United States

Global snow-cover maps have been produced from the MODerate-resolution Imaging Spectroradiometer (MODIS) since 2000 at 500-m resolution, and from the Suomi-National Polar Program (S-NPP) Visible Infrared Imaging Radiometer Suite (VIIRS) since 2011 at 375-m resolution. Development of an Earth system data record (ESDR) that utilizes both MODIS and VIIRS snow maps is underway. In November 2017 the second in a series of VIIRS sensors will be launched on the Joint Polar Satellite System-1 (JPSS-1), with the JPSS-2 satellite scheduled for launch in 2021, providing the potential to extend NASA's snow-cover ESDR for decades into the future. Studies are underway to investigate the continuity of time series of datasets between the MODIS/VIIRS NASA snow-cover data products. In the present study we focus on a time series of daily Terra and Aqua MODIS and NASA VIIRS cloud-gap filled (CGF) snow-cover maps. A MODIS CGF snow map is available every day irrespective of cloud cover. We explore the accuracy of cloud-gap filling at different sites in North America, and also compare the CGF maps with other available snow maps, such as for example, the cloud-free maps derived from the National Oceanic and Atmospheric Administration (NOAA)'s Interactive Multisensor Snow and Ice Mapping System (IMS). The advantages and uncertainties of cloud-gap filling are discussed in the context of various applications of the moderate-resolution ESDR.
Seasonal snow is a main element of the global water cycle and climate system. Accurate, long-term data sets on main snow cover parameters are crucial for climate monitoring and validation of climate models. In order to assess the accuracy and performance of different satellite-based snow cover products of continental to global extent, an international collaborative effort, SnowPEx, was initiated by ESA.

SnowPEx focuses on two parameters of the seasonal snow pack, snow extent (SE) from medium resolution optical satellite data and snow water equivalent (SWE) from passive microwave sensors. 14 continental to global snow extent products and three SWE products were evaluated. Statistical measures and spatial pattern analysis following standardized protocols defined in the project were applied to assess the agreement between the products in different environments and climate zones. For validation of the products reference data sets, derived from more than 450 Landsat scenes, and in-situ data from various organisations in Europe, North America and Asia, were used. SWE products were also compared with output from land surface models driven by atmospheric reanalysis data. In support of climate studies the trends in the hemispheric SE and SWE time series of the different satellite based snow products were compared. We provide an overview on the results of SnowPEx and report on agreement and differences of multi-decadal trends of the various snow products.
An Improved Method for Sea Ice Concentration Estimation from SSM/I and AMSR-E

Tingting Liu¹ (ttliu23@whu.edu.cn), Zemin Wang¹
¹Wuhan University, Chinese Antarctic Center, Wuhan, China

To improve the accuracy of the NASA Team (NT) sea ice concentration (SIC) algorithm, a new SIC estimation method was proposed by combining the NT algorithm and a numerical optimization technique with Special Sensor Microwave/Imager (SSM/I) data and Advanced Microwave Scanning Radiometer for EOS (AMSR-E) data respectively. In this method, the noise was taken into consideration to improve the SIC estimation equation, and then the fully constrained least squares was used to further optimize the estimation results from the improved equation. Validation was performed using comparisons between the proposed method, the NT, the Bootstrap, the NT2, the ASI and in situ data. The quantitative results from SSM/I showed that the proposed method accurately generated SIC with smaller bias (0.2) and RMSE (9.7) than the other methods. The results also indicated that the proposed method consistently performed better in not only summer but also winter (with bias 2.0 in summer and 2.0 in winter, RMSE 13.3 in summer and 7.3 in winter) than the other methods. The accuracies of all methods in summer were lower than winter, among which the accuracy of the Bootstrap was the lowest. The accuracies of the proposed method, NT2 and ASI using AMSR-E indicated that the performance of the proposed method was found to be better than the NT2 algorithm and ASI algorithm in quantitative comparisons. This research demonstrated the benefit of incorporating numerical optimization into SIC estimation.
AIM-North: The Atmospheric Imaging Mission for Northern Regions

Ray Nassar¹ (ray.nassar@canada.ca), Chris McLinden², Chris Sioris², Joseph Mendonca¹,³

¹Environment and Climate Change Canada, Climate Research Division, Toronto, Canada, ²Environment and Climate Change Canada, Air Quality Research Division, Toronto, Canada, ³University of Toronto, Physics, Toronto, Canada

Low Earth orbit (LEO) satellites offer global sampling, but revisit times can be days to weeks. Geostationary (GEO) satellites can observe a selected region multiple times per day, but have difficulty poleward of ~50°N/S. A constellation of 2 satellites in a highly elliptical orbit (HEO) configuration can provide quasi-geostationary observations of the high latitudes. AIM-North is a Canadian mission concept that would provide observations of unprecedented frequency, density and quality for monitoring greenhouse gases (GHGs) and air quality (AQ) over landmasses from ~40-80°N, using a pair of HEO satellites. AIM-North would image the GHGs CO₂ and CH₄, as well as CO in the shortwave-infrared (SWIR) and AQ species: O₃, NO₂, SO₂, HCHO, BrO, aerosol and others, in the ultraviolet-visible (UV-vis), multiple times per day with a pixel size of 3x3 km². Additional IR bands could provide complementary observations for weather, climate and AQ research and operations. AIM-North would improve our ability to monitor the delicate carbon balance of Arctic permafrost and boreal forests, and help to quantify anthropogenic GHGs emissions at multiple scales. Its unprecedented observations could capture emissions from wildfires, the oil sands, or cities improving our understanding and prediction of air quality in the north. Since AIM-North would make valuable observations over many northern countries, scenarios for an international partnership in the AIM-North mission can be explored.
Multiyear Sea Ice Concentration Estimates Using ASCAT and AMSR2 Data

Yufang Ye\textsuperscript{1} (yufang.ye@chalmers.se), Gunnar Spreen\textsuperscript{2}, Mohammed Shokr\textsuperscript{3}, Georg Heygster\textsuperscript{2}, Christian Melsheimer\textsuperscript{2}

\textsuperscript{1}Chalmers University of Technology, Department of Space, Earth and Environment, Gothenburg, Sweden, \textsuperscript{2}University of Bremen, Bremen, Germany, \textsuperscript{3}Environment & Climate Change Canada, Toronto, Canada

Multiyear ice (MYI) concentration can be retrieved from passive or active microwave remote sensing observations. One of the algorithms that combine both observations is the Environmental Canada Ice Concentration Extractor (ECICE). In this study, data from the Advanced Scatterometer (ASCAT) and the Advanced Microwave Remote Sensing Radiometer 2 (AMSR2) are employed to retrieve concentrations of MYI. Combined active and passive microwave data can help to distinguish MYI from first-year ice, however, factors such as ice deformation, snow wetness and metamorphism can cause significant changes in brightness temperature and backscatter, leading to misidentification of MYI. Therefore, two corrections were applied to the MYI concentration retrievals from ECICE with inputs from ASCAT and AMSR2 observations. One correction utilizes air temperature to restore the underestimated MYI concentrations under warm conditions, whereas the other mainly uses sea ice drift to correct the overestimated MYI concentrations. The results are compared with the ice charts from Canadian Ice Service (CIS), sea ice age dataset from NSIDC, and sea ice type product from EUMETSAT OSISAF. The MYI concentration from ASCAT/AMSR2 agrees well with that in the ice charts. Compared to the ice classified as two years or older in the sea ice age dataset, the MYI concentration from ASCAT/AMSR2 is approximately 50% or greater. Besides, SAR images from Sentinel-1 are used to evaluate the MYI estimates in different regions.
Low Power Wide Area Network Deployment for Science

Johan Berte¹ (info@antarctiq.com), Erik Verhagen²
¹Private, Wervik, Belgium

Operations in polar regions have a high cost compromising the scope of scientific campaigns. Equipping sensors in a distributed network with satellite links is impractical and expensive. Furthermore satellite networks are not designed to support large scale multi-parametric studies. A new paradigm has emerged in regional scale telecommunications, the LPWAN (Low-Power Wide Area Networks). This technology is specifically tailored for distributed networks.

AntarctiQ’s mission is to support operations in extreme environments. AntarctiQ has a multiple-year experience in Antarctica ranging from infrastructure design, systems engineering, science support, prototyping, science equipment customisation, expedition planning, logistics and on-site activities.

In 2017/2018, AntarctiQ - in partnership with Sigfox (LPWAN) and Sensolus (sensors) - will demonstrate a case of distributed low-power science sensors and LPWAN deployment in Antarctica, this for future large scale network deployment. A vessel will be hosting an LPWAN base station, ensuring a local +50 km low-power radio network dedicated to remote sensing. Different wireless scientific and operational sensors will be placed in the field to demonstrate operational safety and scientific optimisation. Data will be sent to the project stakeholders over marine satellite communications with a minimal impact on the bandwidth due to the Sigfox communication protocol. Users will be able to collect their data and activities in real-time.
Gravimetric Mass Balance Products for the Antarctic and Greenland Ice Sheet

Martin Horwath¹ (martin.horwath@tu-dresden.de), Andreas Groh¹, Alexander Horvath², René Forsberg³, Rakia Meister³, Valentina R. Barletta³, Andrew Shepherd⁴

¹Technische Universität Dresden, Dresden, Germany, ²Technische Universität München, München, Germany, ³Technical University of Denmark, Copenhagen, Denmark, ⁴University of Leeds, Leeds, United Kingdom

The ESA Climate Change Initiative (CCI) projects on the Antarctic Ice Sheet (AIS_cci) and the Greenland Ice Sheet (GIS_cci) provide Gravimetric Mass Balance (GMB) products based on satellite gravimetry data acquired by the GRACE (Gravity Recovery and Climate Experiment) mission. Monthly solutions produced at TU Graz are utilized to derive two different types of products for the period 2002 - 2016:

1) GMB basin products (i.e. time series of monthly mass changes for the entire ice sheets and selected drainage basins) and
2) GMB gridded products (e.g. mass balance estimates with a formal resolution of about 50km). While a regional integration approach is used by the AIS_cci project, the GMB products of the GIS_cci project are derived using a point mass inversion.

Here we present the final version of the ESA CCI GMB products, which are freely available through data portals hosted by the projects (data1.geo.tu-dresden.de/ais_gmb, products.esa-icesheets-cci.org/products/downloadlist/GMB). Since the initial product release in mid 2016, the applied processing strategies have been improved in order to further reduce GRACE errors and to enhance the separation of signals super-imposed to the ice mass changes. The differences between both processing strategies are investigated through the example of the GIS. Finally, mass balance estimates for both ice sheets as well as their corresponding contributions to global sea level rise are derived from the final GMB products.
Wetlands are common in proglacial areas and are associated with the occurrence of vegetation. Mapping these areas is essential for environmental studies. The aim of this study is to identify vegetation fields in the Fildes Peninsula on King George Island, Antarctica using a combination of image processing techniques. The target vegetation was used to facilitate the identification of flooded areas by satellite images. For the image processing, we chose a Landsat 8 OLI image from 2016. Segmentation was performed for the identification of endmembers that are later used in the linear mixture model. Three fractions were defined: vegetation, snow, and shade. Our results show that those areas presenting the greatest vegetation fraction are coincident with areas of mosses and lichens in the Fildes Peninsula. We plan to compare the results with other images and field data to verify the accuracy of the vegetation fraction.
The development of new technologies applied to cartography and digital mapping allowed the reprocessing of old materials obtained by non-conventional techniques, such as non-metric cameras, generated at a time when the available tools were not so accurate. In this work we reprocessed aerial photos obtained in January 2003 from a flying over Keller Peninsula, located on King George Island, South Shetland, where the Brazilian Research Station in Antarctica is located. 56 photographs were obtained, revealed and digitized, producing a mosaic of the entire area. A total of 50 points were evenly distributed across Keller peninsula in the form of semi-regular grid. With these data it was possible to generate both the new MDS and the orthophotomosaic. The result was a much less time consuming effort in the post-processing of the images, besides determination of the level of accuracy of the data generated. This work demonstrates that past aerial photos obtained in Antarctica through conventional techniques over the last decades can be reprocessed using these new tools and the data of this collection assumes historical importance in monitoring the dynamics of the glaciers of that region. Allied to this technology, the use of light aerial vehicles (VANTS) has great potential in the studies of terrestrial ecosystems of Antarctic ice-free areas and in the monitoring of glaciers, greatly reducing the logistics and costs of this type of work.
Cryosphere measurement capabilities from instruments prior to Landsat 8 were plagued by radiance saturation and limited Polar Region data acquisition. The long term acquisition plan (LTAP) was revised to include imaging of all sunlit land areas with greater than 85° solar zenith with the launch of Landsat 8. This has significantly increased polar region coverage. With Landsat 9’s 2021 launch and commissioning target, the Landsat 8/9 multi-mission LTAP will substantially increase sub-weekly cloud-free measurements over the circumpolar Arctic and Antarctica. Access to Landsat’s archive is evolving with the global Analysis-Ready Data (ARD) concept. Global ARD will deliver well-calibrated geophysical data products with known measurement traceability and quality assurance. Here, we summarize efforts to benchmark Landsat 8’s surface measurement quality over northwestern Greenland by using NIST traceable visible-to-shortwave infrared (VSWIR) spectrometry as part of a NASA ICESat-2 airborne campaign to the Arctic in the summer of 2015. Our July 29, 2015 flight line analysis with near-coincident Landsat 8 acquisitions indicates that the Operational Land Imager (OLI) is measuring land ice surface reflectance and ocean leaving reflectance at 4-30% accuracy, which is wavelength dependent and largely attributable to atmospheric compensation uncertainty. Our goal is to define polar measurement requirements for Landsat’s next generation instruments by learning from Landsat 8 capabilities.
The transformation of Arctic sea ice from mainly perennial, multi-year ice to a seasonal, first-year ice is believed to have been accompanied by a reduction of the roughness of the ice cover surface. This smoothening effect has been shown to:

(i) modify the momentum and heat transfer between the atmosphere and ocean,
(ii) to alter the ice thickness distribution which in turn controls the snow and melt pond repartition over the ice cover, and
(iii) to bias airborne and satellite remote sensing measurements that depend on the scattering and reflective characteristics over the sea ice surface topography.

We will review existing and novel remote sensing methodologies proposed to estimate sea ice roughness, ranging from airborne LIDAR measurement (ie Operation IceBridge), to backscatter coefficients from scatterometers (ASCAT, QUICKSCAT), to multi angle maging spectroradiometer (MISR), and to laser (Icesat) and radar altimeters (Envisat, Cryosat, Altika, Sentinel-3).

We will show that by comparing and cross-calibrating these different products we can offer a consistent multi-mission, multi-decadal view of the declining sea ice roughness. Implications for sea ice physics, climate and remote sensing will also be discussed.
I address three themes: the focus of my research program, lessons learned about governance that are relevant to the polar regions, and the consequences of the onset of the Anthropocene for polar governance. Focusing on governance as a social function centered on steering societies toward desirable outcomes (e.g. long-term sustainability) and away from undesirable outcomes (e.g. the tragedy of the commons), I analyze the creation and effectiveness of governance systems. Key lessons include: (i) regime design matters, (ii) international legally binding instruments often have drawbacks, (iii) regulation is not the be all and end all of governance, (iv) clustering regimes into complexes makes sense under some circumstances, and (v) regimes can produce islands of cooperation even in times of conflict. The onset of the Anthropocene, occurring at a more rapid pace in the Arctic than anywhere else on the planet, will have major consequences for the development and implementation of effective governance systems for the polar regions. Among other things, we will need to: emphasize early warning; beware of the dangers of institutional reductionism; avoid institutional lock in; and learn to live with high levels frequent surprises.
Changes in Southern Ocean circulation and properties: causes and consequences

Mike Meredith (mmm@bas.ac.uk)
British Antarctic Survey BAS, Cambridge, UK

The Southern Ocean exerts significant influence over the rest of Planet Earth, and directly affects the lives and livelihoods of its inhabitants. It is a key regulator of global climate, absorbing large quantities of heat and carbon (including human-produced) from the atmosphere, and storing them deep in the ocean interior. It is also increasingly seen to be a key influence on the stability of the Antarctic Ice Sheet, and is the home for diverse marine ecosystems and species, some of which are of commercial significance. There is strengthening evidence that the Southern Ocean circulation is changing, from the surface to the abyss, and the increasing availability of data from innovative sources is unveiling new levels of complexity to this change. This talk will discuss some specific examples of Southern Ocean circulation change, its importance, and the ongoing requirement for sustained observations from this most challenging of environments.
Local Environmental Gradients Interact to Structure Arctic Arthropod Communities

Toke Høye¹ (tth@bios.au.dk), Joseph Bowden², Oskar Hansen¹, Rikke Hansen¹, Thøger Henriksen¹, Andreas Niebuhr¹, Mathias Skytte¹
¹Aarhus University, Department of Bioscience, Aarhus, Denmark, ²Canadian Forest Service, Corner Brook, Canada

The organization of ecological communities along local environmental gradients provides important information about how such communities may respond to environmental change. By replicating observations along gradients in shrub and moisture at multiple elevations and using space-for-time substitution, it is possible to examine how arthropod communities may respond to future change. We collected and identified 4640 adult specimens of spiders and beetles near Narsarsuaq, South Greenland during the 2014 growing season from 112 pitfall traps. The traps were arranged in plots covering local gradients in either soil moisture or tall shrub dominance at low and high elevation. Multivariate generalized linear models revealed that community composition was significantly related to shrub height and soil moisture, and that this relationship varied between low and high elevation. Among the 46 species we found, more species were unique at high than at low elevation, a finding that was most pronounced for spiders in plots along soil moisture gradients. Indicator species analysis corroborated earlier findings of the indicator value of specific species and suggested that beetles are better indicators of specific habitats than spiders. Placing plots along local environmental gradients allowed us to detect fine-scale variation in arthropod communities. Together, our results suggest that Arctic arthropod community responses to environmental change may differ among low and high elevation sites.
Tundra Fire Alters the Structure and Function of Microbial-invertebrate Food Web

Amanda Koltz¹ (amanda.koltz@gmail.com), Ashley Asmus², Yamina Pressler³, Gaius Shaver⁴, Laura Gough⁵, John C. Moore³
¹Washington University in St Louis, Biology, St. Louis, United States, ²University of Minnesota, St. Paul, United States, ³Colorado State University, Fort Collins, United States, ⁴Marine Biological Laboratory, Woods Hole, United States, ⁵Towson University, Towson, United States

While historically rare, arctic wildfire is becoming more common due to warmer temperatures and drier conditions. The 2007 Anaktuvuk River fire burned over 1000 km² of the Alaskan Arctic, resulting in combustion of most of the organic soil horizon and fundamentally altering the above- and belowground systems. We investigated recovery of the microbial-invertebrate food web six years post-fire in order to understand how fire alters the structure and function of these communities and how recovery varies with fire severity. We constructed comprehensive food webs based on functional groups of microbes, protozoa, and invertebrates from the soil, soil surface and plant canopy at three sites (non-burned, moderately and severely burned) and used an energetic food web model to estimate C flow through the food web and group-specific rates of C and N cycling. We found that soil and canopy invertebrate biomass was disproportionately higher at the severely burned site compared to non-burned or moderately burned sites. Aboveground herbivory increased significantly with burn severity but food webs at all sites were still primarily based on C derived from detrital resources. Contributions to nutrient cycling were highest by soil-dwelling consumers and increased with fire severity. While responses were asynchronous across microhabitats, our results demonstrate rapid recovery of community function to wildfire and suggest that the microbial-invertebrate food web is more resilient than expected.
Microbial Biodiversity in Siberian Ecosystems: Insights into Methane Cycling

Maialen Barret¹, Laure Gandois¹, Roman Teisserenc², Nikita Tananaev², Frederic Thalasso³, Karla Martinez³, Armando Sepulveda³, Léa Cabrol⁴,⁵ (lea.cabrol@mio.osupytheas.fr) ¹Université de Toulouse, Ecolab, UMR5245, CNRS, INPT, UPS, Castanet Tolosan, France, ²P.I. Melnikov Permafrost Institute, Yakutsk, Russian Federation, ³Universidad de Magallanes, Magallanes, Chile, ⁴Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile, ⁵Institut Méditerranéen d’Océanologie, Marseille, France

High-latitude ecosystems are strongly affected by climate change. Methane emissions resulting from the microbial activity in soils and lakes might constitute a positive feedback. Indeed, warming may disrupt the methane cycle, by altering the microbial community composition and the relative abundances of key players in methane cycling, by affecting the metabolic pathways, yields and productivities of methane producers and consumers. Surveying the microbial diversity and functionalities in these ecosystems is essential for a better understanding of their potential feedback to climate change. In this study, 90 samples were collected from various ecosystems in Siberian Arctic (discontinuous permafrost, including 7 peatlands, 5 lakes, and 4 taiga ecosystems representative of the region). In each site, various samples were collected to take into account the local heterogeneity. DNA was extracted, the bacterial and archaeal 16S rRNA genes were amplified by PCR using universal primers. High-throughput sequencing of these amplicons was carried out with Illumina MiSeq technology. This survey of microbial biodiversity evidenced a structuration of microbial communities as a function of ecosystem characteristics. The relative abundance and taxonomy of methane producers (acetoclastic / hydrogenotrophic) and methane consumers (aerobic / anaerobic) was extracted from sequences analysis. These data improved our understanding of the CH₄ cycling in such ecosystems affected by climate change.
Northern high latitudes store significant amounts of carbon (C) in soil organic matter (SOM). There is major uncertainty over the vulnerability of these C stores to both climate and land-use change. Previous research has focused on the direct effects of warming on plant growth and/or SOM dynamics in isolation, but there is increasing evidence that plant-soil interactions complicate these relationships dramatically. Plants not only control litter inputs (both quality and quantity), but may also influence rates of decomposition if the amount of C allocated to the ‘rhizosphere’ (defined as the area of soil in the vicinity of plant roots in which the chemistry and microbiology is influenced by their growth, respiration, and nutrient exchange) is positively related to microbial activity and the breakdown of older, more recalcitrant, organic matter. This process is referred to as rhizosphere ‘priming’, and despite suggestions that it may be critical in determining ecosystem C storage, it remains extremely poorly understood, especially in natural and semi-natural ecosystems.

Here we outline the approach underpinning a new research project (‘PRIME-TIME’) on rhizosphere priming, based in Swedish Lapland, and we present our initial findings. The project deploys state-of-the-art natural abundance 14-C methodologies, and mycorrhizal fungal community analysis, to determine the impacts of shifts in plant (and associated mycorrhizal) functional composition on SOM dynamics and C fluxes.
Decomposition Rates along Two Arctic Shrub Dominance Gradients in West Greenland

Casper T. Christiansen1,2, Regin Rønn3, Daan Blok4 (daanblok@gmail.com), Bo Elberling5, Hanna Lee1,2, Anders Michelsen6

1Uni Research Climate, Bergen, Norway, 2Bjerknes Centre for Climate Research, Bergen, Norway, 3University of Copenhagen, Arctic Station, Qeqertarsuaq, Greenland, 4Lund University, Department of Physical Geography and Ecosystem Science, Lund, Sweden, 5University of Copenhagen, Center for Permafrost (CENPERM), Copenhagen, Denmark

Due to recent climate change, many Arctic tundra regions are currently undergoing a vegetation shift towards increasing growth and ground-cover of deciduous shrubs. Canopy-forming shrubs can alter key ecosystem functions with strong links to climatic feedbacks, such as carbon sequestration into plant biomass and energy balance. However, we know little about the potential biological and physical feedback mechanisms by which these shrubs may affect litter and soil organic matter decay, and thus whole-ecosystem carbon balance. Here, we present summer and annual decomposition data, using the Tea Bag Index, from Disko Island, Greenland (69ºN), where we incubated 800 teabags along two deciduous shrub dominance gradients (Betula nana and Salix glauca, respectively). We incorporated landscape variation in soil temperature and moisture regimes within our shrub gradients by establishing 25 study sites across a 4 km² area. This allowed us to investigate the effect of increasing deciduous shrub dominance on teabag decay rates and nutrient content - and relate these dependent variables to multiple vegetation, and soil microclimate and biogeochemistry parameters.

Summer data show faster decay in the tallest shrub communities, and this vegetation-specific effect appeared unrelated to soil microclimate. Understanding the intricate feedback mechanisms between deciduous shrub growth and decomposition rates is vital to predict the impacts of vegetation-climate feedbacks in tundra environments.
The release of permafrost-derived nitrogen (N) has the potential to fertilize tundra vegetation, modulate plant competition, stimulate productivity, and offset carbon losses from thawing permafrost. To test if Arctic plants can access deep permafrost-derived N, we characterized rooting profiles and quantified acquisition of $^{15}$N tracer applied at the top of the permafrost table in moist acidic tundra subjected to almost three decades of experimental warming at Toolik Lake, Alaska. We harvested roots by depth increment down to the top of the permafrost table in ambient and warmed plots. The average thaw depth in warmed plots was close to 18 cm deeper than in ambient plots (warmed 58.3 cm ± 6.4 S.E.; ambient 40.8 cm ± 1.8 S.E.). Across treatments the deepest rooting species was the forb *Rubus chamaemorus* (warmed 50.3 cm ± 9.8 S.E.; ambient 40.8 cm ± 1.8 S.E.) followed by the sedge *Eriophorum vaginatum*. These species showed the greatest uptake of tracer after 24 hours. Deciduous and evergreen shrubs had more shallow rooting depths and lower tracer enrichment. We will present a conceptual framework for integrating dynamic rooting in relation to thaw depth into a process-based ecosystem model coupled with a dynamic vegetation model to evaluate these effects on vegetation productivity. Future modeling experiments will contribute to more accurate predictions of vegetation change in the Arctic modulated by belowground plant traits and changing soil resources with warming.
Iron (Fe) is a paradox in the Modern Ocean—its sits at the heart of many life-critical enzymes but is barely available across most of its surface. Despite inventive Fe uptake systems, recent works suggest that heterotrophic bacteria are outcompeted by small diatoms, therefore limiting their access to Fe. To test this hypothesis, incubation experiments were carried out in the Subantarctic Zone of the Southern Ocean (Mar.- Apr. 2016). Experiments were designed
(1) to determine whether carbon (C), Fe, or both elements limit the bacterial growth and
(2) to investigate microbial interactions to acquire Fe.
A pronounced response in bulk and cell-specific bacterial production to single (+C) and combined (+C+Fe) additions of C was observed, while no stimulation by Fe addition alone was detected. Moreover, for concomitant Fe and C additions, cell-specific bacterial Fe uptake rate increased by 8-folds compared to control and was up to 240-times larger when small phytoplankton was excluded from incubations. The results suggest that bacterial growth was limited by labile C rather than by Fe, and that C availability enhances the bacterial Fe demand. Consequently, the competition for Fe would arise among prokaryotes and eukaryotes when limitation in C is alleviated. We believe that such interactions among members of the microbial community could have a marked effect on the extent of bacterially mediated Fe and C cycling, especially towards the end of nutrient-limited phytoplankton blooms.
Role of Particle-attached Bacteria in Rendering Iron and Carbon Bioavailable

Ingrid Obernosterer¹ (ingrid.obernosterer@obs-banyuls.fr), Stéphane Blain¹, Pavla Debeljak¹, Andy Bowie², Pier van der Merwe², Thomas Holmes², Manon Tonnard²

¹CNRS/UPMC, Banyuls sur Mer, France, ²UTAS/IMAS, Hobart, Australia

Iron and carbon are essential for microbial heterotrophic activity, but the bioavailability of these elements is low in surface waters of the Southern Ocean. In the present study we tested the hypothesis that the activity of particle-attached heterotrophic bacteria affects microbial dynamics in surrounding waters due to the release of bioavailable sources of iron and carbon. We performed incubation experiments with biogenic and lithogenic particles collected during the Heard Earth-Ocean-Biosphere Interactions (HEOBI) cruise aboard the Australian R/V Investigator (8 January -27 February 2016). Our results reveal pronounced differences in the bacterially-mediated processing of biogenic and lithogenic particles. This contribution will present data on the chemical composition of the particles, the taxonomic composition of the associated bacterial community and their gene expression patterns for a better understanding of the access to particle-bound iron and carbon in the Southern Ocean.
Sea Ice is a Source of Iron-free Organic Ligands

Cristina Genovese¹ (cristina.genovese@utas.edu.au), Marco Grotti², Jessica Pittaluga², Francisco Ardini², Julie Janssens¹, Kathrin Wuttig¹, Sebastien Moreau¹, Delphine Lannuzel¹

¹University of Tasmania / Institute for Marine and Antarctic Studies, Hobart, Australia, ²University of Genoa, Department of Chemistry and Industrial Chemistry, Genoa, Italy

The incorporation and the release of iron in forming and melting sea ice are paramount mechanisms for primary productivity in polar environment. It is thought that iron-binding organic ligands (Lt) can help in stabilizing dissolved iron (DFe) at surface seawater. In order to test the hypothesis that Lt control the DFe distribution in Antarctic pack ice, we investigated iron organic speciation during the Sea Ice Physics and Ecosystem eXperiment-2 voyage, in 2012. Concentration of Lt ranged from 4.9 nM to 41 nM, always in a higher concentration than the corresponding DFe. Their similar profiles and strong correlation suggested that Lt control DFe distribution in Antarctic pack ice. Both strong and weak ligands were observed, with conditional stability constants ($\log K'_{Fe^{3+}L} = 21.7-23.0$) values similar to those previously observed in land-fast ice. Organic ligands were not saturated with iron (Lt/DFe > 1), unlike previous results for fast ice. Flux estimates show that pack ice would release 0.45 µmol/m²/d of Lt during spring melt, 0.21 µmol/m²/d of which are free of Fe, and therefore available for further complexation. This may suggest that the free ligands excess released from sea ice could help in stabilizing Fe at surface, in the marginal ice zone of the Southern Ocean. Given our findings and the fact that sea-ice extent is thought to decrease, the sea-ice capability to stock Fe during winter would also decrease, leading to less bio-available Fe in the marginal ice zone.
Iron-binding ligands are paramount to maintain iron in solution and sustain primary producers. In surface water of the open ocean, ligands are mostly derived from in situ biological activity. Microbial decomposition processes alter and transform organic matter as it is transported at depth, leaving behind refractory humic substances rich in carboxylated aliphatic molecules. Here we compared labile and freshly-produced dissolved organic matter (DOM) collected from a diatom bloom with refractory DOM collected at 1000 m. Both types of DOM contribute to the iron-binding ligand pool, with stability constants similar to those reported in the ocean. However, only the deep DOM has a strong iron-binding humic-like signature, consistent with previous structural characterizations. Ability to support phytoplankton iron assimilation was 4-fold greater for plankton-derived than deep DOM. This observation reinforces the importance of biologically-produced DOM for iron biogeochemistry in surface water. Exposure the deep DOM to full sun spectral light under controlled temperature, showed altered molecular size and structure of the refractory DOM as well as any iron-binding ligands within our analytical detection limit. Therefore, photodegradation of freshly upwelled iron-binding ligands can fuel iron remineralisation and its binding to labile and highly bioavailable DOM present in surface water. These two processes thus act together to sustain primary producers.
Nutrient Recycling Influences Microbial Communities in the Southern Ocean

Lavenia Ratnarajah¹ (lavenia.ratnarajah@utas.edu.au), Ingrid Obernosterer², Stéphane Blain², Philippe Catala³, Pier van der Merwe¹, Kathrin Wuttig¹, Thomas Holmes¹,³, Manon Tonnard³, Ari Friedlaender⁴, Delphine Lannuzel¹,³, Andrew Bowie¹,³

¹Antarctic Climate & Ecosystems Cooperative Research Centre, Battery Point, Australia, ²Université Pierre et Marie Curie-Paris 6, UMR 7621, CNRS, Banyuls-sur-mer, France, ³Institute for Marine and Antarctic Studies, Battery Point, Australia, ⁴Oregon State University, Newport, United States

Phytoplankton and bacteria are two key components of the biological carbon pump. Autotrophic phytoplankton acts as a sink of carbon dioxide. Comparatively, heterotrophic bacteria act as a source of CO₂ but also convert labile dissolved organic carbon to recalcitrant dissolved organic carbon. The widespread scarcity of the trace element iron has been demonstrated to limit phytoplankton and heterotrophic bacterial growth in large areas of the Southern Ocean resulting in potential competition between these groups to access the available iron fraction. We investigated the response of the autotrophic and heterotrophic microbial communities through incubation experiments with whale faecal additions over a 12-day period in the sub-Antarctic Southern Ocean region, close to Heard Island. The addition of 3 types of whale faecal material to surface seawater resulted in an increase in dissolved iron and organic carbon concentrations while major inorganic nutrients were not enhanced. Our results demonstrated that the addition of whale faecal material stimulated the growth of heterotrophic bacteria and heterotrophic nanoflagellates, but not autotrophic pico-nanoeukaryotes. Similar studies in the region have demonstrated that the growth of heterotrophic bacteria is co-limited by iron and organic carbon. Whale faecal material likely provided the heterotrophic community with organic carbon and iron to rapidly increase in biomass.
Biogeochemical Cycling of Metal Micronutrient Isotopes in the Southern Ocean

Matthias Sieber¹ (matthias.sieber@erdw.ethz.ch), Tim M. Conway¹², Michael Ellwood³, Derek Vance¹
¹ETH Zürich, Institute of Geochemistry and Petrology, Zürich, Switzerland, ²University of South Florida, College of Marine Science & School of Geosciences, St. Petersburg, United States, ³Australian National University, Research School of Earth Sciences, Canberra, Australia

The metal micronutrients iron (Fe), zinc (Zn) and cadmium (Cd) play vital physiological roles in phytoplankton and, ultimately, their distributions control primary productivity and sequestration of carbon by the ocean’s biosphere. Dissolved stable isotope ratios of these bioactive trace metals provide useful information, both for understanding their cycling through the oceans and tracing their influence on phytoplankton ecology. Here, we present water column profiles of dissolved Fe (δ⁵⁶Fe), Zn (δ⁶⁴Zn) and Cd (δ¹¹⁴Cd) isotopes from the Pacific and Atlantic sectors of the Southern Ocean, from the recent Antarctic Circumnavigation Expedition. We compare distributions of dissolved isotopes highlighting differences and similarities between the three metals. South of the Antarctic Polar Front δ⁶⁴Zn and δ¹¹⁴Cd are dominated by upwelling of nutrient-rich deep waters. Zn isotopes show no fractionation despite intense uptake by diatoms in the surface ocean. Cd does show biological uptake of light isotopes. While Southern Ocean surface waters also carry heavy δ⁵⁶Fe, indicating uptake of light Fe by phytoplankton, the difference in fractionation between the three metals points to important differences in metal cycling in this region. Overall, we aim to use this data to better understand how the interaction between ocean biogeochemistry and physical circulation affects regional cycling of these metal micronutrients in the Southern Ocean and how this influences their global distributions.
Thresholds for Antarctic Ice Sheet Retreat and the Paris Climate Agreement

Rob Deconto1 (robdeconto@gmail.com), David Pollard2
1University of Massachusetts, Amherst, Geosciences, Amherst, United States, 2Pennsylvania State University, State College, United States

New ice-sheet modeling, calibrated to past and present changes in sea-level, is painting a stark picture of the future fate of the polar ice sheets if greenhouse gas emissions continue unabated. This is especially true for Antarctica, where a substantial fraction of the ice sheet bed rests far below sea level. Here, we explore the climatic thresholds capable of triggering major ice sheet retreat. We use an ice sheet-climate model that considers changes in mass balance and sub-ice melting, ice deformation, grounding line retreat on reverse-sloped bedrock, and previously omitted glaciological processes including hydrofracturing of ice shelves and structural collapse of thick, marine-terminating ice margins.

The results discussed here suggest that previous estimates of the maximum potential rate of future sea level rise might need to be reconsidered, due to ice loss through mechanical failure in addition to basal sliding and deformation. In high emissions scenarios, we find the potential for ~2m (or more) of sea level rise by 2100. We also find that aggressive mitigation strategies, like those discussed at the Paris Climate Conference, substantially reduce the risk of extreme sea-level rise, but a 3°C temperature rise is still enough to trigger major retreat of the West Antarctic Ice Sheet. Finally, we discuss key uncertainties in constraining climatic thresholds, timing, and rates of major ice-sheet retreat.
Continuous Mega-channels Across the Foundation Ice Stream Grounding Zone

Hafeez Jeofry\textsuperscript{1,2}, Neil Ross\textsuperscript{3}, Anne le Brocq\textsuperscript{4}, Martin Siegert\textsuperscript{1} (m.siegert@imperial.ac.uk)
\textsuperscript{1}Imperial College London, Grantham Institute and Department of Earth Science and Engineering, London, United Kingdom, \textsuperscript{2}University Malaysia Terengganu, School of Marine Science and Environment, Kuala Terengganu, Malaysia, \textsuperscript{3}Newcastle University, School of Geography, Politics and Sociology, Newcastle Upon Tyne, United Kingdom, \textsuperscript{4}University of Exeter, College of Life and Environmental Sciences, Exeter, United Kingdom

There is a scant knowledge on the subglacial geomorphology across the Foundation ice stream. MODIS satellite imagery reveals surface lineations from the ice sheet onto the ice shelf, which are thought to be associated with ice flow. While such channels are thought to be formed by organised flow of basal water from the upstream ice sheet, measurement of discrete channels upstream that would demonstrate the process remains elusive. Using data from various airborne geophysical, we discuss evidence from radio-echo sounding (RES) revealing continuously measured basal channels extending from the Foundation ice stream, across the grounding line and beneath the ice shelf. Within the zone of grounding line ambiguity, a massive channel is observed (~800 m in height). This channel can be seen in numerous RES transects and is manifested at the ice surface as a feature detected by MODIS. These data make it highly likely that basal water from the upstream grounded ice sheet is responsible for the channels. While the grounded channels are too large to be ‘le Brocqian’ bed channels (i.e. the flow of water necessary to maintain one of the channels is equal to the flow of the Amazon), their explanation as sediment-filled channels is challenging to rectify against the known glacial geomorphological record. We discuss that while the channels are undoubtedly associated with basal water, as required to form the ice shelf channels, the nature of the channels across the grounding line is obscure.
Recent observational and modeling studies have shown that the behavior and stability of both Thwaites Glacier and Pine Island Glacier in the Amundsen Sea Embayment of the West Antarctic Ice Sheet are modulated by a combination of ocean forcing, bed topography, and basal conditions. Despite this, little research has focused on characterizing the basal condition context for modeling current and potential interaction across their boundary. This is due, in part, to the fact that modern radar data in this region were collected by three different radar systems and much of the Thwaites / Pine Island boundary lies at the boundary of these data sets. These include the 2004 survey of Thwaites Glacier by the UTIG HiCARS system, the 2004 campaign over Pine Island Glacier by the BAS PASIN system, and the 2011 - 2016 surveys by the CReSIS MCoRDS system.

In addition to this modern data, two transects of airborne radio echo sounding data collected in the early seventies cross the Thwaites Glacier catchment. However, the storage of these data on film have made such comparison at the full radiometric and geometric resolution of the data difficult. To address this challenge, we utilized a state-of-the-art high-resolution film scanning system to digitize the entire SPRI/NSF/TUD archive. Here present results from processing, analyzing, and synthesizing four distinct data sets to characterize basal conditions for modeling and interpretation.
Using Terrestrial Radar Interferometry to Understand Calving Processes

Andrea Walter¹ (andrea.walter@geo.uzh.ch), Martin Lüthi¹, Andreas Vieli¹, Martin Funk²
¹University of Zurich, Geography, Zurich, Switzerland, ²ETH Zurich, Zurich, Switzerland

Recently, many marine-terminating glaciers of the Greenland ice sheet revealed rapid retreat, thinning and flow acceleration. These glaciers lose mass by calving, a process which can change on short timescales. Despite their importance for global sea level rise, major limitations in understanding the dynamics of these glaciers remain. Terrestrial radar interferometry provides displacement and topographical data with a high spatial and temporal resolution. We observed two Greenland outlet glaciers in one minute intervals with a spatial resolution of 5 meters during four multi-day field campaigns in the summers 2014 to 2017. We use these data to establish detailed calving event statistics which are compared to environmental forcing like tides or weather conditions. By identifying source areas and ice volumes of individual calving events we quantitatively investigate the relationship between calving front geometry, calving rate and potential drivers. We find for example substantial differences in calving volume statistics between grounded and floating parts of the glacier front. We further compare the observed calving volumes with data of tsunami waves which were continuously recorded with pressure sensors between 2014 and 2017. The resulting relationship between calving volumes and tsunami waves allows us to establish continuous calving catalogs over four years and investigate calving periodicity.
Here we present the first outcomes of ETHZ’s Sun2Ice project, which aims to use a state-of-the-art, highly-optimized, solar-powered Unmanned Aerial Vehicle (UAV), AtlantikSolar, for long-range, and multi-day monitoring of calving glaciers in the Arctic. The “midnight sun” in polar summer time offers unique conditions for solar-powered flights, including potentially energetically perpetual flight, consequently enabling frequent, high-resolution and large-scale glacier surveys. In Sun2Ice, this cutting-edge technology is dedicated to the monitoring of iceberg calving, a still poorly understood process which plays a major role in the observed retreat of many ocean-terminating glaciers. The main achievement of Sun2Ice’s 2017 fieldwork was the undertaking of the first-ever autonomous, solar-powered flights of a UAV in a polar region, including a flight of more than 12 hours duration, and the survey of the calving front of Bowdoin Glacier, Northwest Greenland. This monitoring revealed the opening of a major crack, which led to a major calving event one week later. This presentation will focus on the technical challenges, the glaciological outcomes, and the potential of using such a technology for monitoring the Cryosphere with a spatial and temporal resolution not achievable by satellite remote sensing.
Modelling the Calving Contribution to Sea Level in Alaska and Greenland

Lizz Ultee¹ (ehultee@umich.edu), Jeremy Bassis¹
¹University of Michigan, Climate & Space Sciences, Ann Arbor, United States

Iceberg calving is an important mass loss process for ocean-terminating glaciers and ice shelves. Where ocean-terminating glaciers drain ice sheets, as at the margins of Greenland, the rate of calving modulates a large potential contribution to global sea level. Parametrizing this process for numerical modelling has been challenging due to the widely varying spatial and temporal scales involved. We have developed a new, physically-consistent model that captures the effect of iceberg calving for the evolution of individual glaciers and their tributaries in both Alaska and Greenland. Here, we apply our model to Jakobshavn Isbrae, Kangerlussuaq Glacier, and Helheim Glacier, showing that we are able to reproduce observed patterns of terminus advance/retreat and upstream thickness change over the past decades. We then apply the model to the 30 ocean-terminating glaciers responsible for the majority of Greenland ice sheet discharge. Using a heuristic upstream forcing—a thinning rate that varies linearly, quadratically, or exponentially—we estimate the dynamic contribution to sea level rise that Greenland can make in the 21st century.
Critical to reducing uncertainty in projections of future sea-level rise is an improved understanding of how the Antarctic ice sheet will evolve in response to current and future climate. We discuss efforts towards simulating Antarctic ice sheet evolution within the U.S. Department of Energy's global, coupled, Energy Exascale Earth System Model (E3SM), which includes variable-resolution, atmosphere, land, ocean, sea ice, and land ice components. Importantly, E3SM includes the ability to simulate ocean circulation within Antarctic ice shelf cavities. Part I of this talk focused on the model configuration and tuning. In part II of this talk, we focus on analysis of global simulations aimed at understanding differences due to:

1. The presence or absence of Antarctic ice shelf cavities in global simulations,
2. Prescribed (CORE) versus fully-coupled atmospheric forcing and,
3. Low (non-eddying ocean) versus high (eddy-permitting ocean) spatial resolution.

Simulation differences and biases are discussed in the context of validation against observations of ocean water mass properties, sea ice extent and thickness, and submarine melt rates. We also discuss short- and longer-term strategies for applying validated, E3SM-derived submarine melt rates towards simulations of Antarctic ice sheet evolution and future sea-level rise.
On Ice-ocean Interaction and Ocean Circulation under the Ross Ice Shelf

Michael Williams¹, Natalie Robinson¹ (natalie.robinson@niwa.co.nz), Craig Stewart¹,², Stefan Jendersie¹,³, Alena Malyarenko¹,³, Michael Brewer¹, Craig Stevens¹,⁴
¹National Institute for Water and Atmospheric Research, Wellington, New Zealand, ²Scott Polar Research Institute, University of Cambridge, Cambridge, United Kingdom, ³University of Otago, Dunedin, New Zealand, ⁴University of Auckland, Auckland, New Zealand

The future fate of the Ross Ice Shelf will likely be determined by the ability of the Ross Sea to melt the ice shelf. The Ross Sea has not yet seen the rise in temperatures or the encroachment of Circumpolar Deep Water experienced in other sectors of Antarctica. However, ablation rates equivalent to several meters a year have been observed for short periods near the front of the Ross Ice Shelf, as part of the significant variability between winter and summer in the ice shelf ablation rates and ocean temperature. The observations highlight inconsistencies in existing parameterisations of ice shelf-ocean interaction, and demonstrate the role warm surface water subducted under the ice shelf has in enhancing ice shelf ablation. An ocean model of the Ross Sea region places the existing observations in an inflow region to the ice shelf cavity, and demonstrates the important role of the Ross Sea polynya in driving seasonal ocean variability both at the ice shelf front and within the cavity. This increased understanding of the cavity oceanography asks more questions than it answers. To better understand these questions a new mooring is planned for near the middle of the Ross Ice Shelf in December 2017. The initial timeseries from this mooring will be important for understanding the dominant time scales of ocean variability within the cavity, and if these can be linked to seasonal drivers outside the cavity or if other processes are at play.
Modelling the Retreat of Pine Island Glacier with Bayesian Networks

Elizabeth D Keller\(^1\) (l.keller@gns.cri.nz), Annemarie Christophersen\(^1\), Nicholas Golledge\(^{1,2}\), Nancy Bertler\(^{1,2}\), Robert McKay\(^2\), Richard Levy\(^1\), Anca Hanea\(^3\)

\(^1\)GNS Science, Lower Hutt, New Zealand, \(^2\)Victoria University of Wellington, Antarctic Research Centre, Wellington, New Zealand, \(^3\)University of Melbourne, Melbourne, Australia

The stability of marine-based sectors of the West Antarctic Ice Sheet (WAIS) under future climate change has important implications for the potential WAIS contribution to sea level rise, yet large uncertainties still exist surrounding the magnitude, rate and timing of change. Here we investigate the potential to use Bayesian Networks (BNs) as an approach to model the retreat of WAIS and to explore the sensitivity of marine-based ice sheets in a changing climate.

BNs are probabilistic, graphical models that provide an elegant way of expressing and visualising the uncertain behaviour of a large number of interrelated variables of a system. They have been applied in hazard and risk assessment as decision support tools and to enhance understanding of complex systems. Current modelling of the Earth’s cryosphere relies on deterministic, process-based models. BNs are a complementary approach that provide a rigorous statistical framework in which to explore the relative sensitivity of climatic and topographic features without the need to model detailed ice dynamics.

We focus initially on Pine Island Glacier (PIG) because it is a relatively well-studied, small outlet glacier over retrograde-sloping bedrock, and is currently undergoing accelerated retreat. We present a prototype BN of PIG, including as variables ocean and air temperature, precipitation, ice velocity and thickness, bed topography, and sea ice, which can be adapted and applied to larger and more complex areas of WAIS.
Future Research Directions in Antarctic Surface Hydrology & Ice-shelf Stability

Jonathan Kingslake¹, Alison Banwell², Robin Bell¹, Alexandra Boghosian¹, Julian Spergel¹, Marco Tedesco¹, Kirsty Tinto¹ (tinto@ldeo.columbia.edu), Luke Trusel³
¹Lamont-Doherty Earth Observatory Columbia University, Palisades, United States, ²Cambridge University, Cambridge, United Kingdom, ³Rowan University, Glassboro, United States

We will present recent progress and future research directions in the growing field of Antarctic surface hydrology, with a focus on how surface hydrology could affect the stability of Antarctic ice shelves. We will report the outcomes of a scientific workshop on these topics held in February 2018 and funded by the US National Science Foundation (NSF).

It is widely hypothesized that static meltwater ponds can expedite iceberg calving by flowing into and enlarging fractures and trigger ice-shelf disintegration via stresses generated by melt ponds. When ice shelves collapse, the adjacent grounded ice accelerates and thins, contributing to sea-level rise.

The flow of water across the surface of Antarctica is also increasingly recognized as important. This phenomenon is more widespread than previously assumed and melting is predicted to increase significantly this century. Without considering water flow explicitly, the latest ice-sheet models respond dramatically to increased ice-shelf melting, predicting up to 1 m of sea-level contribution from Antarctica this century.

Our current knowledge of the present state and controlling dynamics of the Antarctic surface hydrological system is poor. Drawing from the outcomes of the NSF workshop, we will summarize present knowledge and look ahead to the key questions, most important for predicting the role Antarctic surface hydrology will play in the ice sheet’s future.
Water on the Antarctic Ice Sheet: Mapping Supraglacial Lake Depth and Volume

Allen Pope¹ (allen.pope@nsidc.org), Mahsa Moussavi¹, Luke Trusel²
¹National Snow and Ice Data Center, Boulder, United States, ²Rowan University, Glassboro, United States

Though Antarctica is Earth's coldest continent, surface melting is widespread across its ice perimeter. Melt plays an integral role in modulating Antarctic sea level contributions via its influence on ice shelf stability and grounding line retreat. Despite their glaciological significance, there has been no systematic study of Antarctic lake occurrence either spatially or temporally. Here, we begin to answer the questions: When and where do supraglacial lakes form in Antarctica? And how much water is stored in these lakes? Put simply, supraglacial lakes are identified by how blue they are and so multispectral data are needed. While many studies in Greenland have used MODIS sensors to track supraglacial lakes, Antarctic lakes have been shown in one comparative study to be smaller and shallower than their Greenlandic counterparts. Accordingly, the workhorses of this study will be the higher resolution Landsat series, complemented by Sentinel-2, and augmented by MODIS. After lake identification, a physically-based (and open source) lake depth retrieval will be used to calculate lake volume. The combination of these sensors will allow us to track supraglacial lake distribution and volume in Antarctica over 30+ years, yielding an unprecedented understanding of lake behavior in Antarctica. First, however, this presentation will show progress toward this goal by beginning with various case study areas around the perimeter of Antarctica.
We predict the location of perennial firn aquifers (PFAs) in Antarctica using the updated regional atmospheric climate model RACMO2.3p2, that is specifically adapted for use over the polar regions. With RACMO2 output we force two firn models, IMAU-FDM and SNOWPACK, that explicitly calculate processes in the snowpack, such as densification, meltwater penetration, refreezing, retention and runoff.

In this presentation, we primarily focus on the Antarctic Peninsula (AP), where conditions are favorable for the formation of PFAs: there is both sufficient meltwater production and snowfall to store the meltwater in the firn during winter without refreezing, as the fresh snow insulates the meltwater from the winter cold wave. These conditions are similar to those locations where PFAs were discovered in Greenland and Svalbard. The firn models predict the formation of PFAs on Wilkins ice shelf and on the northwestern mountain slopes of the AP. Using observations obtained with, amongst others, satellite C-band scatterometry, we evaluate the robustness of these findings. In addition, we try to better understand processes controlling PFA formation, longevity and extent in Antarctica, which clearly differ from Greenland and Svalbard. In Antarctica, we distinguish multiple types of PFAs: long living (>20 years) PFAs, PFAs that frequently disappear and reform and PFAs that are only maintained during individual winters. Finally, we try to locate PFAs elsewhere in Antarctica.
The rapid decline in Arctic sea ice extent, age and thickness is well documented, with such changes due to
cause far-reaching impacts. At present unknowns remain about the nature of the spatiotemporal Arctic sea ice
fluctuations of the Holocene preceding satellite observation, limiting the extrapolation of modern trends to
predictions of future change. Driftwood can be used as a novel and robust proxy for sea-ice reconstructions in
the Arctic, with driftwood transport and deposition determined by sea ice and surface current dynamics. The
collation of driftwood samples from across the western Arctic with spatiotemporal distribution and available
provenance data has enabled the production of a high-resolution proxy-based reconstruction of Holocene
Arctic Ocean surface current and sea ice dynamics. To further constrain this spatiotemporal reconstruction,
isotopic analysis of driftwood using Strontium $^{87}$Sr/$^{86}$Sr radiogenic isotope ratios combined with a framework
of potential source Strontium signatures enables a spatial link between the deposited driftwood and its
originating growth site, leading to a robust reconstruction of the wood-bearing sea ice dynamics. Combined
with links between ice movement with the expansion and contraction of the Arctic Ocean circulations of the
Beaufort Gyre and Transpolar Drift, the method enables a proxy-based reconstruction of Arctic sea ice and
broader climatic states throughout the Holocene.
Arctic Sea Ice Export during the Globally Warm Pliocene

Stijn De Schepper¹,² (stijn.deschepper@uni.no), Caroline Clotten¹,², Kirsten Fahl³, Stein Ruediger³,⁴
¹Bjerknes Centre for Climate Research, Bergen, Norway, ²Uni Research Climate, Bergen, Norway, ³Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, ⁴University of Bremen, Department of Geosciences, Bremen, Germany

Sea ice is an important component in Arctic and global climate, but there is limited knowledge about Arctic sea ice extent and export throughout the geological past. Today, the East Greenland Current (EGC) is the main exporter of sea ice into the Atlantic, yet its behavior in the Pliocene globally warm climate is poorly documented. We reconstructed the EGC and sea ice variability in the Iceland and Labrador seas during the Pliocene (~5-2.4 million years ago) using the sea ice proxy IP25, paleoproductivity biomarkers, alkenone-based sea surface temperatures and dinoflagellate cysts. Our results show that sea ice first appeared in the Iceland Sea around 4.5 million years ago when a proto-EGC developed. A more modern-like Nordic Seas circulation developed around 4.0 Ma, when our data indicate a seasonal sea ice cover in the Fram Strait and Iceland Sea. In the Late Pliocene, prior to 3.0 Ma, a relatively weak EGC likely caused the frequent occurrence of seasonal sea ice in the Iceland Sea, while sea ice rarely occurred in the Labrador Sea. After 3.0 Ma, when global climate cooled, a stronger EGC established a sea ice edge close to Greenland resulting in limited sea ice presence in the Iceland Sea, whereas the Labrador Sea more frequently received sea ice. The changes in sea ice regime are likely driven by oceanographic changes and may have played a role in the gradual expansion of the Greenland Ice Sheet from the Early to Late Pliocene.
Past Sea Ice Variability Derived from Ice Cores: The Bromine Approach

Andrea Spolaor¹ (andrea.spolaor@unive.it), Niccolò Maffezzoli², Paul Valdelonga³, Alfonso Saiz-Lopez³, Francois Burgay⁴, Claudio Scarchilli⁵, Clara Turetta¹, Federico Scoto⁴, Carlo Barbante¹,²
¹Consiglio Nazionale delle Ricerche, Institute for the Dynamics of Environmental Processes, Venice, Italy, ²Niels Bohr Institute, Centre for Ice and Climate, Copenhagen, Denmark, ³Consejo Superior de Investigaciones Científicas, Institute of Physical Chemistry Rocasolano, Madrid, Spain, ⁴Ca Foscari University of Venice, Venice, Italy, ⁵ENEA, Rome, Italy

Sea ice is a crucial parameter in the climate system, and it is declining at a faster rate than models predicted. Bromine plays a central role in sea ice chemistry, from where it is released as BrO during springtime, enriching its abundance in the polar atmosphere. Therefore, bromine enrichment in snow, with respect to the sodium ratio in seawater, can be linked to first year sea ice variability at the Poles. Measurements of Bromine enrichment (Brₑₚₑ) have been carried out in Greenland (NEEM and Renland ice cores), Svalbard, Severnaya Zemlya and Antarctica (Talos Dome, Law Dome and Dome C). These climate ice archives investigated, cover both the satellite era and the older climate periods back to the last glaciation. The results obtained from deep drilling in the Arctic suggest that during the Holocene climate optimum (9-10 ky BP) in summer time open water was present in the Canadian Arctic, whilst multi-year sea ice was present during the last glaciation, with rapid interstadial periods able to change the sea ice structure. The Antarctic results (except Talos Dome) were mainly focussed on covering the last 200 years, the Talos Dome ice core covered back to the previous glaciation (150 ky BP). The results obtained from the Law Dome and Dome C ice cores, support the idea that Br enrichment can also be used in Antarctica and suggests that the variability of sea ice, especially in the Indian sector, might be explained by the changes in the SAM (Southern annular mode).
Today the Bering Sea is characterized by high primary productivity along the eastern shelf, maintained by CO₂ and nutrient rich upwelled deep waters and nutrient release during spring sea ice melting. As such, low oxygen concentrations are pervasive in mid-depth waters. On glacial/interglacial (G/IG) timescales sea ice formation plays a pivotal role on intermediate water ventilation with evidence pointing to the formation of North Pacific Intermediate Water (NPIW) in the Bering Sea during late Pleistocene glacial intervals. Additionally, sea ice plays a significant role in both long- and short-term climate change via associated feedback mechanisms. Here we use a multi-proxy approach to study sea ice and bottom water dynamics, across three intervals prior to, across, and after the Mid-Pleistocene Transition (MPT, 1.2-0.7 Ma) from International Ocean Discovery Program Site U1343. The biomarker-based sea ice record shows substantial increase in sea ice extent across the MPT and the occurrence of a late-glacial/deglacial sea ice spike, with potential consequences for land glacier retreat via the temperature-precipitation feedback. U/Mn of foraminiferal authigenic coatings is used to reconstruct sedimentary redox conditions, a factor of export productivity and bottom water oxygenation. This aids to elucidate the interactions of sea ice with biogeochemical cycling and NPIW formation on G/IG timescales, with potential implications for the North Pacific carbon cycle.
Arctic Ice Sheets and Sea Ice Extent during MIS 6/MIS 5: A Biomarker Perspective

Ruediger Stein¹,² (ruediger.stein@awi.de), Anne Kremer¹, Kirsten Fahl³, Frank Niessen¹
¹Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Geosciences, Bremerhaven, Germany, ²University of Bremen, MARUM & Faculty of Geosciences, Bremen, Germany

The Quaternary glacial history of the Arctic Ocean is characterized by the repeated build-up and decay of circum-Arctic ice sheets on the continental shelves and related changes in ocean-circulation patterns and sea ice cover. Here, we present new biomarker records that give insights into the interactions between the Eurasian-Siberian ice sheets, sea ice extent and Atlantic water inflow during the Penultimate Glacial Maximum (Marine Isotope Stage (MIS) 6) to Last Interglacial (MIS 5e) transition. Along the Svalbard and northern Barents Sea continental margin, the MIS 6 ice sheet and sea ice conditions might have been similar to those of the LGM. An extended Barents Sea Ice Sheet had reached the shelf edge causing polynya-like open-water conditions (triggered by strong katabatic winds) with phytoplankton and sea ice algae production, and the deposition of suspended (terrigenous) material along the slope, as reflected in the biomarkers from this area. Furthermore, the seasonally open-water conditions along the Barents Sea continental margin might have been fostered by the inflow of Atlantic Water. Biomarker records from the southern Lomonosov Ridge area close to the Siberian continental margin support an extended (MIS 6?) East Siberian Chukchi Ice Sheet, with strong katabatic winds and polynya-like open-water conditions in front of the ice sheet. Such a scenario would clearly contradict the hypothesis of a MIS 6 ice shelf covering the entire Arctic Ocean.
Environmental ancient DNA (aDNA) as a tool in paleoceanographic studies is still in its infancy and its potential for sea ice reconstructions is promising but not yet fully explored. To document the sea ice history of the Greenland Sea, we characterized a sediment core using metabarcoding of aDNA, dinoflagellate cyst assemblages and the sea ice biomarker IP25, to determine how plankton dynamics preserved in aDNA corresponds to established proxies for sea ice reconstructions. We extracted total DNA and performed metabarcoding analysis of the V7 hypervariable region of the eukaryotic small subunit ribosomal RNA gene (SSU rRNA) on nine sediment samples ranging in age from modern to ~100,000 years ago. The aDNA sequences in one sample dated ~34 ka were unique in the study interval with nearly-absent diatoms and a dominance of dinoflagellates, cercozoans and unclassified sequences. Notably, we observed a high relative abundance of sequence reads resembling the sea ice-associated dinoflagellate Polarella glacialis in this sample. Together with a dinoflagellate cyst assemblage dominated by the sea-ice-associated genus Islandinium and a clear signal in IP25, this indicates a likely seasonal sea ice cover. Our preliminary aDNA work thus demonstrates (1) the presence of amplifiable aDNA back to ~100,000 years ago in the Greenland Sea and (2) the potential for aDNA to complement traditional microfossil analyses in order to strengthen estimates of past seasonal sea ice cover.
Aerosol Microphysical Effects on Cloud Fraction over the Nighttime Arctic Ocean

Lauren Zamora1,2 (lauren.m.zamora@nasa.gov), Ralph Kahn3, Sabine Eckhardt4, Andreas Stohl4

1ESSIC, Univ. of Maryland, College Park, United States, 2NASA Goddard Space Flight Center, Greenbelt, United States, 3NASA Goddard Space Flight Center, College Park, United States, 4NILU – Norwegian Institute for Air Research, Kjeller, Norway

Cloud fraction is a key component affecting the surface energy balance in the Arctic. Aerosol microphysical processes can affect cloud fraction, for example through cloud lifetime effects. However, the importance of aerosol impacts on cloud fraction is not well constrained on a regional scale at high latitudes. Here a new method is presented for identifying and comparing clean and aerosol-influenced cloud characteristics using a combination of multi-year remote sensing data (CALIPSO, CloudSat) and the FLEXPART aerosol model. This method is used to investigate a variety of aerosol microphysical impacts on nighttime Arctic Ocean clouds on regional and local scales. During the polar night study period, aerosols were associated with noticeable regional cloud fraction differences, suggesting possibly significant changes in longwave cloud radiative effects at the Arctic Ocean surface. We present evidence for combustion aerosols acting as ice nucleating particles at the cold temperatures of high altitude (>4 km) Arctic ice clouds. Potential mechanisms for aerosol-driven microphysical changes on cloud fraction within lower altitude clouds will also be discussed.
The water cycle in the dry and cold Arctic is not well understood, yet it is by far the dominant factor controlling polar climate with strong implications on the midlatitude weather. Optically thin ice clouds (TIC) processes are still poorly represented in atmospheric models. Furthermore, it is now recognized that anthropogenic aerosol can alter cloud microphysics and precipitation. These ubiquitous clouds, sensitive to aerosols via ice nucleation, can significantly modulate the amount of far infrared radiation escaping the Earth, and consequently the temperatures in the upper troposphere, and occasionally in the UTLS region. Since TIC signature in the far infrared is also very sensitive to their microphysical properties (crystals size and shape) and optical depth, these quantities can be retrieved from ground-based and satellite observations. Theoretical calculations demonstrate that the far infrared spectrum of the atmosphere could provide valuable information for weather forecast data assimilation and climate simulations, about its water vapour content, the microphysical characteristics of ice clouds and common light precipitation, especially in dry and cold regions. In the context of YOPP, with the Canadian Space Agency and in collaboration with NETCARE, PAHA and AVATAR, we have initiated new measurements in the mid and far IR range (8-50µm) to advance our knowledge of the water cycle in the High Arctic with the deployment of the Far IR Radiometer (FIRR).
Satellite Observations of Summer Arctic Sea Fog

King-Fai Li1,2 (king-fai.li@ucr.edu), Li Yi3, Xianyao Chen4,5, Ka-Kit Tung2
1University of California, Riverside, Environmental Sciences, Riverside, United States, 2University of Washington, Applied Mathematics, Seattle, United States, 3Ocean University of China, College of Oceanic and Atmospheric Sciences, Qingdao, China, 4Ocean University of China, Physical Oceanography Laboratory/CIMST, Qingdao, China, 5Qingdao National Laboratory of Marine Science and Technology, Qingdao, China

Under global warming, the rapid increase in open water surface area resulting from sea ice melting may lead to an increase in fog (here defined as any cloud with a base height below 1000 ft), which may imperil ship and air transportation in the region. There is a need for real-time monitoring of fog formation over the Arctic. Given that ground-based observations of fog over Arctic open water are sparse, satellite observations are currently the most effective way for real-time monitoring. We developed a fog detection algorithm using the temperature difference between the cloud top and the surface, called $\partial T$ in this work. A fog event is said to be detected if $\partial T$ is greater than a threshold, which is typically between $-6^\circ C$ and $-10^\circ C$, depending on the time of the day (day or night) and the surface types (open water or sea ice). As a test, we apply this method to the coastal regions of Chukchi Sea and Beaufort Sea near Barrow, Alaska. We showed that the $\partial T$ method can detect Arctic fog with an optimal probability of detection (POD) of 77–84% and false alarm rate (FAR) of 13–19%. The feasibility of the $\partial T$ method, however, critically relies on the accuracy of the physical quantities (such as the cloud-top height) determined from the same infrared measurements.
Interactions Between Arctic Clouds, Sea Ice, and Lower Tropospheric Stability

Patrick Taylor¹ (patrick.c.taylor@nasa.gov)
²NASA Langley Research Center, Climate Science Branch, Hampton, United States

Arctic low clouds strongly affect the Arctic surface energy budget and through this impact influence the rest of the Arctic climate system: namely surface and atmospheric temperature, sea ice extent and thickness, and the atmospheric circulation. Arctic clouds are in turn influenced by the Arctic climate system creating the potential for cloud-climate feedbacks. We quantify the influence of atmospheric state on the surface cloud radiative effect (CRE) and the covariability between surface CRE and sea ice concentration (SIC) using instantaneous, active remote sensing satellite footprint data from the NASA A-Train. First, the results indicate significant differences in the surface CRE when stratified by atmospheric state. Second, a statistically insignificant covariability is found between CRE and SIC for most atmospheric states. Third, we find a statistically significant increase in the surface longwave CRE with decreased SIC in fall. Specifically, a +3-5 W m⁻² larger longwave CRE is found over footprints with 0% versus 100% SIC. Because systematic changes of 1 W m⁻² are sufficient to explain the observed reductions in Arctic sea ice, our results (1) indicate a potentially significant amplifying sea ice-cloud feedback that could delay fall freeze-up influencing sea ice variability under certain atmospheric conditions and (2) suggest that a small change in the frequency of atmosphere states may yield a larger Arctic cloud-climate feedback than any cloud response to sea ice.
Antarctic Cloud Microphysics using the DARDAR Synergetic Satellite Products

Constantino Listowski1 (constantino.listowski@latmos.ipsl.fr), Julien Delanoë1, Tom Lachlan-Cope2
1LATMOS, Guyancourt, France, 2BAS, Cambridge, United Kingdom

In Antarctica, surface radiation biases of several tens of watt per square meters are calculated in mesoscale high-resolution models, which point to major problems in the simulation of the cloud phase. Antarctic clouds need to be correctly represented in both regional and global atmospheric models, to improve daily operational forecast as well as for future global climate predictions. Indeed Antarctic cloud microphysics affect lower latitudes too via their impact on the North-South temperature gradient. Because of the inaccessibility of most Antarctica to in-situ cloud science, observations are sparse, and satellite observations appear as a welcome if not crucial complement.

DARDAR satellite products were developed in order to take advantage of both radar (CloudSat/CPR) and lidar (CALIPSO/CALIOP) measurements which are used seamlessly to retrieve cloud properties at a horizontal resolution of 1.7x1.4 km and a vertical resolution of 60 m. We will present results of the analysis of Antarctic cloud thermodynamic phase using the DARDAR products over the period 2007-2010, at the continental and regional scales, paying close attention to the supercooled liquid phase. So far unreported links between Antarctic clouds and the Southern Annular Mode over different regions, and the atmosphere dynamics continent-wide, will be also highlighted.

Acknowledgement: CL acknowledges the post-doctoral funding from CNES.
Vertical Distribution of Aerosol Properties in the Spitsbergen Region

David Cappelletti\textsuperscript{1} (david.cappelletti@unipg.it), Mauro Mazzola\textsuperscript{2}, Beatrice Moroni\textsuperscript{1}, Justyna Lisok\textsuperscript{3}, Kris Markowicz\textsuperscript{3}, Luca Ferrero\textsuperscript{4}, Marion Maturilli\textsuperscript{5}, Silvia Becagli\textsuperscript{6}, Traversi Rita\textsuperscript{6}, Angelo Lupi\textsuperscript{2}, Chiara Petroselli\textsuperscript{1}, Christoph Ritter\textsuperscript{6}, Christine Boeckmann\textsuperscript{7}, Angelo Viola\textsuperscript{2}, Vitale Vitale\textsuperscript{2}

\textsuperscript{1}University of Perugia, Perugia, Italy, \textsuperscript{2}CNR - ISAC - National Research Council, Bologna, Italy, \textsuperscript{3}University of Warsaw, Institute of Geophysics, Warsaw, Poland, \textsuperscript{4}University of Milano-Bicocca, Milano, Italy, \textsuperscript{5}AWI - Alfred Wegener Institute for Polar and Marine Research, Potsdam, Germany, \textsuperscript{6}University of Florence, Florence, Italy, \textsuperscript{7}University of Potsdam, Potsdam, Germany, \textsuperscript{8}CNR - ISAC - National Research Council, Roma, Italy

Primary objective of this long-term research activity is to build a climatology of aerosol vertical profiles in and above the Arctic Boundary Layer. To this aim since 2011 an international research team has performed yearly field campaigns at the Ny Alesund super-site thanks the support of the Italian CNR Arctic station Dirigibile Italia and German AWI Koldway station. Making use various aerosol payloads and tethered balloons systems (TBS) up to date about 500 aerosol profiles have been regularly recorded in the first 2 km, providing detailed information on black carbon concentration, aerosol size distribution, aerosol scattering coefficients and chemical composition. Seasonal trends have been obtained for spring, summer and autumn. Case studies will be highlighted describing the impact of ship emissions, Arctic haze and new particle formation events on the vertical aerosol structure. In situ TBS activities have been often accompanied by parallel lidar profiling and a closure study of aerosol microphysical property retrieval is in progress based on this data and also on a full chemical aerosol characterization both at bulk level on filter samples and on single particles by scanning electron microscopy.

Adv. in Meteorology, Article ID 292081 (2016)
Some of the largest changes due to warming climate have occurred in the Arctic. Historical reconstructions from Earth System Models (ESMs) are in broad agreement with these changes, except for the modeled rates of change, which generally remain outpaced by observations. Such limitations imply a limited skill in ESM projections of future Arctic System states and are likely due to a combination of coarse model resolution, inadequate parameterizations of sub-grid processes, and a limited knowledge of physical interactions. One of the least understood limitations are processes controlling ocean-ice-atmosphere surface momentum and energy transfer.

We demonstrate the capability of the Regional Arctic System Model (RASM) in addressing some of the ESM limitations in simulating observed variability and trends in arctic surface climate. RASM is an example of limited-area, process-resolving, fully coupled ESM. Due to the constraints from boundary conditions it facilitates detailed comparisons with observational statistics that are not possible with ESMs. This talk will emphasize the need for fully coupled climate model simulations, high model resolution and fine-tuning of scale-aware parameterizations of sub-grid physical processes. In support, selected RASM results will be presented on physical processes and resulting feedbacks controlling seasonal cycle and variability of the Arctic ocean-ice-atmosphere boundary layer.
Multidisciplinary Drifting Observatory for the Study of Arctic Climate

Markus Rex¹ (markus.rex@awi.de), Matthew Shupe², Klaus Dethloff¹, Anja Sommerfeld¹

MOSAiC is an international initiative under the umbrella of IASC, designed by an international consortium of leading polar research institutes.
Rapid changes in the Arctic lead to an urgent need for reliable information about the state and evolution of the Arctic climate system. This requires more observations and improved modeling over various spatial and temporal scales, and across a wide variety of disciplines. Observations of many critical parameters have, to date, not been carried out in the central Arctic for a full annual cycle.
MOSAiC will be the first year-around expedition into the central Arctic exploring the coupled climate system. During 2019 to 2020 the research vessel Polarstern will drift with the sea ice from the Siberian Sector of the Arctic across the polar cap towards the Fram Strait.
The focus of MOSAiC is based on a constellation of in-situ observations of the climate processes that couple atmosphere, ocean, sea ice, biogeochemistry and ecosystem. These measurements will be supported by weather and sea ice predictions, and remote sensing operations to aid implementation and extend the observational results in time and space. The project includes coordinated aircraft campaigns and expeditions by icebreakers from MOSAiC partners. All observations will support the main scientific goals of MOSAiC: Enhancing the understanding of the regional and global consequences of Arctic climate change and sea ice loss, and improving weather and climate prediction.
Improving Forecasts of Air-ice-Ocean Interactions in the MIZ during Autumn 2015

Amy Solomon¹ (amy.solomon@noaa.gov), Antonietta Capotondi³, Janet Intrieri², Ola Persson¹
¹University of Colorado, Boulder, United States, ²NOAA, Boulder, United States

The United States Office of Naval Research SeaState campaign took place on the ice breaker R/V Sikuliaq Sept 28-Nov 10 2015 in the Beaufort Sea. This field program was designed specifically to understand the effects of an increasingly dynamic sea state on autumn ice recovery. Comprehensive air-ice-ocean measurements were taken during the campaign to quantify the coupled mechanisms responsible for fluxes at the air-ice/ocean-ice interfaces.

During Oct 9-15 2015, it was observed that pancake ice in the marginal ice zone unexpectedly retreated. This was unexpected because surface measurements indicated water at the freezing point and a loss of heat to the atmosphere, demonstrating that processes other than atmospheric fluxes were responsible for the retreating ice edge.

This modeling study investigates the relative roles of ocean mixing and ice advection in reversing the observed seasonal ice advance during Oct 9-15 2015, and the ability of state-of-the-art forecast models to simulate the observed retreat, with a hierarchy of ocean models (i.e., with and without ocean dynamics) at this time period and location.

Of specific interest is the role of the Pacific intermediate water and the initial ocean conditions required to simulate the observed variability. Results from experiments varying initial ocean conditions will be presented to identify potential model biases and strategies to improve the coupled model forecasts.
The Arctic region has suffered a transformation in the past decades that will very likely continue in the future. Since the late 1970s, declining trends in pan-Arctic sea ice extent and volume, and increasing trends in air and sea surface temperature have been observed. However, the region has a large natural climate variability that can usually be mistaken for a long-term forced response. Furthermore, this natural Arctic variability has been linked to mid-latitude weather extremes in the northern hemisphere, both as a cause and as a response. Disentangling natural variability and forced response is of critical importance from a climate change perspective.

Using observational evidence and advanced statistical methods (K-mean clustering), we studied natural modes of variability in key Arctic climate variables (i.e. sea ice concentration, sea surface and near surface air temperature). The main objective was to identify spatio-temporal coherence in the series and lag-lead correlations between variables after detrending them.

Sea ice concentrations show three main modes of variability, as previously found. Both atmospheric near surface temperature and sea surface temperatures can individually affect sea ice and partly explain some regional patterns of natural variability on seasonal timescales. Pan-arctic sea ice extent shows a delayed response of 1-3 months to near surface air temperature and about a year to sea surface temperature variations.
Satellite-derived Sea Ice Export and its Impact on Arctic Ice Mass Balance

Robert Ricker¹ (robert.ricker@awi.de), Fanny Girard-Ardhuin², Thomas Krumpen¹, Camille Lique²
¹Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany, ²Ifremer, Brest, France

Sea ice volume export is affecting the Arctic ice mass balance, and certainly the multiyear ice volume variability. Climate relevance is also given by the significant fresh water input into the North Atlantic, affecting the thermohaline circulation. The Fram Strait represents the main sea ice export gate in the Arctic. Here, we present the first estimates of winter sea ice volume export through the Fram Strait using CryoSat-2 sea ice thickness retrievals and three different ice drift products for the period 2010-2017. The export rates vary between 20 km³ and 550 km³ per month. We find that sea ice drift is the main driver of seasonal and interannual ice volume export variability. Moreover, 79 % of the interannual variability can be explained by the relation to the North Atlantic Oscillation index (NAO). The seasonal trend, however, is driven by the mean ice thickness, associated with the thermodynamic ice growth, which is typically peaking in March. Considering Arctic winter multiyear ice volume changes, 50 % of the seasonal variability can be explained by the ice volume export through the Fram Strait.
Contrasting Antarctic and Arctic Atmospheric Responses to Projected Sea Ice Loss

Mark England¹ (mre2126@columbia.edu), Lorenzo Polvani¹,², Lantao Sun³
¹Columbia University, Applied Physics and Applied Mathematics, New York, United States, ²Lamont-Doherty Earth Observatory of Columbia University, New York, United States, ³NOAA, Boulder, United States

By the end of this century, annually-averaged Antarctic sea ice area is projected to decline by an amount comparable to the one in the Arctic. However, the impact of future Antarctic sea ice loss is largely an open question, having received very little attention to date. Here, the atmospheric response to future sea ice loss in the Antarctic is investigated, and contrasted to the Arctic case, using the Community Earth Systems Model Whole Atmosphere Coupled Climate Model (WACCM). Comparing time-slice model runs with historic sea ice concentrations to runs with sea ice in each hemisphere reduced to values representative of the late 21st-century (from a high CO2 emission scenario) allows us to disentangle the effect of future sea ice loss on the atmosphere from other aspects of the coupled system. It is found that both Antarctic and Arctic sea ice loss act to shift the tropospheric jet equatorward, acting as an internal negative feedback to the net poleward shift associated with increased greenhouse gases. Furthermore, the atmospheric response to Antarctic sea ice loss is found to be of slightly smaller amplitude, more vertically confined, and less seasonally varying than in the case of Arctic sea ice loss. Finally, our model shows that the surface temperature response to Antarctic sea ice loss is unable to penetrate the Antarctic continent, suggesting that the sea ice increases of recent decades cannot explain the observed lack of warming over much of the Antarctic continent.

Dynamics of Peat Frontiers in the Arctic and Antarctic under a Warming Climate

Zicheng Yu1 (ziy2@lehigh.edu), Kathleen Cleary1, Julie Loisel2, David Beilman3, Charly Massa1, Jonathan Stelling1
1Lehigh University, Bethlehem, United States, 2Texas A&M University, College Station, United States, 3University of Hawaii, Honolulu, United States

Amplified climate warming in the Arctic and Antarctic Peninsula in recent decades has caused a multitude of changes, including ice/snow reduction, permafrost soil thaw, and vegetation greening. Peat-forming ecosystems are "hotspots" of long-term carbon (C) sequestration in the high northern latitude region during the Holocene. However, we don't know if peat-forming ecosystems are expanding under a warming climate and whether they contribute significantly to regional C balance. Here we use some case studies from the North Slope of Alaska and from the Antarctic Peninsula to show potential peat expansion in both polar regions. In Arctic Alaska, we found that shallow “peat patches” (typically dominated by peat moss Sphagnum)—that may represent the initial stage of peatland formation—are distributed across some tundra landscapes. Our results from 6 soil cores indicate the onset of rapidly-accumulating Sphagnum peat at ~1930 AD, likely responding to regional climate warming directly or indirectly through permafrost dynamics. In the Antarctic Peninsula, we found rapid increase in C accumulation rates in recent decades from peat cores collected from aerobic moss-dominated peatbanks. Furthermore, we observed the re-appearance of waterlogged peatlands responding to rapid warming climate. The possible transformation of polar landscapes to more peat-forming ecosystems has implications for a sustained C sink, impacting the regional and global C balance over decadal or century timescales.
Linking C Sequestration Service and High Arctic Ecosystem Multi-functionality

Patrick Saccone¹, Alexandra Bernardová², Michala Bryndová², Francesco de Bello²,³, Miloslav Devetter²,⁴, Tomáš Hájek², Ladislav Háněl⁴, Veronika Jilková⁴, Petr Kotas², Jana Macková⁴, Petra Polická⁴, Josef Starý⁴, Petr Macek⁵ (maca@prf.jcu.cz)

¹Faculty of Science, University of South Bohemia, Centre for Polar Ecology, České Budějovice, Czech Republic, ²Faculty of Science, University of South Bohemia, České Budějovice, Czech Republic, ³Institute of Botany, Czech Academy of Sciences, Trebon, Czech Republic, ⁴Institute of Soil Biology, Biology Centre, Czech Academy of Sciences, České Budějovice, Czech Republic, ⁵Faculty of Science, University of South Bohemia, Centre for Polar Ecology, České Budějovice, Czech Republic

The mechanistic response of Arctic terrestrial ecosystems to ongoing climate changes is the key of carbon (C) sink status of the soil. The assessment of the sustainability of Arctic soils C sequestration service requires deeper understanding of the ecological mechanisms leading to C accumulation in the soil. We explored the links among plants, soil invertebrate and microbial communities, and the C biogeochemical cycle along environmental gradients in different valleys of central Svalbard. This multifunctional approach integrates the holistic aspect of the ecosystem structure and aims at stressing the association of ecosystem service resilience with the functional links among the compartments. We sampled (1) plant composition, abundance, above and belowground traits, (2) soil invertebrate composition, abundance and feeding traits, (3) soil microbial communities functional composition and activity; and (4) soil C organic and inorganic contents.

Our preliminary analyses showed functional clustering across the compartments and also different levels of sensitivity to environmental gradient depending upon the compartments. Analyses need to be deepen and complete with manipulative experiments to disentangle the mechanisms but our results already illustrate a breakthrough in functional ecology with an explicit consideration of multitrophic functionality.
Until recently the scientific literature has seen an abundance of papers describing the “greening” of the Arctic; from a remote sensing perspective this has meant an increase in the Normalized Difference Vegetation Index (NDVI), or a similar satellite-based index. More recently, there have been more widespread observations of tundra “browning.” Here, we use a circumpolar remote sensing dataset to evaluate the spatio-temporal patterns of arctic tundra vegetation dynamics (greening and browning), and its control by summer warmth, at the circumpolar, continental (North America, Eurasia), and tundra subzonal (i.e. latitude) scales over the past 35 years. Significant warming trends, significant greening trends, and significant inter-annual relationships between NDVI and summer warmth were not spatio-temporally consistent. Significant warming trends tended to occur further north, whereas significant greening trends tended to occur more in the southern tundra. Some significant browning trends were observed in the northern tundra subzones. Significant relationships between NDVI and SWI were more likely found in the middle tundra latitudes. Over the satellite record, the number of years of greening was similar to the number of years of browning, with the exception of the most southern tundra subzone (Subzone E). The spatio-temporal dynamics of tundra vegetation and the controls on greening and browning appear to be highly complex and in need of continued study.
Spatial Redictions of Essential Biodiversity Variables: A Bird Perspective

Nasrin Amini Tehrani\(^1\) (nasrin.aminitehrani@unil.com)
\(^1\)University of Lausanne, Geoscience and Environment Institute of Earth and Dynamic, Lausanne, Switzerland

With increasing human pressure on biodiversity, populations of sensitive species become more isolated and decrease in size as their suitable habitats become fragmented and degraded. In this context, landscape composition, especially the arrangement of mountain is often key for population persistence and biodiversity conservation. Monitoring how landscape changes affect biodiversity should be a central component of landscape planning. Biodiversity includes too many dimensions, so defining which of them are essential is key to successful monitoring. For this reason, the concept of essential biodiversity variables (EBV) was defined, with the intent to identify key elements to monitor. One way to derive EBVs spatially may be through the use of species distribution models (SDM) based on quantification of species' habitat suitability, and use them to support planning and decision-making over large areas. One can further use stacked species distribution modelling (S-SDM) of constituent species to approximate the properties of assemblages. S-SDM outputs can then be used to predict various EBVs spatially. We aim to develop and test new approaches based on SDMs, to build spatial predictions of EBVs for birds in a mountain area of the Swiss Alps. We first study the power of different environmental and geographical factors for building S-SDM predictions, then we use these to derive bird EBVs as support to biodiversity management and help identifying priority bird conservation areas.
Climate Warming Accelerates Increase in Plant Species Richness on Alpine Summits

Christian Rixen¹ (rixen@slf.ch), Sonja Wipf¹
¹WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland

Species climate envelope models predict that a large proportion of Europe's alpine flora is threatened by local extinction in a warmer climate, as stronger competitors move to higher altitudes and might out-compete cold climate specialists.

We study how the species composition in the Arctic and Alpine, particularly on mountain summits, has changed over the past decades, especially during the pronounced warming since approx. 1980. We compare historical and recent plant occurrences in a summit re-visitation study.

The comparison of historical and recent plant occurrence data from c. 250 mountain summits in European mountain ranges showed that species richness increased considerably due to upward migration of species, while there was little evidence for extinctions of high-alpine specialists. Fine-scale species distribution revealed that "successful" and less successful species differ in the type of microhabitats they occupy. This spatial and ecological segregation might explain why colonization with new, potentially highly competitive species has not (yet) been followed by a wave of local extinctions.

Our findings shed light on processes that drive the spatial distribution of plant species in alpine terrain and thus may, in the longer term, help to refine predictions of threats to particular plant species.

On behalf of the E Summit Flora consortium.
European Alpine Glacier Reveals one Millennium of Fire and Vegetation Dynamics

Sandra Brügger1 (sandra.bruegger@ips.unibe.ch), Erika Gobet2, Michael Sigl3, Dimitri Osmont3, Margit Schwikowski3, Willy Tinner2
1University of Bern, Physics Institute & Oeschger Centre for Climate Change Research, Bern, Switzerland,
2University of Bern / Institute of Plant Sciences and Oeschger Center for Climate Change, Bern, Switzerland,
3Paul Scherrer Institute, Villigen, Switzerland

Wild fires are a disturbance agent across the continents, driving ecosystem dynamics and societal hazards. We analyze ice-core pollen and spores as proxies for vegetation composition and land use, microscopic charcoal for fire activity, and spheroidal carbonaceous particles for fossil fuel combustion. The results derive from the highest glacier of Europe (4452 m asl), from Colle Gnifetti. To our knowledge they provide the first long-term and high-resolution palynological record of Europe from an ice-core.

The central position and large microfossil catchment of the Colle Gnifetti allows us to address vegetation and societal responses to climatic change and wildfire disturbance on a subcontinental scale, presumably covering substantial parts of Western, Central and Southern Europe. The ice core record provides an excellent chronological control for the past millennium, particularly over the most recent 200 years, the period that experienced important climatic changes and an increasing globalization of economy.

We reconstruct large scale impacts such as extreme weather, societal innovations, agricultural crises and pollution in Europe. Surprisingly, pollution tracers occur in the record as early as 1750 AD. They anticipate industrialization but coincide with a shift to large-scale maize production in Northern Italy and strongly increased fire activity. Our multiproxy record may allow desentagling the role of climate and humans for vegetation composition and biomass burning.
Understanding the response of phytoplankton communities to specific environmental drivers in different Southern Ocean water masses is critical to improve projections under current threats of global change. We show the importance of understanding of the role the biological pump play in the future global climate and more specifically the effect of different phytoplankton communities. Different phytoplankton play different roles in the ocean biogeochemical cycles, especially carbon export, and thus on climate feedback processes. This study presents changes in the community composition across a South-Africa to Antarctic transect along with an assessment of the effects of increased micronutrients using a series of on-board iron/light bulk incubation experiments. Phytoplankton composition was assessed using their photosynthetic pigments. Diatoms are dominant in the Sub-Antarctic, Polar Frontal, and - along with Phaeocystis antarctica - the Antarctic zone. This was re-enforced when cultivated under increased light/iron conditions and the new bulk community was diatom dominated. Incubations also revealed that P. antarctica acclimated its pigment ratios to function more efficiently within different light and iron conditions and that community compositions in the Antarctic zone depend more on iron availability than that of the Polar Frontal zone. We conclude that both light and iron are significant controls on the phytoplankton community and that their effects varies regionally.
Southern Ocean Phytoplankton Silica Uptake Relating to Leakage and Carbon Export

Ian Weir¹ (ianweir1992@gmail.com), Susanne Fietz¹
¹Stellenbosch University, Earth Sciences, Stellenbosch, South Africa

The silicic acid cycle is closely linked to the carbon cycle in oceans as diatoms, a dominant, siliceous phytoplankton in the Southern Ocean (SO), are estimated to be responsible for the removal of approximately 55% of the total organic carbon in modern oceans.

The incorporation of silicic acid into the diatom cell wall structure, carbon export, productivity and biogenic silica distribution are reported in this paper through incubation experiments and transect data addressing pitfalls of the Silicic Acid Leakage Hypothesis. Upon iron (Fe) fertilization, the potential for the community to utilize less silicic acid from the water column is evaluated. The study spans a winter and three summer cruises, including the Atlantic and Indian Sectors of the SO. Biogenic silica is coupled with ancillary trace metal, macronutrient, particulate organic carbon (POC), Chlorophyll a and community composition data.

Incubation experiments within the community illustrate a noticeable increase in biogenic silica under high iron and light regimes, whilst transect data reiterate these limitations. Results suggest an increase in productivity across all oceanic zones. Scanning Electron Microscopy imaging indicates that upon Fe fertilization, changes in the thickness of the diatom cell wall are species-specific. To conclude, Fe addition drastically increases diatom production with certain species displaying a thinning of the cell wall marking potential for excess silicic acid in the water column.
Impact of Light and Iron Availability on Antarctic Phytoplankton Ecophysiology

Scarlett Trimborn1,2 (scarlett.trimborn@awi.de), Silke Thoms1, Kai Bischof2, Sara Beszteri1

1Alfred Wegener Institute, Bremerhaven, Germany, 2University of Bremen/BreMarE, Bremen, Germany

Although iron (Fe) availability sets primarily the rate of phytoplankton growth and primary and export production in the Southern Ocean, other environmental factors, most significantly light, also affect productivity. Due to wind-induced vertical mixing, the total irradiance dose can be reduced, but exposing phytoplankton also to periods of excessive irradiance when residing near the surface. As these dynamic alterations between low and high irradiance in low Fe-waters are important drivers of species distribution, we investigated the effects of light (20, 200 and 500 µmol photons m⁻² s⁻¹) in combination with low and high Fe availability (0.4 and 2 nM Fe) on the physiology of the two ecologically relevant species Chaetoceros debilis and Phaeocystis antarctica. Fe-limited cells of P. antarctica displayed similar high growth rates at all irradiances. In comparison, Fe-limited C. debilis cells grew much slower under low and medium irradiance and were unable to grow at the highest irradiance. Compared to C. debilis Fe-limited P. antarctica cells fixed more particulate organic carbon at all irradiances. When exposed to short-term excessive irradiances C. debilis could cope better than P. antarctica under low Fe conditions, but this was at the expense of lowered carbon production. Overall, our results show that P. antarctica was more tolerant to changes in the availability of Fe and light, providing it a competitive advantage under a dynamic light regime in Fe-deficient waters.
Phytoplankton Group-specific Contributions to the Subantarctic Biological Pump

Heather J Forrer1 (hjforrer@gmail.com), Thomas G Bornman2, Samantha C Waterworth3, Angela N Knapp4, Rachel K Thomas5, Rosmary A Dorrington3, Sarah E Fawcett1

1University of Cape Town, Department of Oceanography, Cape Town, South Africa, 2Elwandle Coastal Node, South African Environmental Observation Network, Port Elizabeth, South Africa, 3Rhodes University, Department of Biochemistry and Microbiology, Grahamstown, South Africa, 4Earth, Ocean and Atmospheric Science Department, Florida State University, Tallahassee, United States

Summer Subantarctic surface waters are characterized by high concentrations of unconsumed nitrate (NO₃⁻), likely due to combined iron, light and silica limitation of phytoplankton growth. Phytoplankton diversity and community structure response to such nutrient limitation is not well understood. The degree to which phytoplankton consume NO₃⁻ (“new production”) is proportionate to net carbon (C) removal to the deep ocean, while growth fueled by recycled ammonium (NH₄⁺) yields no net C flux. The N isotopic composition (δ¹⁵N) of upper ocean biomass can be used as an integrative tracer of NO₃⁻ vs. NH₄⁺ uptake; however, surface particles include heterotrophs and detritus in addition to phytoplankton, complicating the use of bulk particle δ¹⁵N as a metric for new vs. recycled N uptake. This is overcome by coupling cytometric cell sorting (FACS) - isolating important populations (e.g., cyanobacteria, picoeukaryotes, diatoms) - with group-specific δ¹⁵N analysis. On the summer 2016/2017 Antarctic Circumnavigation Expedition cruise across the Indian sector of the Subantarctic Ocean, we collected particles for FACS-δ¹⁵N analysis and seawater samples for analysis of nutrients and nitrate δ¹⁵N. Four phytoplankton groups appear to be dominant across the basin. Their contribution to new production and C export will be discussed, as will that of Subantarctic island populations occupying waters where iron and possibly silica are no longer limiting due to mesoscale upwelling and island runoff.
Coccolithophore Controls on the Southern Ocean Carbon Cycle

Cara Nissen1 (cara.nissen@usys.ethz.ch), Meike Vogt1, Matthias Münnich1, Nicolas Gruber1
1Environmental Physics, Institute of Biogeochemistry and Pollutant Dynamics, ETH Zürich, Zürich, Switzerland

Southern Ocean (SO) phytoplankton biogeography impacts carbon cycling and the transport of macronutrients to lower latitudes. The relative importance of calcifying coccolithophores is especially important, since calcification and photosynthesis have opposing impacts on seawater pCO2 and air-sea CO2 fluxes. Further, calcite acts as ballast material for exported organic matter, enhancing the sequestration of organic carbon. Recent evidence suggests areas of high coccolithophore abundance in the SO, yet, the quantitative contribution of coccolithophores to SO biogeochemistry is not well understood. Here, we address this question using a regional high-resolution ocean circulation model for the entire SO (>24°S) with an embedded biogeochemistry module and an explicit representation of coccolithophores (ROMS-cBEC). Comparing our standard simulation to one without calcification by coccolithophores, we find the net air-sea flux of CO2 to increase by 50% when neglecting calcification, making the SO a larger CO2 sink. In contrast, we find little change in NPP and carbon transfer efficiency (< 5%), implying only a small ballasting effect. When coccolithophores are excluded from the model's phytoplankton community, preliminary results suggest a 15% increase in the northward transport of nitrate relative to silicate. Thus, future changes in the relative importance of coccolithophores could substantially impact carbon cycling not only in the SO, but potentially at lower latitudes as well.
Main Drivers Regulating the Strength of Carbonate Counter Pump in the SO

Clara Manno¹ (clanno@bas.ac.uk), Federico Giglio², Gabriele Stowasser¹, Sophie Fielding¹, Geraint A. Tarling¹
¹British Antarctic Survey, Cambridge, United Kingdom, ²National Research Council CNR-ISMAR, Bologna, Italy

The Biological Carbon Pump (BCP) is counteracted by the Carbonate Counter Pump (CCP), which causes an increase in surface ocean CO₂ through the export of Particulate Inorganic Carbon (PIC). The ability to precipitate carbonate as well as the ballasting effect change according the different plankton calcifying structures. Thus understanding the variability in calcifying assemblage and/or their relative abundance it is crucial in order to forecast the fate of CO₂ uptake and sequestration in the deep ocean. Here, we describe a 2-year-long series of particles flux, as measured by deep moored sediment traps located at two sites close to South Georgia (Northern Scotia Sea). The aim of this study is to assess the specific contribution of the whole calcifying organism compartment (pteropods, foraminifera, coccolithophores and ostracods) to the Carbonate flux as well as their role in regulating the strength of the CCP. We found that when pteropods drive the magnitude of Carbonate flux, the total annual reduction of CO₂ transferred to the deep ocean double respect to the other year (when conversely foraminifera and coccolithiphores are dominants). This work provides an insight into the importance of the plankton calcifying assemblage to drive the magnitude of the CCP in a sensitive region such as the Southern Ocean which is responsible for 40% of the global anthropogenic carbon uptake.
Major 20th Century Contribution to Sea-level Rise from Uncharted Glaciers

Ben Marzeion¹ (ben.marzeion@uni-bremen.de), David Parkes¹,²

¹University of Bremen, Bremen, Germany, ²University of Innsbruck, Innsbruck, Austria

Global mean sea-level rise (GMSLR) during the 20th century was primarily caused by glacier and ice sheet mass loss, thermal expansion of ocean water, and change of terrestrial water storage. Whether based on observations or results of climate models, the sum of estimates of each of these contributors tends to fall short of the observed GMSLR. All estimates of the glacier contribution to GMSLR rely on the application of glacier inventory data, which are known to under-sample the smallest glacier size classes. Here we show that missing glaciers (those small glaciers that we expect to exist today, but which are not represented in the inventories) may have contributed 42.7±6.5 mm to GMSLR during the period 1901 to 2015, even though their total 2015 ice mass is very small (2.4±0.4 mm GMSLR equivalent). Additionally, disappeared glaciers that existed in 1901, but had completely melted away by 2015, and which are therefore not included in modern global glacier inventories, may have contributed 5.3±2.4 mm to GMSLR. Together, these uncharted glaciers (missing glaciers and disappeared glaciers combined) made an estimated contribution of 48.0±8.9 mm to GMSLR. Failure to consider these glaciers may be the cause of difficulties in closing the GMSLR budget during the 20th century. We suggest that accounting for uncharted glaciers in some fashion is essential for accurate historical glacier GMSLR contribution estimations.
Data Assimilation & Uncertainty Analysis of a Stochastic Subglacial System Model

Inigo Irarrazaval\textsuperscript{1} (inigo.irarrazavalbustos@unil.ch), Gregoire Mariethoz\textsuperscript{2}, Frederic Herman\textsuperscript{1}

\textsuperscript{1}University of Lausanne / Institute of Earth Surface Dynamics, Lausanne, Switzerland

\textsuperscript{2}University of Lausanne / Institute of Earth Surface Dynamics, Lausanne, Switzerland

The subglacial drainage system plays a crucial role not only in ice flow dynamics, but also in erosion of the bedrock, catchment hydrology, and potential hazards related to glacier outburst floods. The study of subglacial drainage system is challenging due to the inaccessibility of such environments, resulting in a lack of direct observations. Even though physical deterministic models have been built, it is difficult to constrain their outputs to observations and to perform sensitivity analysis and independent validation of these models.

In this context, we aim to infer the spatial structure and hydraulic parameters of the subglacial drainage system based on indirect data such as water pressure and tracer experiment. To this end, we develop an approach that uses a combination of stochastic and physical processes. An inversion procedure is used to determine a set of possible models that all agree with the data, and to determine parameters uncertainty. The proposed methodology incorporates three main components:

1) a stochastic channel generator to produce realistic geometries for the subglacial drainage system;
2) a physical model where distributed water pressure and mass transport are computed over the domain;
3) an inverse loop where the results (pressure, mass concentration) are compared with observed data in order to assess the channel network geometry and hydraulic properties of the system.
Rock debris at the surface of a glacier often insulates the underlying ice from incoming energy fluxes thereby reducing the local melt rate. The relation between debris thickness and melt suppression is nonlinear and consistent throughout many field studies. Debris that is about 10-15 cm thick can reduce the local melt rate by half and debris >50 cm thick can reduce melt to near zero. The distribution of debris cover on glaciers globally is not explicitly known at the time of writing, but is estimated at around 17%. The impact of debris cover on glacier melt is neglected in most large-scale glacier melt models and is likely one of the leading sources of error. The spatial distribution of debris on glaciers is fairly simple to derive from remote sensing, yet the governing term, the thickness of the debris, is much more difficult to resolve. We use time-lapse thermal imagery collected in the Alaska Range coupled with classical glacier field data and satellite based thermal imagery to (1) test the hypothesis that thermal data can be used to derive debris thickness at wide spatial scales, and (2) develop a simple model for estimating the impact of debris cover on glacier melt at a regional scale. Modeling efforts that are successful at a regional scale are an essential step towards larger-scale efforts. This work is targeted towards the inclusion of a debris cover term in global glacier melt models.
Recent Changes to Glaciers on Northern Ellesmere Island, Nunavut, Canada

Adrienne White1 (awhit059@uottawa.ca), Luke Copland1
1University of Ottawa, Department of Geography, Environment and Geomatics, Ottawa, Canada

Using optical satellite scenes, this study quantifies change in the extent of 1755 glaciers across northern Ellesmere from 1999-2015. Our results show that ice coverage decreased by ~6% over the 16-year period. This indicates an acceleration over the 3.4% loss recorded by Sharp et al (2014) between 1960-2000. Our results show that ice shelves had the greatest losses relative to their size, a loss of ~25%. Tidewater glaciers reduced by 3% and included the transition of two tidewater glaciers to land-terminating. 18 glaciers that were identified as marine-terminating with an ice tongue in 1999 had their tongues disintegrate. Past studies have linked the loss of ice shelves to warmer summer air temperatures, and the loss of the protective barrier created by multi-year landfast sea ice (MLSI). These factors may have also played an important role in the loss of the floating ice tongues observed in this study, particularly in Yelverton Inlet where several ice tongues have disappeared since the recent loss of MLSI in this region. Land-terminating glaciers lost 5% of their area, including the complete loss of three small ice caps (< 1.5 km²). This is consistent with trends observed from other regions where ice loss has been dominated by small, remnant glaciers, due to their greater sensitivity to climate. Overall our work suggests that the rate of ice loss has increased and that the ice masses most susceptible to accelerated loss are glaciers with floating termini and small ice caps.
The Canadian Arctic hosts the largest area of ice outside of Greenland and Antarctica and is currently the largest contributor to modern global sea level rise as a result of Arctic amplification. Since 1960, annual measurements of surface mass balance have been conducted on three ice caps and one mountain glacier on Meighen, Melville, Devon, and Axel Heiberg Island in the Canadian Arctic. Together, these records indicate a trend of increasing mass loss over the past two decades alongside rising equilibrium line altitudes and shrinking accumulation area ratios. The sensitivity and long-term stability of these glaciers is closely linked to ice dynamics, and specifically the rate of ice transfer from cold, high elevations to lower, warmer elevations where melt conditions prevail. We present a synthesis of the long-term mass balance records in the Canadian alongside a case study from White Glacier on Axel Heiberg Island, Nunavut, to demonstrate the role of thinning, retreat, and ice dynamics in the long-term stability of high-Arctic glacier response.
Greenland peripheral glaciers and ice caps are sensitive key indicators of climate change but recent evolution of ice volume along Greenland's periphery is still poorly understood. The restricted number of geodetic glacier thickness changes on Greenland is probably related to the absence of digital elevation models (DEM) of sufficient accuracy.

In this study we used the reanalyzed AeroDEM (late 1970s to mid-1980s) and the two recently released high resolution DEMs ArcticDEM (2012-2015) and TanDEM-X (2010-2014) to calculate geodetic glacier elevation changes. Thereby, the main challenge was to appropriately deal with the data voids and artefacts occurring in all three DEMs. In the framework of a pilot study, the ArcticDEM was subtracted from the AeroDEM over the Holm Land ice cap, northeast Greenland. The data voids were filled (A) by spatial interpolation and (B) by interpolating the mean of the respective elevation bin, resulting in a mean elevation changes of $-9.3$ m and $-9.9$ m, respectively. Based on the results of this pilot study, we are applying these approaches to calculate glacier elevation changes for larger regions on Greenland.

This work is carried out in the framework of the Copernicus Climate Change Service (https://climate.copernicus.eu/about-c3s) for which the World Glacier Monitoring Service (WGMS) aims at generating glacier specific elevations changes for regions around the world.
Ice Shelves Buttressing and Ice Sheet Flow

G Hilmar Gudmundsson¹ (hilmargudmundsson@googlemail.com), Ronja Reese², Ricarda Winkelmann², Anders Levermann²

¹University of Northumbria, 8ST, United Kingdom, ²Potsdam Institute for Climate Impact Research, Potsdam, Germany

Ice shelves buttress ice at the grounding lines of the Antarctic Ice Sheet and changes in the geometries of ice shelves can affect upstream flow. We review theoretical concepts related to ice-shelf buttressing and grounding-line stability, and use numerical ice flow models to quantify the impact of loss of ice shelves on ice flux across grounding lines. We give both a general overview over the sensitivity of grounding-line ice flux to changes in ice-shelf thickness, and more specifically estimate the impact that recent thinning may have had on ice flow in Antarctica. We find that the spatial pattern of observed current ice loss matches closely that predicted by numerical modelling. Hence, loss of ice shelf buttressing appears to be modulating grounding line ice flux in Antarctica today. While these findings are in good agreement with prevailing views on the importance of ocean-induced thinning over ice shelves, this is the first time that such a link is explicitly derived using numerical ice flow models.
An Observation Based Approach to Calculating Ice Shelf Calving Flux

Eleri Evans\textsuperscript{1,2} (eleri.evans@utas.edu.au), Alexander Fraser\textsuperscript{2}, Sue Cook\textsuperscript{2}, Richard Coleman\textsuperscript{1,2}, Ian Joughin\textsuperscript{3}

\textsuperscript{1}University of Tasmania, Institute for Marine and Antarctic Studies, Hobart, Australia, \textsuperscript{2}Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia, \textsuperscript{3}University of Washington, Applied Physics Laboratory, Polar Science Center, Seattle, United States

Traditionally it has been very difficult to determine the non-steady state behaviour of ice shelves from observations. In order to define the state of an ice shelf one of the key components, the calving flux, is required. Antarctic wide calculations of ice shelf calving fluxes have tended to ignore the smaller ice shelves and/or smaller calving events, often assuming that the calving flux of an ice shelf is temporally constant and so not accounting for non-steady state behaviour. An approach is needed that captures the sum total of all calving along with the variation in calving front position between calving events. We have developed an observation based approach that uses a combination of ice flow velocities, ice thicknesses and a time-series of calving front positions to calculate the calving flux of an ice shelf at a high temporal and spatial resolution. The Sør Ral Glacier of East Antarctica is used as an example. The sensitivity of the approach to the input datasets (e.g. ice velocities and ice thicknesses) is investigated. Quantifying the calving fluxes of smaller ice shelves at a high temporal and spatial resolution will allow a more accurate estimate of the mass loss from the Antarctic Ice Sheet due to ice shelf calving. Using such an observation based approach to quantify the calving flux will also give an insight into ice shelf dynamics and how these may change with changing environmental forcings.

Nature or Nurture? Rift Generation(s) at the NE front of the Ross Ice Shelf

Martin Forbes¹ (martin.forbes@postgrad.otago.ac.nz), Christina Hulbe², Karuna Sah²

¹University of Otago, National School of Surveying, Dunedin, New Zealand; ²Dickinson College, Carlisle, United States

Understanding the conditions that drive ice shelf rift geometry and propagation is critical to understanding contemporary change in Antarctic systems. Rifts become the planes along which tabular icebergs calve and thus play an important role in ice shelf mass balance and response to climate change. We use a linear elastic fracture mechanics (LEFM) modelling approach coupled with an ice shelf model to investigate a family of rifts at the front of the Ross Ice Shelf, between Roosevelt Island and the Shirase Coast. This is an ideal section of the ice shelf for our study because stress conditions are straightforward and spatial variation in ice properties appears to be relatively straightforward as well. The propagation of two generations of rifts is recorded in images collected between 1986 and 2017 by Landsat 4, 7, and 8. Rifts originating from very different spatial circumstances are observed to develop into similar near-front geometries. We consider both differing origins and similar fates of these features, simulating both using the same far-field stress conditions.
Study on Fracturing of Ronne-Filchner Ice Shelf using Multisource Satellite Data

Rongxing Li\textsuperscript{1,2} (rli@tongji.edu.cn), Haifeng Xiao\textsuperscript{1,2}, Shijie Liu\textsuperscript{1,2}, Xiaohua Tong\textsuperscript{1,2}

\textsuperscript{1}Center for Spatial Information Science and Sustainable Development Applications, Tongji University, Shanghai, China, \textsuperscript{2}College of Surveying and Geo-Informatics, Tongji University, Shanghai, China

Ice shelves play a very important role in buttressing the Antarctic ice sheet. Monitoring the stability of the ice shelves is an integral part of the study of AIS mass changes and the associated sea level rise. We propose a new framework of systematic fracture mapping and major calving event prediction for the large ice shelves in Antarctica using optical imagery, SAR imagery, altimetric data, and stereo mapping imagery. It is implemented and applied for a comprehensive study of the fracturing of Ronne-Filchner Ice Shelf using a long time dataset dating back to 1957. New remote sensing data that have been made available in the past decade, including Landsat 8, WV-2, ZY-3 and others, greatly enhance our abilities to detect new fractures and monitor large rifts in three dimensions. Two large rifts, Rifts 1 and 2, were newly detected and are comparable to the Grand Chasm that caused a major calving event in the region in 1986. Based on the results of the 2D and 3D fracture mapping, the spatial and temporal analyses of the overall fracture changes and large rift evolutions, the level of fracturing in RFIS was slightly increased, particularly at the front of the ice sheet. The overall fracture observations do not seem to suggest immediate significant impacts on the stability of the shelf. However, the most active regional fracturing activities occurred at the front of Filchner Ice Shelf. A potential upcoming major calving event of FIS is estimated to occur around 2051.
Ice shelves of Antarctica are rapidly changing and could largely affect the Antarctic ice sheet stability. Ice rises, grounded ice domes, affect ice-shelf stability and are useful sites to investigate the proxy records of Antarctic climate variability. Dronning Maud Land (DML) is characterized by small ice shelves that are punctuated by ice rises. To fill the knowledge gap and to undertake a detailed study of ice shelves and ice rises of coastal DML, an Indo-Norwegian project named MADICE (Mass balance, dynamics, and climate of the central Dronning Maud Land coast, East Antarctica) was initiated. During the 2016-17 season, the first joint MADICE campaign was undertaken within the Nivlisen Ice Shelf and adjacent ice rises (Djupranen and Leningradkollen). This campaign successfully collected a range of glaciological data using GPS and radar, and recovered two ice cores at the summits of the ice rises (depth 122 and 51 m, respectively). The ice core from Djupranen ice rise includes negligible melt features, whereas the ice core from Leningradkollen shows many melt features. This is primarily caused by the difference in surface elevations (150 m). We are analyzing the stratigraphy, stable isotope other properties of these ice cores. The second MADICE campaign is currently underway. We will present scope, outline and initial results of this project. Details of geophysical/glaciological findings are proposed as another presentation in the same session (Lindbäck and others).
Multi-disciplinary Observation Network to Monitor Rapid Changes in Antarctica

Won Sang Lee¹ (wonsang@kopri.re.kr), Choon-Ki Lee¹, Yongcheol Park², Sukyoung Yun¹, Christopher Zappa³, Craig Stevens⁴, Don Blankenship⁵, Alex Forrest⁶, Robert Dziak⁷, Mechita Schmidt-Aursch⁸, Christine Dow⁹, Ted Scambos¹⁰, Jinseok Kim¹, Jiyeon Lee¹, Seung Hyun Lee¹, Seungtae Yoon¹

¹Korea Polar Research Institute, Unit of Ice Sheet and Sea Level Changes, Incheon, Korea, Republic of, ²Korea Polar Research Institute, Incheon, Korea, Republic of, ³Lamont-Doherty Earth Observatory Columbia University, NY, United States, ⁴National Institute for Water and Atmospheric Research, Wellington, New Zealand, ⁵University of Texas at Austin, Jackson School of Geosciences, TX, United States, ⁶University of California, Davis, CA, United States, ⁷NOAA Pacific Marine Environmental Laboratory, OR, United States, ⁸Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research, Bremerhaven, Germany, ⁹University of Waterloo, ON, Canada, ¹⁰National Snow and Ice Data Center, CO, United States

The Polar Regions have been experiencing dramatic changes particularly including glacier retreating, ice thinning, declining in sea ice extent, and so on. Recent literatures illuminate that the melting rate of ice sheets and glaciers in the West Antarctic has accelerated, which may lead significant contributions to global sea level rise. In an attempt to understand the complex forms of interaction between the Lithosphere, the Hydrosphere, the Atmosphere, and the Cryosphere, Korea Polar Research Institute has been operating an integrated Cryosphere monitoring network (EGGNet; Extreme Geophysics Group observation Network) in the Terra Nova Bay (TNB) since December, 2010. The EGGNet consists of local broadband seismic stations, GPS stations, AMIGOS systems, Ocean Bottom Seismometers, oceanographic moorings, and Autonomous Underwater Hydrophones. In addition to operation of the year-round stations, we have performed magnetotelluric survey near Mt. Melbourne, CTD castings in TNB, airborne geophysical surveys on Nansen Ice Shelf, Drygalski Ice Tongue and David Glacier. In this presentation, we show some of interesting features observed through the EGGNet: identification of David Glacier subglacial lakes, basal melting occurring under Drygalski Ice Tongue, existence of super-cooled water in TNB, seismic velocity structure under Mt. Melbourne, etc. We anticipate that these in situ observations could help to improve our understanding of physical processes for ice sheet models.
Drivers of Southern Ocean Sea Ice Trends in CMIP5 Models

Will Hobbs1 (whobbs@utas.edu.au)
1Antarctic Climate & Ecosystems Cooperative Research Centre, Hobart, Australia

Formal change detection studies indicate that the observed trend in Southern Ocean sea ice cover is within the range of internal variability. However, this result depends on global coupled models that fail to capture strong local trends, in especially during summer in the western Ross and Bellingshausen sectors. Additionally, the model response to individual forcings has not been considered except for total sea ice extent changes. In this work, optimal fingerprinting has been applied to Southern Ocean sea ice, and to the local atmosphere and ocean, to individually explore the sea ice response to anthropogenic greenhouse gas and anthropogenic ozone depletion. The former is characterised by a thermodynamic reduction in sea ice at all seasons and sectors; the latter shows a seasonally and spatially-dependent response that is driven by the atmosphere and is similar to observed patterns. The all-forcings response, which has been used in previous detection studies, is dominated by the thermodynamic greenhouse gas forcing. This indicates that the models over-represent the thermal response in the high latitude Southern Hemisphere.
In contrast to the Arctic, where total sea ice extent (SIE) has been decreasing for the last three decades, Antarctic SIE has shown a small, but significant increase during the same time period. However, in 2016, an unusually early onset of the melt season was observed; the maximum Antarctic SIE was already reached as early as August rather than end of September, and was followed by a rapid decrease. The decline of the sea ice area (SIA) started even earlier, namely in July. The decay was particularly strong in November where Antarctic SIE exhibited a negative anomaly (compared to the 1979-2015 average) of approximately 2 Mio. km², which, combined with reduced Arctic SIE, led to a distinct minimum in global SIE. ECMWF-Interim reanalysis data were used to investigate possible atmospheric influences on the observed phenomena. The early onset of the melt and the rapid decrease in SIA and SIE were associated with atmospheric flow patterns related to a positive ZW3 index, i.e. synoptic situations leading to strong meridional flow. Particularly, in the first third of November northerly flow conditions in the Weddell Sea and the Western Pacific triggered accelerated sea ice decay, which was continued in the following weeks due to positive feedback effects, leading to the extraordinary low November SIE. In 2016, the monthly mean SAM index reached its second lowest November value since the beginning of the satellite observations. SIE decrease was preconditioned by SIA decrease.
Exploring Kinematic Contributions on Antarctic Sea-ice Extent

Petra Heil\textsuperscript{1} (petra.heil@utas.edu.au), Glenn Hyland\textsuperscript{1}
\textsuperscript{1}Australian Antarctic Division, Antarctica and Global System, Hobart, Australia

The recent collapse of annual maximum extent of Antarctic sea ice brings the long-term evolution of Antarctic sea ice into line with the polar response to global warming. For about the last two decades the Antarctic winter ice cover had expanded, exceeding 20Mio km\textsuperscript{2} in 2014. The underlying processes for this expansion are thought to be due to either melt-induced cold freshwater lenses at the ocean surface in the Southern Ocean or a combination of wind-driven advective and thermodynamic changes. Here we investigate the contribution of advection on the ice extent using SAR and MODIS imagery. Since 2001 during most years in the region off East Antarctica, strengthened synoptic-scale surface winds increased the northern sea-ice extent. However, during some years, including the most recent once, winds acted to compact the near-coastal sea ice, and by virtue of deformation increased the ice thickness. In the Weddell Sea and to a lesser degree in the Ross Sea, ice advection was found to modulate the strength of the regional northward ice export. Off East Antarctica and in the Weddell Sea ice advection correlated with shear and has been linked to deformational thickening. A pathway of ice advection affecting the regional sea-ice extent and ice-thickness distribution can be identified for most Antarctic regions.
Sea Ice Type Distribution in the Antarctic from Microwave Satellite Observations

Christian Melsheimer1 (melsheimer@uni.-bremen.de), Gunnar Spreen1, Mohammed Shokr2, Yufang Ye3

1University of Bremen, Institute of Environmental Physics, Bremen, Germany, 2Environment and Climate Change Canada, Toronto, Canada, 3Chalmers University of Technology, Göteborg, Sweden

Sea ice can be classified into several types, such as young ice (YI, thin and smooth new ice), first-year ice (FYI, formed during one cold season), and multiyear ice (MYI, ice that has survived at least one melt season). As the physical properties of sea ice differ significantly for the different ice types, knowledge of the sea ice type is essential, e.g., for properly modelling the ice-ocean-atmosphere system.

Here we apply a new satellite-based retrieval of sea ice type in the Antarctic. This retrieval has originally been developed and tested for the Arctic, where it can distinguish YI, FYI and MYI. The motivation to apply the sea ice type retrieval in the Antarctic is that there is a considerable amount of MYI in the Antarctic (albeit less and younger than in the Arctic), and that, however, the ice type distribution in the Antarctic has not yet been investigated much.

The retrieval method uses input data from active and passive microwave instruments (radar scatterometer and radiometer, respectively) for the retrieval but in addition applies several correction schemes to account for the effect of melt-refreeze processes, snow metamorphosis and sea ice drift on the sea ice type retrieval. The needed satellite data have been available since 1999, there is daily full coverage (but no retrieval during summer melt), and the spatial resolution is about 25 km.

We will present first results of the new retrieval applied to Antarctic sea ice and compare with results from the Arctic.
Sea Ice Thickness Estimates from Icebridge over the Weddell Sea in 2009-2016

NASA’s Operation IceBridge (OIB) aircraft flights aim at extending the laser altimeter time series through the gap between the end of ICESat data collection in 2009 and the launch of the ICESat-2 lidar in 2018. OIB data is used to estimate sea ice total freeboards and thicknesses over the Weddell Sea during 2009-2016. Local sea level heights are extracted from the ATM (lidar) L1B over leads/thin ice mapped by the DMS images. Total freeboard of sea ice is then derived from the ATM L2 by subtracting the nearest local sea level height. For the 2011 flights, our results are also compared with a previously published result that used the ATM L1B of the lowest reflectance threshold (< 0.25) as local sea level. Ice thickness derived by using the empirical equations shows reasonable spatial and temporal distributions, with thickest ice in the coastal northwest Weddell Sea. The averaged ice thickness estimated at each track varies from 1.27m to 2.25m, with an overall increasing linear trend of 0.035 m/yr from 2009 to 2016, although statistically insignificant (p = 0.13). Our next step is to bring into the analysis the ICESat data (2003-2009) for the same tracks and thus generate a longer time series (2003-2016) and more complete picture of sea ice variability in the Weddell Sea.
Obtaining accurate measures of the Antarctic sea-ice thickness (I) is becoming increasingly relevant given below-average sea-ice extents observed after 2014 and the reappearance of the Weddell Sea polynya during winter/spring 2017. Satellite laser altimeter observations of the total (sea ice plus snow) freeboard (F) have proven to be useful in this context. However, in addition to uncertainties in F the conversion from F into I is subject to several uncertainty sources, e.g., snow density and snow depth (S). Here we present a novel method which combines several approaches. We derive F with the well-known lowest-level elevation method. We avoid known uncertainties in the conversion from F into I by using a simplified buoyancy equation in concert with the idea to consider sea ice and snow as one layer. The density of this layer required for the F-to-I conversion can be computed as product between ice density and the ratio S/I. We derive the latter dynamically from first guess values of I and S computed using two empirical equations based on in-situ observations. Hereby we assume that contemporary application of these empirical equations to F results in a smaller uncertainty in sea-ice thickness than when utilizing a potentially biased snow depth from another data source. We show and discuss results of our enhanced sea-ice thickness retrieval method for ICESat / ICESat-2 in a circum-Antarctic as well as regional context.
Relative humidity with respect to ice (RHwri) is often reported close to or at saturation in the surface atmosphere of the Antarctic plateau. However, this does not exclude the possibility that the air is actually supersaturated because conventional hygrometers cannot measure supersaturation and rather stick to their 100% instrumental ceiling. While they are frequent at high altitude, ice supersaturations do not generally occur in the surface atmosphere where measurement is obviously much easier. Atmospheric conditions close to those occurring at the tropopause are, however, found at the surface of the Antarctic plateau, both in terms of temperature and humidity, and of low concentration of ice nuclei. Frequent reports of saturation probably actually reflect poorly sampled supersaturation. Adapted sensors that can measure beyond saturation show that at Dome C supersaturation is frequent and the norm rather than the exception (https://www.atmos-chem-phys.net/17/691/2017/), and RHwri can occasionally reach 150% or more in winter. In summer, RHwri rises to supersaturation as temperature decreases in the evening, then the vapor often coalesces to form surface haze. RHwri decreases as the haze develops then as temperature increases, to reach undersaturation during the day. This succession and chronology of events could offer a fair test for cold microphysics parameterizations increasingly implemented in meteorological and climate models to simulate high-altitude cirrus clouds.
Empirical Trace Gas Gradients in the Arctic and the Polar Dome Location

The Polar Dome has long been recognized as a transport boundary for mid-latitude air travelling into the Arctic. Measurement based identification of the Polar Dome is difficult due to the temporal and spatial variability and a lack of consistent measurements in the lower few kilometers of the Arctic. Particularly the climatological role of the Dome as a transport boundary for pollution tracers has not yet been fully addressed on the basis of in-situ measurements.

We present aircraft based trace gas measurements in the Arctic during different seasons since 2014 (NETCARE 2014/2015, RACEPAC 2014, PAMARCMiP 2015/2017, ALOUD 2017) covering an area from Svalbard to Alaska. We analyze the distribution of CO and CO2 in different coordinate systems and identify the Dome location from observed trace gas gradients. Significant differences regarding the Dome location and transport between winter/spring and summer appear. During winter/spring the Dome is characterized by an almost isentropic distribution of CO and CO2, whereas in summer diabatic processes introduce isentropic gradients. Consistent with the tracer measurements the analysis of kinematic 10-day back trajectories revealed different transport regimes with contributions of mid-latitude air ranging from 15%-55%. The North American continent is the dominant source region of air masses in the Canadian Arctic. However, erratic WCB transport originating in Eastern Asia affects the composition of the high Arctic troposphere.
Chemical Composition and Growth of Newly formed Particles at Chacaltaya, Bolivia
